The Pharmaceutical Journal

AND

Transactions.

INTRODUCTORY.

Hard upon thirty years ago the first number of the 'PHARMACEUTICAL JOURNAL' was printed for "the purpose of circulating information respecting the nature and objects of the Pharmaceutical Society . . . the Editor solicited the support and assistance of his friends in the supply of scientific articles." That Editor was Jacob Bell; and, in his zeal to advance his order, he determined to continue the publication until he saw his way clear to "propose the establishment of a monthly or quarterly journal of pharmacy."

The soil on which he proposed to work had always lain fallow; there might be, and were, cultivated spots in the land of pharmacy, but so hedged in as to be utterly useless to all save their owners: there were no highways through which their produce could be carried, no courses through which their pleasant waters could escape to fertilize the surrounding fallow.

Bell's Journal furnished the needed outlet, and at the end of six months he found that the influx of scientific papers and other matter had increased to such an extent that it was difficult to restrict the dimensions of each number within the prescribed limits. Chemists and druggists found the advantage of a periodical interchange of ideas, and the old notion, that they were the most exclusive of Englishmen as regarded each other, was happily dispelled.

Through eighteen years Bell laboured and was rewarded by success,—the advancement of pharmacy and the elevation of pharmacists were to him the highest of all rewards. But then came a cloud over the scene, and, in what appeared to be the full tide of his energy, the guiding spirit of the Journal and of the Society was called away. So ended the first series of the 'PHARMACEUTICAL JOURNAL.'

But living and dying, the welfare of the Pharmaceutical Society was an object of the deepest interest to its originator, and in the immediate anticipation of the close of his labours, Jacob Bell passed the copyright of his Journal over to the Society as a free gift of what had become a valuable property, accompanied by suggestions for its maintenance, founded on the experience of the past eighteen years,—suggestions of dangers to be avoided as well as objects to be pursued.

THIRD SERIES, No. 1.

The Council on whom, as trustees, the duty of publication was thus conferred, resolved unanimously to carry out their work in the manner indicated by Mr. Bell, and accordingly secured the services of those gentlemen who had from the commencement been his coadjutors, to co-operate with a Committee, consisting of the President of the Society for the time being, Mr. Morson, and Mr. Daniel Hanbury: thus the second series of the Journal was commenced, which ended last month on the completion of its eleventh volume.

Other members of the Council were afterwards added to the Publication Committee, but twelve months since it was deemed that single responsibility was better than divided authority for such work. The Journal seemed to lack that unity of purpose and independence of tone which it had possessed originally; and when we remember that Mr. Bell, as sole proprietor, was responsible to no man for its contents, it is easy to account for the absence of a certain amount of spirit which had in his day characterized its articles.

As proof, however, that the interest of the work has not flagged, we may point to the resolution just arrived at, to alter the monthly to a weekly issue, in accordance with which we this day send forth the first number of the third series.

Various circumstances combine to render this change desirable; the enlarged sphere of operation which has been accorded to the Pharmaceutical Society by recent legislation; the great extension of the Society, but chiefly the greater demand for such information as it is our province to convey in these pages,—a demand first engendered, and since increased by the 'PHARMACEUTICAL JOURNAL' itself, an appetite increased by the food supplied. We believe, could Jacob Bell look down on the present condition of Pharmacy in Great Britain, he would say, "Well done!" He would say, too, "Go on, but ever remember the principles on which we founded our Society and its Journal; let private interest find no place among you; love of science has increased immeasurably in the minds of Chemists and Druggists, let the special sciences of our trade have due space accorded to them; but fail not also to remember that we have still *a trade* to care for, and let not the questions concerning that trade be overlooked; let Pharmaceutical ethics be inculcated on broad general principles, and trouble not yourselves, except in flagrant cases, with private modes of conducting business; the Journal is the property of the Society, and should ever be mindful of its interests, but, although the organ, it must not sink into the mere tool of the Council. One point more: if you would secure for the Journal an increase of that distinct influence which it is surely exercising upon public opinion generally, and on the opinion of the medical profession particularly, be sure that those who are immediately concerned in conducting it are so independent that, whilst they realize their responsibility for all that may be admitted to its pages, they may have ample play for the exercise of those honourable motives which are too often, under like circumstances, hampered by unnecessary restrictions; in fact, unless its Editor be independent, it will be impossible to ensure unity of aim and purpose."

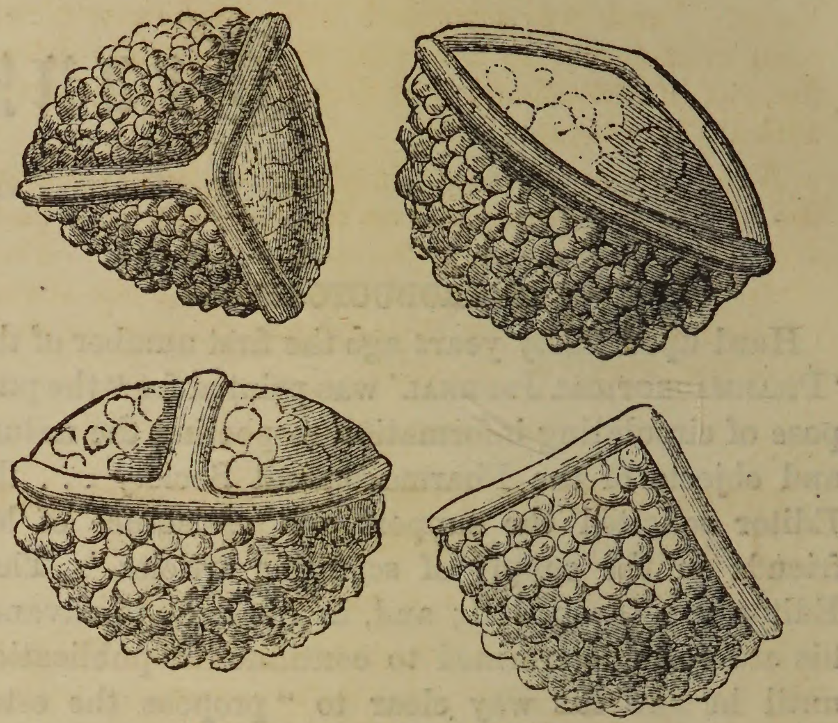
HASAN-i-YUSAF.

BY M. C. COOKE.

One of the obscure substances occasionally and locally employed in India for medicinal purposes by the natives is known by the name of "Hasan-i-Yusaf." This is seldom mentioned, and does not appear to be generally known in India itself. Lahore, and probably Kashmir, seem to be almost the only places where it has any reputation, and for what diseases it is supposed to be a remedy we have no information. After some ineffectual attempts we at length succeeded, through the kindness of Dr. J. L. Stewart, in obtaining a sample of this drug by post from Mr. B. Powell, of Lahore.

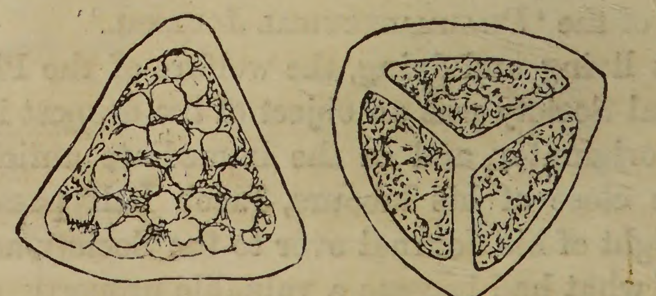
The description of this substance given by Honigberger in his 'Thirty-five Years in the East' is very brief. "Hossen Jussif," he writes, "is officinal in Lahore. It is a whitish seed of the smallest size, very likely to be mistaken for unripe poppy seeds." In reference to this, there is a note in the 'Handbook of the Economic Products of the Punjab' (p. 384), to the effect that the "Hasan-i-yusaf is a minute, siliceous shell of a triangular form, found floating on lakes and ponds in the hills of Kashmir, whence it is skimmed off and dried. Erroneously described by Honigberger and others as a seed." A little more explicit information on the same subject is given in another portion of that work (p. 320). Repeating the name as "Hussan Yusuf," it states:—"This is a very interesting specimen of the siliceous frustule of one of the *Diatomaceæ*. It is of a pyramidal form with a convex base, and on each triangular face is a prominent, rounded knot. These markings are not affected by acids, and remain after heating to redness. When heated in a reduction tube, it gives off a peculiar smell and combustible gas, showing that it is quite in a fresh state, otherwise it appears somewhat similar to a fossil. 'Hussan Yusuf' is collected in lakes and ponds in the hills around Srinagar, in Kashmir. It floats on the surface, and is skimmed off and dried."

A momentary glance is quite sufficient to convince any one practically acquainted with the *Diatomaceæ* that this white granular powder is not composed of diatoms, and has no affinity with the *Diatomaceæ* whatever. It was suggested that it might be foraminiferous, to which there is a greater resemblance. Fortunately we sent a little to Dr. Henry Carter, F.R.S., who was well acquainted with microscopic objects in India, and foraminifera in particular. This gentleman at once suggested its affinity with the spores of



"Hasan-i-Yusaf" from Kashmir.

Selaginella, and furnished for comparison those of *Selaginella cernua*, referring at the same time to the figure at page 436 of the 'Micrographical Dictionary.' The spores of *Selaginella* are almost identical in size, but more globose, less definitely ribbed, and, although allied, are not alike. Keeping in view the place at which this substance is said to be collected, "from the surface of lakes," it occurred to us at once that some species of *Isoëtes* would be the probable source. There being a family relationship between *Selaginella* and *Isoëtes*, it seemed probable that the spores of *Isoëtes* would resemble those of *Selaginella* and the "Hasan-i-Yusaf." A reference to the figures of the fruit of *Isoëtes capsularis*, in Griffith's 'Icones Plantarum Asiaticarum,' part 2, plates 116 to 118, has confirmed the opinion that the curious substance, instead of being a diatom, consists of the macrospores of a species of *Isoëtes*, allied to, even if not identical with, the *Isoëtes capsularis* of Roxburgh, or the common European species. Especially should figure 4 of the 116th plate be compared with the "Hasan-i-Yusaf." It is, moreover, perfectly true that this substance does not appear to be at all influenced by contact with cold nitric acid; and even when subjected to boiling in acid, very slow and gradual, as well as imperfect, disintegration takes place, unless the spores are first broken up. This fact, however, is by no means fatal to the conclusion that they are *Isoëtes* spores, in which, if



Spores of *Isoëtes capsularis* from Griffith's 'Icones Plantarum.' Facsimile from Plate 116.

we mistake not, a similar result will accrue, at least, if we may judge from the treatment of *Selaginella* spores with cold acid.

It only remains to ascertain what species of *Isoëtes* is found on the lakes of Kashmir, and to compare the spores with this substance. The form, texture, porcellanic appearance, resistance to acid, place, and mode of collection, affinity to *Selaginella*, and agreement with Griffith's figures, all indicate one source, which we have indicated, for the "Hasan-i-Yusaf;" and we commend this explanation with some confidence, as removing the chief difficulties in the way of identification of this mysterious substance with its botanical source.

Note. Since writing the above we have consulted the 'Flore d'Algérie,' and on the 36th and 37th plates find excellent figures of the spores of *Isoëtes*. Those of *Isoëtes velata* are almost identical with the Hasan-i-Yusaf, and leave not the slightest ground for doubt as to the source of the latter.

FATAL CASE OF POISONING WITH CHLORAL HYDRATE.

BY J. F. BROWN.

At the present time, when the last new and fashionable remedy—hydrate of chloral—occupies so large a share of our attention, and we are very frequently called upon, both by the medical profession and the public, to answer inquiries respecting it, the following particulars can hardly fail to be interesting.

Their consideration, too, may prompt scientific men to pursue what appears to me a highly important inquiry, viz. what means exist for counteracting the effects of an excessive dose of this substance, now so extensively used.

It appears that Mrs. —, a married lady, about 59 years of age, had suffered from sleeplessness and mental agitation, and that her husband, on their quitting England, had procured an ounce bottle of the hydrate, with the view of trying its effect, and fearing that in the Continental capital to which they were proceeding, there would be a difficulty in obtaining it.

Suffering greatly from want of rest, she became very solicitous to carry out their intention, but her husband deemed it prudent to consult first a local physician. This was done, and he promised, on seeing her in consultation with an eminent professor, to send a mixture or potion containing the desired remedy. But scarcely had he quitted the room than she obtained possession, by opening a drawer, of the bottle which they had brought with them; finding, probably, some little difficulty in removing the lumps from the bottle, she placed the latter in a glass, and dissolved or washed them out by pouring into it successive quantities of water, finally swallowing in this way the whole or very nearly the whole of its contents. On his return from taking leave of the medical attendant, Mr. — learnt from his wife what she had done, and being alarmed by her saying, "I feel so ill," he started instantly to recall medical aid; so quickly, indeed, had all this passed, that he overtook the physician while descending the last flight of stairs of their hotel.

The remedies applied were an emetic, hot mustard poultices to the chest, and *bleeding from the arm;* but although these were promptly used, they were ineffectual, as the unhappy lady expired within an hour.

These circumstances were related to me by a gentleman intimately acquainted with the deceased lady and her husband, and I have only, in conclusion, to express my indebtedness to him for the permission to make them public.

Dover, June 23rd, 1870.

UNGUENTUM SABINÆ.

BY T. H. BATEMAN.

To judge from the limited demand for this ointment, it does not now find much favour among the medical profession generally, although, in the opinion of some eminent surgeons, forming one of the best external irritants and escharotics we have, acting much more efficiently in keeping open blisters, etc., than does the ung. elemi of the British Pharmacopœia, which, to some extent, has taken its place.

Looking at this ointment from a pharmaceutical point of view, it is exceedingly unsatisfactory; the specimen I have before me (supplied by a London wholesale house) is perfectly rancid, and resembles in appearance "old green elder ointment."

Dr. Royle says, "When made in a porcelain vessel, or a water-bath, it is of a yellowish-green colour, efficient and active, and will keep good for a long time," which it certainly does not, as far as my experience goes.

The B. P. orders fresh savin-tops, collected in spring, to be used, thus compelling manufacturers to make their year's stock at once, which is decidedly objectionable, as it is thus frequently sent out rancid. Although this condition does not in any way interfere with its effect as an irritant, yet it prevents its coming under the category of "elegant preparations."

Pharmaceutists (excepting those in a large way) are in the habit of trusting to their wholesale druggists for it, the demand, as a rule, being too small to justify their making even the quantity ordered in the Pharmacopœia; besides, made on a small scale, it is exceedingly wasteful, the savin-tops being so bulky as to render it difficult to strain the ointment from them.

For satisfaction's sake I have prepared some myself, adopting the following somewhat modified formula, which differs only from the B. P. in the addition of gum benzoin :—

Fresh Savin-tops (bruised)	8 oz.
Yellow Wax	3 oz.
Prepared Lard	16 oz.
Gum Benzoin (coarse powder)	1 oz.

Melt the wax and lard on a water-bath, add the gum benzoin, and digest for half an hour, constantly stirring, then add the savin-tops, and further digest for twenty minutes; lastly, strain with pressure through calico or flannel, stirring occasionally until cold.

Resulting ointment, pale yellowish-green, with the odour of savin distinctly marked, which odour I have failed to detect in most, if not all bought specimens. The addition of gum benzoin (judging from its preservative effect on other ointments) will, in this case I hope, tend to prevent any decided change from taking place.

Manbey Grove, Stratford, June 2nd, 1870.

CHLORIDE OF ETHYLIDENE.

It is curious to observe how, occasionally, medicinal agents which have been used, reported on, and laid aside, crop up again. This week the daily papers report from Berlin that Liebreich has been employing as an anæsthetic the chloride of ethylidene—that is, the monochlorinated chloride of ethyle, with which Dr. Snow made us familiar nineteen years ago. Some of our most eminent surgeons, Mr. Bowman, Sir W. Fergusson, Mr. Henry Lee, and others, operated on patients under this agent, and there was almost an unanimous opinion in favour of it, Snow himself being peculiarly impressed with its safety. The chloride when pure boils at a temperature a few degrees lower, and has a lower specific gravity and a lower vapour density than chloroform. It has a higher boiling-point, a higher specific gravity, and a higher vapour density than bichloride of methylene. Its composition is $C_2H_4Cl_2$; chloroform is $CHCl_3$; and bichloride of methylene is CH_2Cl_2. It is isomeric with Dutch liquid, but differs in boiling-point. The dose required to produce deep anæsthesia is about half an ounce. The notice of monochlorinated chloride of ethyle recalls to us the remembrance that our distinguished countryman, Snow, was suddenly seized with his fatal illness while in the act of writing on this agent. He was drawing near to the conclusion of the chapter in his work which treats of this subject, when in the middle of a sentence he wrote his last word on the page—the word was "exit."—'*Medical Times and Gazette*,' *June* 11*th*, 1870.

ON THE USE OF TINFOIL FOR PRESERVING SUBSTANCES LIABLE TO CHANGE ON EXPOSURE TO AIR.

BY ERNEST BAUDRIMONT.

Tin reduced to thin sheets has for many years been employed for preserving a great number of substances from the action of air and moisture. The thin leaves (foil) of this metal are essentially repellent of moisture. When cemented to the surface of damp walls, they protect the paperhangings which may be afterwards applied, and they are in like manner used for lining the interior of boxes and drawers in which dried medicinal leaves and flowers are kept. It has long been the practice to enclose chocolate in tinfoil, to prevent the fatty matter contained in it from soiling the paper which forms the outside wrapper; in the same way butter of cacao itself is preserved, and some sorts of sweetmeats, sausages, and cheese are among the articles similarly protected. Tobacco-pouches are lined with tinfoil to preserve the flavour and humidity of the tobacco. Cakes of opium are kept in a moist and uniform state by wrapping them in this material, and bisulphate of soda is kept in the same way, for use in making artificial Seltzer water with Briet's apparatus. Lastly, on account of the opacity of tinfoil to the rays of light, bottles are coated with it for the purpose of excluding light from vegetable substances which would be injured by its action.

Notwithstanding the knowledge of all these facts, it might be said that the application of tinfoil for the preservation of substances liable to change is still rather limited, and there seemed to be a prospect of its admitting of a more general use than has hitherto been made of it. At the same time there was an absence of any precise experiments for the purpose of determining in a scientific manner the degree of impenetrability of tinfoil. Having been engaged for some time in the investigation of this subject, I have obtained the following results:—

For many years past I have observed that cacao butter, which readily becomes rancid even when kept in bottles into which it has been introduced in the melted state, if the bottles be opened from time to time, does not undergo the same change when moulded in tablets and wrapped in tinfoil. This fact, which was confirmed by many observations, and could only be explained by assuming the impenetrability of tinfoil to atmospheric air, formed the starting-point for some experiments in the same direction, which proved satisfactory. Thus, a piece of well-burned quicklime, enclosed in a double wrapper of tinfoil, was exposed in the atmosphere of the laboratory by the side of another similar piece which was exposed without protection. While the latter became slacked, that which was protected by the tinfoil, and weighed 92·2 grams on the 1st of December, 1867, had only gained 3 decigrams in weight at the expiration of a month, and after being kept until the 25th of March, 1868, it had only increased to 94 grams. It had thus gained only 1·8 grams in four months. On being then taken out of its metallic envelope much heat was developed from absorption of moisture, and it fell into powder.

Satisfied by this experiment of the efficacy of tinfoil for preserving bodies from the action of air and moisture, it seemed probable that substances the most susceptible of change might be kept in the same way. It was found that substances so deliquescent as chloride of calcium and liver of sulphur, and efflorescent salts such as carbonate and sulphate of soda, remained almost unchanged when wrapped in tinfoil, increasing or diminishing only to a few thousandths of their weight in several weeks.

Other experiments were made of a more precise character. It is well known that fresh lemons become rapidly dried and ultimately hard when exposed to the air, and that they also become perished and covered with mould. I had endeavoured to prevent this drying and moulding by placing the lemons in close vessels, in dry air, in sand, and also in bran, but none of these methods proved efficacious. Thus, for example, in twenty-one days the lemons lost on an average, 17·33 per cent. of their weight in sand, and 17·13 per cent. in bran. Experiments were made for the purpose of ascertaining the effect of enveloping the fruit in tinfoil, and also of coating it with a film of collodion. Some of the fruit prepared in each way, and some unprepared, was weighed, exposed to the air, and again weighed at intervals of a month. This method was applied to lemons and oranges, and the following results were obtained:—

1. The unprepared fruit became rapidly dried. In two months the lemons had lost 42 per cent. of their weight, while the oranges, in the same time, had lost only 26 per cent.

2. Collodion, when applied to the fruit alone, exerted but a feeble preservative influence in retarding spontaneous evaporation. In two months lemons coated with collodion had lost 29 per cent., and oranges 22·5 per cent.

3. Tinfoil almost entirely prevents the drying of the fruit. In two months lemons lost only 1·58 per cent., and in three months 3·16 per cent. In one case, indeed, the loss was only 0·92 per cent. during the longer period. Oranges lost about 5 per cent. in two months. On the removal of the metallic envelope, the fruit was found to be as fresh and fragrant as when the experiments were commenced. These observations and experiments will tend to show the remarkable power of tinfoil in preserving substances enclosed in it from the influence of air and moisture derived from air, and may induce those who are interested in the subject to extend the application of this preservative means.—*Journal de Pharmacie et de Chimie.*

EFFECT OF BISULPHIDE OF CARBON ON WOOD.

Bisulphide of carbon, according to Sidot, renders wood very sonorous, and makes it an excellent conductor of heat and electricity. Sidot passed vapours of bisulphide of carbon over pieces of wood in a porcelain tube, first in the cold, in order to expel the air, and then at high temperature, the tube being slowly and gradually heated for an hour until it was red-hot. The various kinds of wood yield, by this treatment, a coal which is not surpassed by the most sonorous substances known. Sidot made a bell of oak wood, and subjected it to this treatment with bisulphide of carbon. The sound it gave after the process compared favourably with that of a metallic bell of equal diameter. The hardest kinds of wood seem to produce the purest and most harmonious tones. On account of its capacity of conducting heat and electricity, Sidot recommends the coal prepared in this manner for use in Bunsen's galvanic batteries, and for pencils for the electric light. Such pencils give a much intenser light than those made from the graphite of gas-retorts; they become gradually white-hot throughout their whole mass, without burning at a single point, and cool down immediately as soon as the fire is removed. Linen, hemp, cotton, paper, and silk behave similarly to wood, and the action of methylated spirits (wood naphtha), hydrocarbons, etc., resembles that of bisulphide of carbon. The coal from wood has superficial metallic lustre, is denser than common charcoal, and has a greater absorbing power for gases.—*Journal of Society of Arts.*

CULTIVATION OF IPECACUANHA IN INDIA.

The Supplement to the 'Gazette of India' of 23rd January, 1869, contained a strong representation to Government from the Inspector-General of Hospitals, dated 5th October, on the advisability of introducing the cultivation of the ipecacuanha plant in an analogous manner to that of cinchona.

The suggestion was forwarded to Dr. Anderson, the Superintendent of the Botanical Gardens, Calcutta, who stated that he had, for some years past, thought of the subject, but had been unable to procure any plants on trial until April, 1866, when one plant was sent out overland by the Director of the Royal Gardens at Kew. This original plant died soon after arrival, but, at the date of his writing, December, 1868, nine plants were in existence, artificially propagated from the original one, besides five growing at the cinchona plantations at Darjeeling, to which place a cutting had been sent in 1867.

The 'Indian Medical Gazette,' on the authority of Mr. Clarke, now acting for Dr. Anderson, quotes the remarks of that gentleman:—"When I took charge of the Gardens, in 1869, there were seven plants, all under glass, and in a very low state of vegetation. The plant had been found to grow very slowly, and, moreover, to be very shy of propagation by cuttings.

"It is very possible that when the plant once gets up, it may not prove slow-growing, and that when we once have plants that seed, it may not prove slow of propagation; but I fear many days will elapse before any produce is likely to be obtained."—*The Medical Press.*

PRODUCTION OF SOLID MANURE FROM SEWAGE.

The A B C Process.

One of the most important economic and sanitary questions of the day is that of the best means of utilizing the sewage of towns. It has occupied the attention of many eminent men among chemists, agriculturists, and engineers, and numerous processes have been suggested with a view to its solution, some of which are now undergoing extensive practical trial. Among these is the process commonly designated the A B C process, by which sewage water is deprived of most of its impurity, which is separated in the solid state, and rendered fit for use as manure, while the residual water is said to be so far purified as to be incapable of polluting the rivers it may be allowed to run into. Although it cannot be said that the purifying effect of this method of treating sewage water has been proved to be sufficient, there are many who believe in it, and still more who are interested in the trial, and wish to be acquainted with the details of the process. The following description, which has been published in the 'Engineer,' relates to the works recently erected at Hastings. It has evidently been written in the interest of the Company by whom the process is carried out, and some of the statements should therefore be received with a little reservation; but it serves, nevertheless, to explain the general nature of the operations:—

"The beauties of Hastings are too well-known to seaside visitors to require description here, and we will therefore at once take our readers to the beach, where the works of the Hastings Sewage Manure Company are situated, and where they are carrying on the 'A B C' process of utilizing sewage. We may premise that this name has been given to the process from the initial letters of the principal ingredients used in deodorizing and precipitating the sewage, viz. alum, blood, charcoal, and clay; other less important chemical materials are used, but the effect produced by the mixture with the sewage causes its instant deodorization and precipitates a manure which has been appropriately called native guano, and by which all the well-known valuable manurial qualities of sewage are retained, and the whole is converted into a dry portable manure, something similar in appearance to, and with many of the valuable properties of, Peruvian guano. Leaving the railway station and proceeding along the beach road, and passing in front of the old esplanade to the extreme eastern limit of the town, we come upon the works of the sewage company. These are situated close under the overhanging cliffs, which are 220 feet high, under which they seem to nestle, and from the neatness of the elevation of the buildings, form no unappropriate and unsightly termination to the seabeach.

"The elevation consists of a two-storied building of red, relieved by bands of black and yellow bricks, with simple windows with Gothic heads. The roof is of corrugated iron, and from the side nearest to the cliff springs up a chimney 65 feet in height, of good proportions, and giving a very effective finish to the whole.

"Entering by the western door, the visitor is first struck by the line of iron pillars supporting the drying floor, between which the eight centrifugals used for drying the manure, each with its accompanying engine, may be seen. Passing between these, we will take the visitor to the spot where the sewage first enters the works, and will do our best to describe the process which so quickly converts this offensive substance into clear water and into valuable manure.

"The sewer is egg-shaped, 6 feet by 4 feet, and conveys the whole sewage of Hastings. This is received into a square chamber, 13 feet by 10 feet, in which an agitator revolves at great speed, not only to thoroughly mix the 'A B C' with the sewage, but to tear up all extraneous and heterogeneous matters which are brought down the sewers. On one side of this agitating pit are two smaller pits to contain the 'A B C' mixture; these are used alternately, and in them the various chemicals above mentioned are mixed with water, and also stirred up by an agitator.

"A chain of endless buckets delivers this mixture into the agitating chamber, where it is thoroughly stirred with the sewage. In less than a minute the chemical part of the 'A B C' process is over, deodorization has taken place, the solid part of the sewage has curdled into flakes, and the remainder of the process is entirely mechanical. The sewage thus treated then flows into the settling tanks, originally built by the local board of Hastings some years previous to the sewage company commencing their operations. The size of the original tank was 214 feet long, 100 feet wide, and divided by seven lines of piers, which carry arches in the direction of its length, the crown of these arches being a few feet below the level of the beach. The reason for the tank being covered in this instance is owing to the tank being below the level of the sea, and as the sewage can be pent up during the hours of high tide. Under other circumstances the company would have preferred to put up tanks of their own construction, open to the air, so as to admit of the oxidization of the effluent water, the process being entirely free from all disagreeable odour from the moment the 'A B C' process touches the sewage.

"The tank is divided lengthwise by a wall, each portion being used alternately. The sewage, treated as previously mentioned, remains quiescent, allowing the solid particles of both the previously soluble and suspended matter to settle. At the end of the tank nearest the sea, an angular brick weir, about 4 feet high, encloses the outfall. It is pierced by falling penstocks or sluices, which can be regulated as becomes necessary. Over this the effluent water flows to the outfall sewer, consisting of a line of 4 feet cast-iron pipes, carried out nearly a quarter of a mile to the eastward to low water.

These iron pipes, constructed and laid out at an enormous cost—a relic of the old system of discharging sewage into the sea,—are entirely unnecessary to the 'A B C' process. This effluent water is perfectly clean and inodorous, and is the only part of the Hastings sewage which is allowed to escape, thus preventing all future pollution to the neighbouring bathing beach. At Leamington, where the 'A B C' process is also in operation, the effluent water runs into the river Leam so free from impurity that it has been declared by Dr. Letheby to be practically innocuous.

"Having thus followed the process to the discharge of the effluent water, we will now return to the remaining and most important part of the operations, viz. the manurial part of the sewage. The mud deposited at the bottom of the tanks is pumped through a 6-inch iron pipe, direct into the centrifugal or into a storage tank as may be required. The adoption of these centrifugals to the purpose of drying the manure is one of the most interesting features of the process. They are eight in number, each worked by an attendant engine of 4-horse power, and which have all been christened by the names of, we doubt not, some favourites among the fair sex, as seen by the plates attached, Mabel, Maggie, Edith, Harriet, etc. They consist each of a circular wire gauze basket, 40 inches in diameter, enclosed in a cast-iron case of about 2 feet in depth, rotating on a powerful spindle and driven by means of a band round the fly-wheel of their respective engines, at the rate of about 1200 to 1500 revolutions per minute. Through the gauze of these the moisture of the mud is driven off by centrifugal force, leaving a partially dried solid deposit on the sides of the basket. The moisture or water thus driven off is returned to the agitating pit, to assist in re-treating fresh sewage.

"The solid manure is then removed to the acidifying chamber, where it is sprinkled with sulphuric acid, the object being to entirely fix its ammonia and prevent its escape until absorbed by the roots of the plants. The gases which are generated at the moment of this mixture are conducted by a flue to the boiler furnaces, and there harmlessly consumed. Applied to one of the centrifugals is a clever self-emptying machine, which discharges the mud without hand labour in the form of a solid pipe, which will eventually be conveyed on an endless band into the acidifying chamber. From this chamber the manure is lifted to the drying room above, where it is spread to the depth of 8 inches on a steam floor, which is supplied by the exhaust steam from the various engines employed. It is first deposited on the hottest portion of the floor, and as the moisture is driven off removed to the cooler portion, thus avoiding any chance of over-heating the manure. After twelve hours, the manure, now really become native guano, is made into heaps, where it is allowed to remain until the fermentation, which immediately begins, has ceased. By this fermentation all animal life, such as entozoa, tape-worm eggs, etc., is entirely destroyed. The manure is then lifted and put into bags ready for the farmers' use. This manure has earned already a high reputation among them, as is satisfactorily proved by the increased orders received from the farmers who have tried it. Its price, delivered at any railway station in England or Wales, is now £5 per ton, whilst we believe its cost does not exceed 30*s*. The demand for it has been so great at the Leamington works, we were informed lately, when on our visit of inspection, that it has been found impossible to meet it, and orders that would exhaust the supply until the autumn are still unexecuted. An engine of 16-horse power nominal, which drives the pump of the agitators, was constructed by Manlove, Alliott, and Co., of Nottingham, who also supplied the centrifugals and their engines. The pumps, shafting, and piping are from the works of Mr. Thomas Middleton, of Southwark. The contractor for the building was Mr. John Howell.

"The plans were designed by the managing directors of the Native Guano Company, and executed and carried out by their staff, assisted by Messrs. Ellis and Birch, of Westminster. We were surprised to hear how quickly these works have been erected, manure having been actually made within seven weeks from the issue of the contracts."

The Sulphur Beds of California.—Sulphur has been chiefly supplied from the sides of Mount Etna, in Sicily, but the works on the shore of Clear Lake produce now four tons a day. The Sicilian brimstone costs in California 4 cents per lb., but the domestic article is sold for 3½ cents. Clear Lake occupies the crater of an extinct volcano, and the evidences of volcanic action abound in the vicinity. Within a triangle of about twenty-five miles to the side there are volcanic scoria, trap, lava, obsidian, tufa, warm springs, and other remains of eruptions, with signs of subterranean heat not far from the surface. The sulphur bed of Clear Lake consists of a bank resembling ashes, containing numerous alkaline and sulphur-springs with vent-holes, from which sulphurous fumes escape. Pure sulphur crystals deposited from the fumes surround these holes. The earth, containing about 50 per cent. of sulphur, is placed in an iron retort heated to a high temperature, so that the sulphur is driven off in fumes into a receiver, where it settles in a liquid form, and runs out into pine boxes 2 feet long and 1 foot square. The lump sulphur is used chiefly for making powder and sulphuric acid, which last is employed in making bluestone, giant-powder, nitric acid, and muriatic acid, and in refining gold and silver. The consumption of sulphuric, nitric, and muriatic acids on the coasts amounts to 2,000,000 lb., and the entire demand is supplied by home manufacture. Flowers of sulphur have also been produced at Clear Lake. The fumes passing off from the retort are in this case led into a large cool chamber, where they condense into a flaky snow-like condition.—*Scientific Opinion.*

Immunity of Monkeys to Strychnia.—In a former number of this Journal we recorded a case in which a monkey was found to be perfectly insusceptible to the action of strychnia. This subject has been investigated by Dr. Theobald Ringer, and the results have been published in the 'Indian Medical Gazette.' The following facts have been elicited:—1st. That the "lungoor" may be said to be proof against strychnia; 2nd, That the "pouch-cheek" monkey is susceptible, but not so readily as a human being; 3rd, That the old saying that a monkey will never eat anything that is "poisonous" is clearly shown; the "lungoor" readily eating and relishing the strychnia, which produced no ill effects upon him, whilst the "pouch-cheek" monkey refused the same, and fell a victim to the poison.

A New Insect Poison.—M. Cloez considers the following to be a complete annihilator for plant lice, and other small insects:—Take 3½ ounces of quassia chips, and 5 drachms of stavesacre seed powdered; these are to be put into seven pints of water, and boiled until reduced to five pints. When the liquid is cooled, strain it, and use with a water-pot or syringe.

The Pharmaceutical Journal.

SATURDAY, JULY 2, 1870.

THE 'LANCET' AND THE MUTUAL MEDICAL AID SOCIETY.

We are glad to find that the leading medical journal has taken up the subject of co-operative trading as applied to the medical profession. There is no doubt that the Mutual Medical Aid Society, to which we alluded in our last number, would affect medical men much more than pharmacists; for although it is proposed that medicines as well as advice should be supplied to those who subscribe to the association, yet the subscribers would, in most cases, belong to the class of persons who generally get advice and medicine together from a general practitioner. But, admitting that our members would probably not be directly affected by the particular institution referred to, to so great an extent as others, still the influence of this extension of a system from which chemists are already suffering would be felt as an aggravation of the evils they have so much cause to complain of. The 'Lancet' denies the statement which had been made in one of the daily papers, to the effect that the proposal to establish a Mutual Medical Aid Society had received the sanction of the medical profession, and says "the exact contrary is the case."

Referring in a subsequent article to a statement in the 'Graphic,' that, if the Mutual Medical Aid Society is not really self-supporting, persons of honourable feeling, however strained in means, would shrink from associating themselves with it, while, on the other hand, if it is self-supporting there could be no reason for refusing any one desirous of subscribing, —for why should persons of unlimited means pay more for services than the market value?—the 'Lancet' very justly observes, "We would advise the eminent medical promoters of this trading scheme to look out sharply for their own fees. How do they know that the Committee will not begin by putting up the posts of consulting surgeon and physician to public competition, in order to ascertain the market value of the commodity they require? Such a competition might not add to the dignity of the profession, but it would perhaps enable us to estimate the value of consultees from a trading point of view."

THE TREATMENT AND UTILIZATION OF SEWAGE.

Many of our readers are no doubt aware that a Committee, appointed by the British Association, "to report on the treatment and utilization of sewage," has been in operation for some time. It was first appointed in 1868 at the meeting of the Association at Norwich, and was reappointed last year at Exeter. The subject was considered by the Association to be one deserving of a thorough investigation, but this would necessarily involve considerable expense for experiments, especially analyses; and as the Association has no funds adequate and available for such purpose, an appeal was made to the various municipal authorities and other governing bodies officially interested in the subject, for the funds required for the investigation. It appears that a sufficient amount to defray the expenses has thus been raised, and the Committee, comprising men eminent in their respective departments, and possessing the requisite engineering, chemical, medical, and agricultural knowledge, to qualify them for such an inquiry, have already obtained much valuable information, especially with reference to the methods adopted in most civilized countries of dealing with town refuse, and with reference to the engineering questions involved in methods that have been adopted or suggested. Much of this information was obtained in the first year of the Committee's operations, with a grant of only £10, but, with the accession of much larger funds, disagreement has arisen among the members of the Committee as to the method of doing and paying for the work.

It appears that a majority of the Committee have decided that the independence and disinterestedness of the members of the Committee should be placed beyond suspicion by their duties being of a strictly honorary character, and all paid work being obtained from without, while two of the chemists in the Committee differ on this point, and contend that it would be perfectly consistent with their position, and conducive to the interests of those who have contributed the funds, that the chemical work should be done under the guidance and supervision of chemical members of the Committee, to whom mere working expenses should be paid.

Both of these appear to be legitimate modes of proceeding under special circumstances, the nature of which may determine the preference for one or the other, and it is much to be regretted that the successful issue of an important investigation should be endangered by a public dispute on such a question.

SALE OF POISONS (IRELAND) BILL.

The Bill for regulating the sale of poisons in Ireland, which, as introduced in the House of Commons on the 24th of May, by the Solicitor-General for Ireland, was given *in extenso* in our number issued on the 1st of June, is now waiting a second reading in the House of Lords. It has undergone one or two slight alterations, as, for instance, in section 1, the proviso that the Apothecaries' Hall of Dublin might, with the sanction of the Privy Council, add to the schedule of poisons, has been struck out, and that power is now given to the King and Queen's College of Physicians in Ireland. In the schedule of poisons, the preparations of prussic acid, of the cyanides, and of atropine, have been struck out. With these exceptions the Bill appears to remain intact.

BETTS'S METALLIC CAPSULES.

PROSECUTIONS AGAINST RETAIL CHEMISTS.

The long-pending suits in Chancery, which were commenced by Mr. Betts about five years ago, against a number of retail chemists and perfumers, for selling articles capped with metallic capsules which the plaintiff alleged were not of his manufacture and the use of which was an infringement of his patent rights, have at last been decided by Vice-Chancellor James, and we are happy to say that the decision is wholly in favour of the defendants. The circumstances under which the suits were instituted are described at page 41, Vol. VII., 2nd series, of this Journal, and allusion has been made to the subject several times since. In our next issue we shall give an account of the trial, which has occupied two days. We can only state here that the cases were all dismissed with costs, and that the Vice-Chancellor, in giving judgment, condemned in strong terms the conduct of the plaintiff in this affair.

PROFESSOR HUXLEY ON MATERIA MEDICA AS A BRANCH OF MEDICAL EDUCATION.

In an address delivered by Professor Huxley the other day, on the occasion of the distribution of prizes to the medical students at University College, in alluding to subjects he would omit from the curriculum of medical education, the following remarks were made:—

"I must confess, if I had my way, I would abolish Materia Medica* altogether. I recollect, when I was at the University of London, Dr. Pereira was the examiner,—and you know that Pereira's 'Materia Medica' was a book *de omnibus rebus*. I recollect my struggles with that book late at night and early in the morning (I worked very hard in those days), and I do believe that I got that book into my head somehow or other, but then I will undertake to say that I forgot it all a week afterwards. Not one trace of a knowledge of drugs has remained in my memory from that time to this; and really, as a matter of common sense, I cannot understand the arguments for obliging a medical man to know all about drugs, and where they come from. Why not make him belong to the Iron and Steel Institute, and learn something about cutlery, because he uses knives? But do not suppose, after all these deductions, there would not be ample room for your activity. Let us count up what we have left. I suppose, at the outside, all the time that can be hoped for for medical education is about four years. That is taking the outside limit. Well, what have you in those four years upon my estimate? Physics applied to physiology, chemistry applied to physiology, physiology, anatomy, surgery, medicine, obstetrics, hygiene, and medical jurisprudence,—nine subjects for four years! And when you consider what those subjects are, and that the acquirement of anything beyond the rudiments of any one of them may tax the energies of a lifetime, I think that even those energies which you, young gentlemen, have been displaying for the last hour or two might be taxed to keep thoroughly up to what is wanted for your medical career; and I entertain a very strong conviction that any one who adds to medical education one iota or tittle beyond what is absolutely necessary is guilty of a very grave offence."

* "It will, I hope, be understood that I do not include Therapeutics under this head."

"AN AGE OF PROGRESS."

TO THE EDITOR OF THE PHARMACEUTICAL JOURNAL.

Sir,—I beg you will allow me space in your next issue to protest against the character of one of the leading articles in your last.

I could excuse, though I could not approve the tone of some of the speakers who were borne along in the storm of debate at the annual meeting; and I could extenuate, though certainly I could not justify the conduct of a scrutineer who allowed his excited feelings to eclipse his judgment; but I can acknowledge no excuse for the publication of a leading article, professedly giving a deliberate opinion,—a calm judgment founded upon the superior knowledge of the writer,—in contrast to the ignorance and impetuosity of the bulk of the members of our Society, yet containing statements which, though partial truths, are virtually misrepresentations, and containing remarks which can only be regarded as sneering and unjust towards the men whom it professes to honour.

I could not have imagined, Sir, that an article so puerile and undignified could have fallen from your pen, nor that your judgment, which I have always held in high estimation, could have yielded a place of honour to a communication which was scarcely entitled to space in the columns of anonymous correspondence.

Were it not that the editorship is vacant at the moment I write, I would say that justice demands a public apology, and a fair representation of the case in your next number; but as the Journal in July may appear under the authority of a new editor, or, perhaps, without an editor at all, I beg to draw attention to one or two points which may enable your readers to form a more just estimate of the merits of the case than they are at present likely to possess.

In saying that Mr. Bottle has attended no committee meeting, does not justice require that the context should clearly state that he has never been called to one? The partial truth is, that he has never attended a single committee; the lurking injustice is the statement of this truth in such a way as to leave the impression that he has neglected his duty.

Might it not be said with equal truth that the London members, being in majority, elected one another to the committees, and fixed the days of meeting at such times as would not be convenient to any one at a distance? and as your article states three-fourths of the business of the Council is pre-arranged at these committee meetings, and a country member attending Council without the knowledge which committee work would give him, has no chance against his metropolitan brethren,—might we not, with equal justice, conclude that the country members of the Council were thus virtually set aside, and hopelessly helpless till their constituents had placed a majority on their side to enable them to arrange matters better, and thus to save the Society from being entirely in the hands of the London tradesmen, who form but a small minority of its members?

This is a conclusion which might be drawn from a more careful examination of the published information than that which you have offered us, and not unlikely to be arrived at by the provincial pharmacists, if party spirit is fostered by such one-sided writing being allowed to appear as official matter.

The truth is, that the country members of the Council do not feel that their distance disqualifies them for the acceptance of committee work, for they *have* accepted the same; they now *have* elected one another to work along with their London brethren in *all* the committees; they have elected *every country member* of Council to at least one committee, and two of them—Mr. Abraham and Mr. Edwards—to as many as four committees each; they have arranged the times of meeting of the committees, so that a frequent attendance of the country members will not be impracticable; and, though their presence will always involve twice as great a sacrifice as is required to be made by those residing within a cab drive of Bloomsbury, it is an injustice to condemn them before they have had a trial.

May I ask why Mr. Deane is mentioned among those who are geographically unable to attend? unless it be to mislead those, if there are such, who do not know that Clapham is an easy omnibus ride from Bloomsbury Square. And may I ask why an unfair view of the attendance of London members is given by drawing attention to those who have been many times present, and omitting to notice those who have been absent so often as to show that the geographical qualification is no guarantee of regularity?

I sought to justify this omission on the ground of your remarks having reference to members of the new Council only, but this I find is not the case, as the number fifteen applies to Mr. Morson, who is not on the present Council. Then, in the hope of yet justifying the omissions, I expected to find then the names of founders of the Society,—men who are willingly acknowledged to have earned their laurels and their ease, and would be gladly seen at a meeting without constant attendance being expected of them. But against this, Sir, I find the first name you have thus omitted is that of Mr. Ince, who has been called to the library committee seventeen times, and has attended it only once.

I can, therefore, come to no other conclusion than that you have picked out the good numbers, with the intention of implying that residence in London ensured good attendance, and omitted to notice that the London list also included two attendances in response to twenty-one summonses (Ince), two attendances in response to thirty-four summonses (Orridge), and six attendances in response to thirty-one summonses (Squire), because these facts detract from the apparent strength of your position. One would think that the first of these names, so intimately associated with ethics, should have prompted a fairer statement of the case. I can only imagine that some unfortunate circumstance disturbed your usual cool judgment when you wrote this article, or you could not have offered to your provincial friends the information that the Council is not a Young Men's Mutual Improvement Association,—a piece of information which a day's reflection would, no doubt, show you is both uncalled for and offensive; nor could you, as editor of a scientific journal, have penned a sentence implying that Mr. Brady is less worthy of our respect in consequence of his pursuit of natural history.

Barnard S. Proctor.

11, *Grey Street, Newcastle, June 24th*, 1870.

TO THE READERS OF THE PHARMACEUTICAL JOURNAL.

I wrote the Leader entitled "An Age of Progress." It has excited undue praise, but there are some who take exception to the statements it contains.

It struck me that it might prejudice the Editor of the 'Pharmaceutical Journal' were he supposed to be the author. The only part he has had in the transaction was to tone-down, modify, and materially improve my sentences, to their great advantage. I see not one syllable I wish to retract or alter: in obedience to Journal usage the article was not signed, a circumstance I regret. I define the word *Council* to prove that it is an assembly for deliberation and not at all for discussion. I object to reporting its proceedings for reasons I have given so often that I am afraid of their repetition. Amongst them are. First, conclusions are arrived at, in the main, by conversational means, perfectly legitimate but unadapted for publication. Secondly, the actual work is done in Committee, and it has happened to myself and others, that in order not to be eternally present before the board, or to gain the reputation of being heard for much speaking, I and others have used the friendly services of a councillor to bring forward our particular Resolutions. In that case, a gentleman in the Country, wishing to know his man and give his vote, is led into error. A sign post is an excellent institution but it is desirable that it should not point the wrong way. Thirdly debates do arise occasionally. I have accurately described them as a storm passing over otherwise tranquil waters. These of necessity often involve personal matters which it would be most unwise to reveal. Their publication would sow an abundant harvest of ill-will, misunderstanding and estrangement.

But this is not the point about which I am called in question. I have stated the truism that neither as I could direct the home affairs of a firm in Manchester, neither can those residing at a long distance from the metropolis conduct home London business. Fearing however that this paragraph might be misinterpreted into a slight passed on our Provincial friends, the identical sentence was submitted to the President and met with his approval. Desiring to make assurance doubly sure, I added, that these very persons were amongst the utterly best men of our Society. Was it possible to take more care? Could sentences be more guarded? Moreover the directors of this Journal and other Editors know with what elaborate trouble I prepare my press communications. Easy writing is never read. Two gentlemen in another periodical have ventured on a description of the same affair, namely the *character* of the Election. One, formerly a member of Council, (not myself) supplied the materials; the Editor did the text. Between them, they termed the transaction of the month of May, "Reaping the Whirlwind." With them, I regret the non-election of Mr. Williams.

To me besides it is a grief that Mr. Charles Savory has not been allowed to take that position to which he is so fully entitled, and to discharge the duties of which he is so admirably competent. But one thing disturbs me—that I should have been so fearfully misinterpreted as to cause a suspicion that I had raised a sarcasm at the expense of Mr. Brady. This was not particularly probable as with one exception he is the nearest friend I have, and no Pharmacist can be prouder of his scientific reputation than myself.

It is my fortune, or misfortune, in this case the latter, to be a diligent reader of French. In that language the commonest of all common things is to impute as a fault a known, acknowledged excellence. When a celebrated songstress was addressed thus, "Madame vous êtes charmante, bien que vous savez chanter," the lady did not resent as an insult the remark regarding her vocal abilities. That a pharmacist at Newcastle should be engaged in scientific pursuits or devoted to the study of Natural History, is to his highest praise. My Leader assumed this to be understood.

What is this about? I state that to appoint on Committee work those who live at considerable distances is unwise and injudicious. So it is. Should this sentiment be considered a depreciation of Provincial ability, I repudiate the notion. I am an officer and Member of the British Pharmaceutical Conference which alone would be sufficient denial. Last month I left for the next five years, the thorny path of Journalism: but I would ask the readers of this Journal not always to expect to be written to as an Infant School. Let them give and take—let them allow a man to have an opinion of his own.

Meanwhile do not visit my sins on the Editor. He was less likely to scrutinize my short essay because I was on the regular staff, and my contributions have never yet been refused. I had requested that space should be reserved for my article among the leaders, and there was little time left for deliberation after the manuscript was sent. The issue of the Journal was delayed to admit of alterations which the Editor suggested, but I am solely responsible for the article as it stands.

Nothing remains but for me to thank Professor Redwood for his courtesy and his editorial care in this instance.

JOSEPH INCE.

26, *St. George's Place, Hyde Park Corner, S.W.,*
June 25th, 1870.

Transactions of the Pharmaceutical Society.

EXAMINATION IN LONDON.

June 15th, 1870.

Present—Messrs. Allchin, Bird, Carteighe, Cracknell, Davenport, Deane, Edwards, Gale, Garle, Haselden, and Southall.

Thirty-four candidates presented themselves for examination; the following passed, and were duly registered:—

As PHARMACEUTICAL CHEMISTS.

*Fryer, Charles .... Guildford.
Horsley, Thomas Wood .... Manchester.
Furmston, Samuel Chambers .... Wycombe.
Tuck, William Henry .... Surbiton.

As CHEMISTS AND DRUGGISTS.

*Masson, George .... London.
*Appleby, Calvert .... East Retford.
*Powell, Thomas Henry .... Hornsey Rise.
*Pick, Richard .... Hull.
*Wing, Lewis .... Torquay.
Davison, Anthony .... Kidderminster.
Wallis, Herbert Boyd .... London.
Warren, William .... Chertsey.
Griffin, Thomas .... Bromley.
Horton, Walter Charles .... Windsor.
Browne, Joseph Alleyne .... London.
Botterill, George Thomas ...... Boston.
Goodenough, Joshua .... Norwich.
Barclay, Arthur Edward ...... Lee.
Read, Henry Holditch .... Peterborough.
Wonfor, Herbert Ison .... Southampton.
Osborne, James .... Ashbourne.
Hill, William Edward .... Leicester.
Vincent, Philip .... Fulham.

The above names are arranged in order of merit.

FIRST, OR PRELIMINARY EXAMINATION.

The following, having presented to the Board certificates of examination by legally constituted Examining Bodies, and the said certificates having been approved, were registered as

APPRENTICES OR STUDENTS.

Barclay, Arthur Edward .... Lee.
Green, Marryat Hahnemann .... Peckham.
Webb, Frederick Brooks .... Birmingham.

EXAMINATION IN EDINBURGH.

May 30th, 1870.

Present—Messrs. Ainslie, Brown, Buchanan, Kemp, and Young.

Eight candidates presented themselves for the Major and Minor Examinations; the following passed, and were duly registered:—

MAJOR (as Pharmaceutical Chemists).

Duncan, Joseph .... Edinburgh.
Finlay, James .... Edinburgh.

MINOR (as Chemists and Druggists).

Gilmour, David .... Edinburgh.
Howie, William Lamond .... Edinburgh.
Macfarlane, Patrick .... Alexandria, N.B.
Paton, James .... Edinburgh.

MODIFIED EXAMINATION.

Seven candidates presented themselves for examination; the following six passed, and were registered as

CHEMISTS AND DRUGGISTS.

Campbell, William .... Glasgow.
Chalmers, William .... Glasgow.
Campbell, Lorne John Malcolm .. Helensburgh.
Drysdale, Robert .... Glasgow.
Greig, William, jun. .... Glasgow.
Yoxall, Henry .... Belfast.

FIRST, OR PRELIMINARY EXAMINATION.

Eleven candidates were examined; the following eight passed, and were registered as

APPRENTICES OR STUDENTS.

Gilmour, David .... Edinburgh.
Hardie, Alexander .... Edinburgh.
Macauly, John .... Helensburgh.
Macfarlane, Patrick .... Alexandria, N.B.
Macfarlane, William .... Girvan.
Paton, James .... Edinburgh.
Thomson, Charles M. .... Edinburgh.
Todrick, William .... Edinburgh.

* Passed with honours.

Provincial Transactions.

ABERDEEN ASSOCIATION OF ASSISTANT CHEMISTS AND DRUGGISTS.

The half-yearly General Meeting of the above Association was held in the U. P. Hall, St. Paul Street, on the 13th inst.; Mr. James Thorn, President, in the chair.

Mr. W. Donald, Secretary, submitted a report of the proceedings of the Association for the past six months, showing that a number of scientific and interesting subjects had been brought before the Society, and much research and ability had been displayed by those members who had contributed papers during the session. The finances were also reported to be in a very satisfactory state, and the attendance of the members has been such as to leave no doubt of the continued prosperity of the Association. During the half-year, ten gentlemen have been elected as members, making a total of fifty-two since the formation of the Society in 1868; but several of those, from various unavoidable causes, have left the Society, leaving on the roll at present forty-five members; but as that includes representatives from almost every shop in town, we have every reason to feel gratified at the success already attained.

Classes have been formed in connection with the Society under the tuition of Mr. Roy, the subjects taught being those embraced in the preliminary examination of the Pharmaceutical Society, and thirty-seven members have already availed themselves of the opportunity thus afforded them of preparing for examination.

Messrs. Thorn and Donald received hearty votes of thanks for their exertions on behalf of the Society, and the following were then elected office-bearers for the ensuing six months, viz.:—Mr. W. Donald, *President;* Mr. J. Bertie, *Vice-President;* and Mr. J. Thorn, *Secretary and Treasurer.*

LIVERPOOL CHEMISTS' ASSOCIATION.

Fifteenth General Meeting, held May 13th, 1870; the President, Mr. J. Abraham, in the chair.

Messrs. W. L. Fewster and W. Hope were duly elected members of the Association.

The President read an extract from the 'Scotsman' relative to Sir James Simpson's obligations to Mr. D. Waldie for the suggestion of chloroform as an anæsthetic. Mr. Waldie had prepared it to make chloric ether of constant composition.

Mr. Redford said that chloral seemed to act best when given in small doses. It was not of uniform quality, some having a fetid smell, which may explain the unsatisfactory results sometimes following its administration.

The Secretary read a paper recently published on "Crab-oil," a sample of which had been shown at a previous meeting. It is a vegetable oil obtained from the fruit of the *Carapa Guianensis*, and is said to be useful in rheumatism.

Mr. Jones gave the results of some experiments on the use of chloral in photography. He found that it gave considerably greater sensitiveness.

The meeting then adjourned to the tea-room, where the remainder of the evening was spent in the examination of microscopic objects.

Sixteenth and concluding Meeting, held May 26th. In the absence of Mr. Abraham, the chair was taken by the Vice-President, Mr. J. T. Robinson.

A letter was read from Dr. Symes, recommending that the Association should provide four or five books for autograph prescriptions, and offering to fill one of them himself.

Mr. Shaw proposed that the thanks of the meeting should be given to Dr. Symes for his generous offer, and that the question be referred to the Council to consider the best means of carrying out the suggestion.

Mr. Robinson seconded the motion, which was carried unanimously.

Mr. Mason exhibited a sample of artificial alizarine, beautifully crystallized, manufactured by Dr. Calvert; and Mr. Davies showed two pieces of print dyed with it.

Mr. Tate suggested that copies of the list of subjects proposed for papers at the Pharmaceutical Conference should, if possible, be distributed among the members. He thought that apprentices and others actually engaged in making preparations might give some valuable information.

Mr. Redford said that the meetings of the Association were the proper times for such communications, and that at the Conference the results of men of experience were wanted rather than first efforts.

Mr. Tate then read a paper, entitled, "Notes on Pharmacy," Part 2. The paper contained a short *résumé* of the principal discoveries or improvements in pharmacy since the beginning of the year. Referring to the "Adulteration of Food and Drugs Bill," Mr. Tate pointed out that probably medical men would be almost exclusively appointed analysts under the Act. He considered Pharmaceutical Chemists to be far more competent, and thought that the Pharmaceutical Society should carefully watch such legislation.

After a few remarks from Messrs. Robinson, Shaw, and Davies,

Mr. Robinson closed the session with some valedictory remarks. He said that as he had only known that day that he would have to supply the place of the President, he had not prepared an address, but he wished strongly to urge upon the members the necessity of greater earnestness in contributing papers for the meetings. Unless young men would exert themselves, and come forward in the place of those whose years entitled them to rest, the Association would die out, and it would serve it right. The Pharmaceutical Conference was coming, and he hoped that, by seeing and hearing men who had made a position for themselves by hard work, new life would be infused into the younger members of the Association. He concluded by expressing the pleasure which he had felt in listening to some of Mr. Davies's lectures, of which he spoke in complimentary terms.

Mr. Tate proposed a vote of thanks to Mr. Robinson, and said that he hoped to hear fuller and freer discussion at the meetings.

Mr. Redford seconded the motion, and agreed thoroughly with Mr. Robinson's remarks, thanking him for his frank strictures on the results of the session.

The vote was carried by acclamation, and the session closed.

MIDLAND COUNTIES CHEMISTS' ASSOCIATION.

The First Annual Meeting of the above Association was held at the Temperance Hall, Birmingham, on May 27; the President, Mr. W. Southall, in the chair.

There was not a large attendance of members.

The Hon. Sec. read the Report of the Council and Statement of Accounts, which show that the Association is of service to its members, and has a balance in hand of upwards of £12.

Report presented by the Council of the Midland Counties Chemists' Association, May, 1870.

The Council in presenting their first Annual Report to the members of this Association, prefer giving simple statements of their proceedings for the past year, and submitting the same without comment, either congratulatory or otherwise. The object of this Association being the general advancement of the interests of the trade, it will be perceived how far the Council have kept that object in view.

After three preliminary meetings, a General Meeting was held on May 7th, 1869, which was numerously attended, and there were appointed the President, Treasurer, Hon. Secretaries, and Council, who were entrusted more especially with the preparation of a Dispensing and Retail Price List. In compliance therewith the Council held no less than nine consecutive meetings, which were followed by a General Meeting, and the price list, as it now stands, was adopted and circulated to each member of the Association; a charge of 1*s*. per copy was made to non-members beyond the precincts of Birmingham.

In the course of these meetings efforts were also made to unite the members of the trade in the one common object; your Council canvassed the whole of the town, when the number of enrolled members reached just over one hundred; also, about 250 chemists of the neighbourhood were invited, by circular, etc., to join, and upwards of thirty of these sent in their names and subscriptions.

An invitation from the Pharmaceutical Conference was received and acknowledged for a deputation from this Association, but its formation being too recent, it was deemed advisable to decline. The supper at Nock's Hotel was not so well attended as desirable, but a very pleasant evening was spent by those present.

Your Council have had their attention called to the objectionable practice of a small shopkeeper vending paregoric, but on this occasion could not take further proceedings.

A deputation was appointed to wait upon the Borough Inspection Committee, relative to the exorbitant charge for the licence for the sale and storage of petroleum, under the new Act, which took place on December 22nd, 1869, and although letters were read from Liverpool, Manchester, and Bristol, stating the low terms for the licence in those places, the Borough Inspection Committee refused to make any alteration.

An appeal from the Birmingham Chemists' Assistants' Association, applying for accommodation to hold their weekly meetings, was made to the Council, when it was unanimously resolved that arrangements should be entered into with the Temperance Hall Committee to grant them the use of a room for that purpose for a period of six months, ending June, 1870. Action was also taken in unison with other Associations objecting to any legislation interfering with the storing and dispensing of poisons.

The Association has been the medium of compelling a self-styled chemist and druggist to take down his signboard, and the Secretaries, with the consent of the President, deemed it expedient to caution the members against being duped by a vendor of questionable vermin eradicator.

Your Council now retire from their duties, which they have endeavoured to carry out faithfully, and hope that their successors will be able to accomplish much more for the welfare of Chemists and Druggists, and for this Association in particular.

The election of officers for the ensuing year, and the consideration of Mr. Arblaster's letter to the Home Secretary on the amount charged for the petroleum licence in Birmingham, formed the chief business of the meeting.

Joseph Lucas, 4, Calmore Row, } *Hon. Secs.*
A. Stirling Grieves, 16, Spiceal Street, }
June, 1870.

NOTTINGHAM AND NOTTS CHEMISTS' ASSOCIATION.

The adjourned Annual Meeting of this Society was held at the Exchange Rooms, on Friday evening, May 27th; the President in the chair.

The minutes of the previous meeting having been adopted, the Hon. Secretary then read the following

Report.

In presenting their first Annual Report, the Council of the Nottingham and Notts Chemists' Association take the opportunity of congratulating the members upon the very satisfactory position of the Society generally, as well as financially.

The Society was established in December, 1868, for the purpose of advancing the interests of chemistry and pharmacy in the district, for providing means for the scientific education of the Assistants and Apprentices, and for the encouragement of feelings of mutual goodwill and esteem amongst its members.

The Inaugural Meeting was held at the Exchange Rooms in February, 1869.

The number of Members enrolled at and since that meeting, was 53, and of Associates, 48.

During the Session which now terminates, several very interesting papers have been read:—

On February 12, "The President's Address."

On March 12, "The evening was devoted to the discussion of the Pharmacy Act."

On April 8, Address on "Pharmaceutical Education." H. S. Evans, Esq.

On May 14, A paper "On the Results of Examination of Some Samples of Tincture of Opium." Mr. Mayfield. A paper "On Botany and its Relations to Pharmacy." Mr. Rayner.

On October 19, "Address," by the President.

On November 19, "Hints on Dispensing." Mr. R. Fitzhugh.

On December 10, "French Pharmacy." Mr. Mayfield.

On February 11, 1870, "On Accidental Poisoning and the Precautions Adopted for its Prevention, with Special Reference to the Proposed Bye-laws of the Pharmaceutical Society."

On March 11, "Adjourned Discussion on the Subject of the Previous Meeting."

On April 8, An address on "The Amusement and Recreation to be Derived from, and the Advantages Accruing to the Pharmaceutist by the Study of Botany." T. Burnie, Esq.

The meetings have afforded opportunities for the discussion of matters of interest to the profession generally,—such as the Pharmacy Act, the operations of the Petroleum Act, etc.

A deputation was appointed to wait on the Watch Committee with a view to modify the local regulations of this Act; the result of which was satisfactory.

A lengthened discussion took place on the proposed compulsory regulations respecting the keeping of poisons, and a resolution was unanimously adopted against any compulsory measures in that direction, it being considered that chemists did generally, in their ordinary course of business, adopt sufficient precaution for their own and the public safety. The resolution was forwarded to the Pharmaceutical Society. Your Council acknowledge, with gratitude, the kindness of the then Vice-President, now President, of the Pharmaceutical Society, Mr. H. S. Evans, in coming from London to deliver an address to the Society on such a subject as "Pharmaceutical Education." Such an address was very encouraging to a young Society, when coming from so high an authority. The Society, as a mark of their appreciation of Mr. Evans's kindness, honoured themselves by electing that gentleman as their first honorary member.

Amongst other donations made to the Society, not the least useful and interesting are a cabinet, containing materia medica specimens, from Messrs. Evans, Son, and Co., and a second one from Southall, Son, and Dymond. These cabinets are of great service to the students, and the Council have consented that they should circulate amongst the members for the use of the Associates, under certain restrictions.

Arrangements were made by which the collection of books, formerly in the possession of the old Society, were transferred to the new. Several valuable works, standard as well as elementary, have been added to the library, and a good nucleus is now formed, which your Council hope soon to see developed into a good reference as well as circulating library,—useful alike to all connected with the Association; and while they acknowledge with thankfulness the donations which have been made to it from time to time, your Council would earnestly impress upon members the necessity of using their utmost endeavours to add to its extent and usefulness.

The librarian announces a tolerably good circulation, which, has, however, somewhat diminished during the last few months. The Council are anxious that the Associates should avail themselves of the advantages of the library, which is even now capable of supplying them with suitable books in the various branches of science to which their attention must be called.

A petition was presented to the Council, signed by most of the Associates, praying that they might unite to form a section for their own instruction; your Council had great pleasure in complying with their request, reserving to themselves the right to direct their studies, and suggesting that a Secretary to the section should be appointed to confer with the Council in the interests of the Associates.

Mr. Overton was appointed Secretary, and your Council engaged a room in the house of the Constitutional Association, for the purposes of the section, and engaged Mr. Hughes as teacher. The section meetings have been held weekly, on Monday evenings, and a good attendance has been the result,—Pharmaceutical Chemistry and Materia Medica being the subjects appointed for study; at the completion of the course, two prizes were offered by the Council for competition, and awarded respectively to Mr. Bathamley and Mr. Johnston. Messrs. Parker and Smith kindly offered two prizes for competition amongst the younger students, which were obtained by Mr. Evan Jenkins and Mr. Ward. As an inducement to the Associates to prosecute their studies, your Council throw this course open, free of charge. Your Council made arrangements with the lecturer on chemistry at the Mechanics' Institution, in connection with the Science and Art Department, for the admission of Associates to this class at half the usual fees.

Your Council also provided a Latin Class, which has been in operation for nine months with satisfactory results. At the end of the first course a prize was presented by your Council to Mr. Johnston as being the most advanced Student, and your President presented a second prize to Mr. Copley, who passed the best examination amongst the Junior Associates. Arrangements have been made for a course of lessons on botany, which commenced in April, and will be continued weekly during the summer months. Your Council have to acknowledge with gratitude the kindness of Mr. Burnie in offering to conduct this class entirely free of charge; and also the kindness of Dr. Mills for his assistance by demonstrating to the students the wonders of structural botany by aid of the microscope. These meetings are held at the room of the Society in Friar Lane, every Monday evening, commencing at nine o'clock.

As the attendance has been hitherto rather limited, your Council would earnestly request the Associates to make every endeavour to attend this class, and the employers also to use their influence with those who are unwilling, and to extend their permission to those who are willing to study so important a branch of their business.

In conclusion, your Council hope that their work, as embodied in this report, will give satisfaction to the members and show the great use of such societies as this, and, in resigning their trust, would like to add a few words on the practical working of the Society.

In the first place, at the Monthly Meetings every exertion has been made to provide subjects for discussion which would be a means of mutual instruction.

Your Council regret that the attendance of members has been very poor; they would respectfully urge upon all the difficulty of sustaining societies like this without the presence and aid of the members.

A cordial spirit of co-operation is the one thing wanting to assure the success of this Association, and to enable the Council to carry on those works so auspiciously begun, which have already produced great results, and by which much greater are yet to be anticipated. The educational advantages have in no way been better exemplified than in the many admirable answers given by the Students in reply to the examination questions, and your Council hope that every Associate will endeavour, during the ensuing Session, to make a point of attending the various classes provided for him, as far as the exigencies of business will allow. Your Council, though thankful for what they have been enabled to do, feel that the usefulness of the Society would be much enhanced by a "local habitation" of its own, and would suggest to their successors in office, the desirability of taking a room or rooms in a central position, which might be devoted to all purposes of the Society,—as reading-room, library, class and general meeting room, where the property of the Society might be preserved, and the nucleus of a museum collected. The purchase of a good working microscope would be beneficial, and various other instruments and apparatus not frequently used, but often useful. Your Council believe that this would be a means of giving a practical value to the Society, and would tend to promote a greater personal interest and a greater personal attendance.

The Treasurer's report was afterwards read, showing the state of the Society's funds to be as follows:—

		£	s.	d.
Session 1869–70.	Receipts . . .	44	9	0
" "	Expenditure . .	30	1	1
	Balance in Treasurer's hands .	£14	7	11

It was afterwards proposed and carried that the reports be printed and circulated amongst the Members and Associates of the Society, and all chemists resident in the town and country.

After passing an alteration of the bye-laws with respect to the Annual Meeting, a cordial vote of thanks was accorded to the President, Mr. Atherton, for his services during the past Session.

The following officers were then appointed for the ensuing year:—

President: J. H. Atherton, F.C.S.
Vice-President: R. Fitzhugh, F.C.S.
Treasurer: J. Rayner.
Honorary Secretary: J. T. Mayfield.
Council: Messrs. Bailey, Jas. Jenkins, W. H. Parker, W. Smith, White, Whitworth, Waterall, and Woodward.

Meetings of Scientific Societies.

CHEMICAL SOCIETY.

The last of the Scientific Meetings of this Society for the session which has just ended was held at Burlington House on Thursday, the 16th of June; Professor Williamson, F.R.S., President, in the chair.

A paper was read by Mr. James Bell "On Fermentation," in which the author described a number of experiments which had been made for the purpose of determining what forms of ferment may be obtained by submitting albumen derived from different sources to a variety of conditions.

When egg albumen was mixed with cane sugar, and the mixture allowed to ferment at 75° F., a species of yeast was formed, consisting of fungoid cells, which differed from those of ordinary yeast, and by which only a very small quantity, 0·2 per cent., of alcohol was produced.

The albumen of flour and of malt, used in the same way, yielded results similar to those previously described, the yeast so produced having very little fermentative power.

Cold water extracts of flour and of malt, added to solution of cane sugar, with which was a little glucose, became mucilaginous, and the production of yeast-cells in this mucilage may be easily watched.

The blue mould which forms on infusion of malt, and the mould from lemon-juice, were found to act as good ferments in solution of grape sugar.

From some comparative experiments made with grape juice, to which various quantities of glucose had been added, the author concluded that the fermentation of must would be rendered more complete and exhaustive by the addition of a certain quantity of glucose.

The President, in remarking on this paper, said that, although it was usual to speak of the yeast *plant* in connection with fermentation, the organism appeared in all its functions to be animal rather than vegetable. The products of its secretion, he said, are less complex than those it takes in. Moreover, it does not, like plants, require light for its vital process; nor does it absorb heat, but, on the contrary, gives it off.

Another paper read at the same meeting was "On Organic Matter in Water," by Dr. Heisch.

The author, having been consulted by a manufacturer of lemonade, who suddenly found that all his lemonade after a few days became turbid, and acquired a disagreeable odour, found, on examining the liquid under the microscope, that it was full of small spherical cells, with, in most cases, a bright nucleus.

Further investigation of the subject led to the conclusion that the source of the evil was organic contamination of the water used in the manufacture. On putting a few grains of the purest crystallized sugar into some of the water, it became turbid in a few hours, and was found to contain the cells previously described. It seemed probable, from inquiries made, that sewage had gained access to the well, and to this Dr. Heisch was disposed to ascribe the result. Experiments were made with various samples of water, to which sugar was added, as already described; and in every case in which the water used had produced diarrhœa, or other mischief of that sort, when employed as a beverage, on treating it with sugar, the characteristic cells were developed, usually within twenty-four hours, the temperature being kept at 60° or 70° F., and light freely admitted to the liquid. A minute quantity of sewage itself was added to a solution of sugar, which had been previously ascertained to be free from the cells, and the solution was soon afterwards found to contain them.

A number of experiments were made with the view of ascertaining whether other substances besides sewage were capable of producing organisms such as had been observed in the cases referred to, when added to solution of sugar; but, although in a few instances growths were produced, they never resembled the cells caused by sewage.

The author states that filtering the water through the finest Swedish paper does not remove the germs, and boiling for half an hour does not destroy their vitality. Filtration through a good bed of animal charcoal was found to be the most effectual mode of removing them, and even in this case the charcoal must be freely exposed to the air from time to time, or it soon loses its purifying power.

Chapters for Students.

CHEMICAL NOTES TO THE PHARMACOPŒIA.

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

Acidum Arseniosum. *Arsenious Acid.*—White arsenic of commerce is procured by heating certain ores in a current of air. These ores are compounds of arsenicum and sulphur, with the metal copper or iron, or sometimes nickel and cobalt. Atmospheric oxygen, combining with the sulphur, gives rise to sulphurous acid gas, SO_2; with the metal it forms an oxide; with the arsenic, As_2O_3. This last collects in the flues of the furnaces, whence it is removed and purified by resublimation.

[§ Occurs as a heavy white powder, or in sublimed masses, which usually present a stratified appearance, caused by the existence of separate layers, differing from each other in degrees of opacity. When slowly sublimed in a glass-tube, it forms minute brilliant and transparent octahedral crystals.]

White arsenic belongs strictly to the class of bodies already described as anhydrides; it is not itself an acid, for it contains no hydrogen, but it is supposed to form the acid when boiled with water, in which it dissolves only sparingly. The formula of the acid, although it cannot be isolated, is inferred to be H_3AsO_3,

$$As_2O_3+3H_2O=2H_3AsO_3$$

from the composition of its salts; arsenite of silver being Ag'_3AsO_3. The potassium arsenite is probably formed in preparing Fowler's solution (liquor arsenicalis) by boiling white arsenic, water, and carbonate of potash together.

When white arsenic is mixed with charcoal, and heated in a flask or tube, it loses its oxygen, which combines with carbon, and escapes in the form of carbonic oxide, and a crystalline sublimate of the element arsenicum is formed in the cool part.

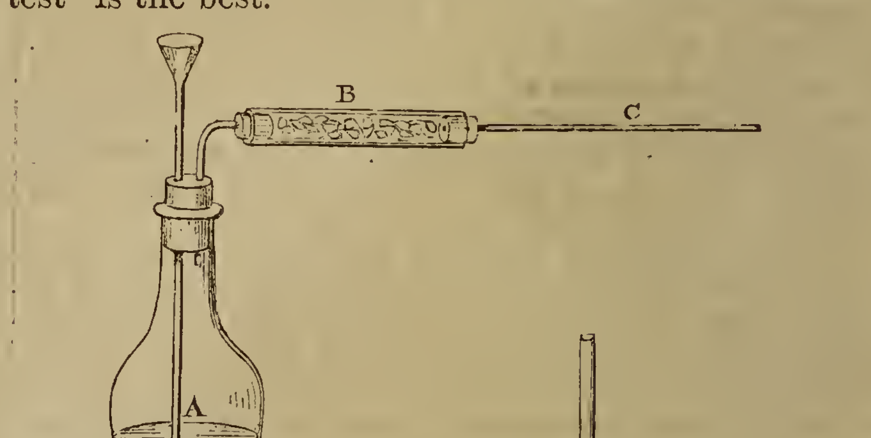
$$2As_2O_3+3C_2=As_4+6CO.$$

Arsenious anhydride and soluble arsenites may be recognised by the tests following:—

[§ Its solution gives with ammonio-nitrate of silver a canary-yellow precipitate (Ag'_3AsO_3), insoluble in water, but readily dissolved by ammonia, and by nitric acid. Sprinkled on a red-hot coal, it emits an alliaceous odour.]

Sulphuretted hydrogen passed into a solution of it acidified with HCl, gives a yellow precipitate, As_2S_3, which is readily soluble in sulphide of ammonium. Sulphide of cadmium, which is like it in colour, is not soluble in sulphide of ammonium.

To detect a compound of arsenic, whether pure or mixed with other matters, a modification of "Marsh's test" is the best.



A is a six-ounce flask fitted with funnel-tube, and containing pure granulated zinc and dilute sulphuric acid. The hydrogen produced in A is conducted through B, a short wide tube, containing chloride of calcium, to absorb moisture from the gas. C is a tube of hard glass, which will bear the heat of the

Bunsen gas flame without collapsing. The solution of arsenic introduced into A gives, by the action of the zinc and acid, arsenuretted hydrogen:—

$$As_2O_3 + xZn + xH_2SO_4.$$
$$= xZnSO_4 + 3H_2O + 2AsH_3 + (x-6)H_2.$$

[x=any indefinite number of atoms.)

The mixture of hydrogen and arsenuretted hydrogen escapes through C, which is heated to redness after the air has all been driven out. The elementary arsenic is then deposited as a brown or black shining stain on the glass, just beyond the lamp, whilst the hydrogen passes on and escapes.

For estimating the amount of pure white arsenic in any of its preparations, the Pharmacopœia indicates that 4 decigrams of it dissolved with about twice its weight of bicarbonate of soda, discharge the colour of 80·8 cubic centimetres of the volumetric solution of iodine.

White arsenic, when treated with iodine in the presence of water, gives rise to hydriodic acid and arsenic anhydride; both these are colourless, and therefore the brown colour of the iodine disappears.

$$As_2O_3 + 2OH_2 + 2I_2 = As_2O_5 + 4HI.$$

One molecule of white arsenic (198 grams), according to this equation, will reduce 4 atoms ($127 \times 4 = 508$ grams) of iodine. Now 508 grams iodine are contained in 40,000 cub. centims. of the solution (for in making it 12·7 grams are dissolved in 1000 of the liquid), so that 40,000 cc. would be the quantity decolorized by 1 gram-molecule of white arsenic. Such an amount would never be used in an experiment, but a simple calculation shows that the quantities indicated in the B. P. are in the same proportion to each other. For

Grams of As_2O_3.		Cc. of Vol. Sol. of I.		Gram As_2O_3.		Vol. Sol. I.
198	:	40,000	as	·4	:	80·8

The best antidote to white arsenic is freshly made ferric hydrate; it gives rise to an insoluble ferrous arseniate.

Arsenic Acid.—The substance generally known by this name is again the anhydride, not the true acid. It is prepared by boiling white arsenic with nitric acid, and evaporating to dryness; the residue is a white powder, the anhydride, As_2O_5. By dissolving this in water, and concentrating the solution, the acid, H_3AsO_4, is obtained in deliquescent crystals. Arsenic acid and its salts are distinguished from arsenites, and also from phosphates, by giving a red precipitate with nitrate of silver, Ag_3AsO_4.

Sodæ Arsenias. *Arseniate of Soda*, $Na_2HAsO_4, 7H_2O$.—Arsenious acid, nitrate of soda, and dry carbonate of soda, are thoroughly mixed, and then fused at a red heat in a crucible. When the effervescence (caused by the escape of N_2O_3 and CO_2) has ceased, the fused salt is poured out upon a stone. As soon as it has solidified, the mass is boiled in water and the liquid set by to crystallize. The ingredients react in the following manner:—

$$\overset{198}{As_2O_3} + \overset{85\times2=170}{2NaNO_3} + \overset{106}{Na_2CO_3}$$
$$= \underset{\text{Sodium pyro-arseniate.}}{Na_4As_2O_7} + N_2O_3 + CO_2.$$

It will be seen that the proportions of the ingredients ordered in the B.P. are nearly identical with those required theoretically, as shown in the equation; the carbonate of soda only being in trifling excess.

Parts of As_2O_3.		$NaNO_3$.	Na_2CO_3.
Theory . . .	198	170	106
Being nearly =	10	$8\frac{1}{2}$	$5\frac{1}{3}$
B.P.	10	$8\frac{1}{2}$	$5\frac{1}{2}$

Arseniate of soda crystallizes sometimes with 12 instead of 7 molecules of water; the tests of the B.P. must, therefore, be made use of to identify the official salt. At 300° F. it loses the whole of its water of crystallization, amounting to 40·38 per cent. 1 gram of the residue, that is, of anhydrous arseniate of sodium, mixed with 5·3 cubic centimetres of volumetric soda (which converts it into trisodic arseniate, Na_3AsO_4), continues to give a precipitate of arseniate of silver with volumetric nitrate of silver, till 161·3 cubic centimetres of the latter have been added.

Ferri Arsenias. *Arseniate of Iron.*—Made by mixing together solutions of arseniate and acetate of soda and sulphate of iron. The arseniate and sulphate of iron would alone give rise to the production of an acid arseniate of iron, which would not be precipitated, probably thus:—

$$4Na_2HAsO_4 + 4FeSO_4$$
$$= 4Na_2SO_4 + Fe_32AsO_4 + Fe''H_42AsO_4.$$

But the addition of the acetate of soda remedies this, and the whole of the iron is precipitated as arseniate.

$$2Na_2HAsO_4 + 3FeSO_4 + 2NaC_2H_3O_2$$
$$= 3Na_2SO_4 + Fe_32AsO_4 + 2HC_2H_3O_2.$$

[§ A small quantity boiled with excess of caustic soda and filtered, gives, when exactly neutralized by nitric acid, a brick-red precipitate on the addition of solution of nitrate of silver.] This distinguishes it from the phosphate, which it closely resembles in appearance.

Acidum Benzoicum. *Benzoic Acid.*—May be prepared,—

1. By mixing benzoin with sand, and heating cautiously; the benzoic acid rises and condenses in the cool cover of the pot in crystals.

2. By boiling benzoin with half its weight of slaked lime, which forms, with the acid present, benzoate of lime, filtering, concentrating, and adding hydrochloric acid. On cooling, the acid crystallizes.

3. By boiling hippurate of lime, obtained by adding lime to cows' and horses' urine, with hydrochloric acid.

$$\underset{\text{Hippuric acid, or benzo-glycocine.}}{HC_2(C_7H_5O)H_3NO_2} + \underset{\text{Water.}}{H_2O}$$
$$= \underset{\text{Glycocine.}}{C_2H_5NO_2} + \underset{\text{Benzoic acid.}}{HC_7H_5O_2}.$$

4. By oxidizing naphthaline with nitric acid,

$$\underset{\text{Naphthaline.}}{C_{10}H_8} + \underset{\text{Oxygen, from the nitric acid.}}{4O_2}$$
$$= \underset{\text{Phthalic acid.}}{H_2C_8H_4O_4} + \underset{\text{Oxalic acid.}}{H_2C_2O_4}.$$

and converting the phthalic acid into a salt of lime, and heating this pretty strongly with hydrate of lime. The phthalate of lime is converted into benzoate and carbonate.

$$\underset{\text{Phthalate of lime.}}{2CaC_8H_4O_4} + \underset{\text{Hydrate of lime.}}{Ca2HO}$$
$$= \underset{\text{Benzoate.}}{Ca2C_7H_5O_2} + \underset{\text{Carbonate.}}{CaCO_3}.$$

5. By exposing essential oil of almonds (benzoic aldehyde or hydride of benzoyl) to the air, it absorbs oxygen.

$$2C_7H_5OH + O_2 = 2C_7H_5OHO.$$
Hydride of benzoyl. Hydrate of benzoyl, or benzoic acid.

Benzoic acid is never manufactured in this way, but the reaction is interesting and important. Benzoic acid is crystalline, volatile, very soluble in spirit and in alkaline solutions, but only slightly soluble in water. Cinnamic acid resembles it closely in this respect, but differs from it in giving a calcium salt, which is much less soluble in water than the benzoate, and also by this test. [§ Boiled with solution of bichromate of potash and sulphuric acid, it evolves an odour of hydride of benzoyl.]

$$2HC_9H_7O_2 + 5O_2$$
Cinnamic acid.

$$= 2HC_7H_5O + 2H_2O + 4CO_2.$$
Benzoic hydride.

Benzoic acid does not, under the same reagents, evolve any odour.

Reviews.

Lecture Notes for Chemical Students. By Edward Frankland, F.R.S., Professor of Chemistry in the Royal School of Mines. Vol. I. Inorganic Chemistry.

We are very glad to welcome the reappearance of Dr. Frankland's 'Lecture Notes.' Whatever may be the views of individual teachers on the question of chemical notation, and whatever may be the objection to the particular system adopted in the present instance, a book which gives a really systematic form to the fragmentary and discursive snatches of commingled fact and theory hitherto found in most manuals, cannot but be acceptable to professors as well as to students. The chief object of the small volume before us, as explained in the preface, is to relieve the student from the task of making very copious notes in the lecture-theatre, and so allow him to concentrate his attention upon the arguments and explanations of the speaker. Now it not only well fulfils this purpose, —a sufficiently useful one, when it is considered how rare among students is the art of making good notes such as will be afterwards serviceable in private,—but it gives a framework, the outline and connecting links of which stand out quite boldly through the scanty drapery of description with which it is clothed. The description of the properties of the bodies treated of is almost entirely omitted, but on looking through the book it will be seen that all the reactions which serve to establish the relationship between the several members of any series of bodies, are brought into sufficient prominence, and every pains seems to have been taken to supply all the information required to back up the system of classification advocated.

The arrangement of the matter is in accordance with the classification of the elements founded on their atomicity or quantivalence; but this classification is presented in a judiciously modified form. The elements are arranged as monads, dyads, etc., according to the number of atoms of hydrogen which their atoms are capable respectively of representing; but the monads, for example, are subdivided into four subclasses or sections. The first contains hydrogen only. Even now that everybody quite believes in the thoroughly metallic character of hydrogen, it is still necessary, considering its physical peculiarities and small atomic weight, to set it apart from the solid metals potassium, sodium, and silver. The second section of monads includes fluorine, chlorine, bromine, and iodine; the third comprises cæsium, rubidium, potassium, sodium, and lithium; the fourth, thallium and silver: and so on through six groups up to the hexads. One of the strange results of this sort of arrangement, however, is that we have to look for lead, which is at least as closely related to thallium as any of the alkaline group, in the fourth column among the tetrads. Oxygen is, in like manner, dissociated from its kindred sulphur, aluminium from chromium and iron, copper from silver, zinc from cadmium. But of course, all these questions would be fully discussed in the lectures, of which these notes are but the skeleton. Such objections are moreover applicable to every scheme of classification which has hitherto been proposed.

We have to congratulate the learned author upon having laid aside in this his second edition, the greater part of the cumbrous and, to our mind, objectionable graphic formulæ, with which the pages of his first edition were so obtrusively overloaded.

So much has been urged both for and against the employment of this kind of notation in the pages of this Journal, as well as elsewhere, that it would be superfluous to reiterate those arguments. We would merely direct notice to the fact that either his opponents' remonstrances, or the late discussion in the chemical world on the (we had almost said the *late*) atomic theory, or possibly original considerations have certainly induced Dr. Frankland to think better of it, and expunge from his reprint the greater number of these intricate and ingeniously disposed patterns. A few, it is true, linger, but they are mere ghosts, which no one need be afraid of. And that no doubt may remain that Dr. Frankland has modified his teaching, if not his creed, we quote the first lines of his former volume, and set them side by side with the words he now writes.

"*Definition.*—Chemistry is the science which treats of the—

1866.	1870.
atomic composition of bodies, and of those changes in matter which result from an alteration in the relative position of atoms.	composition of all kinds of matter, and of those changes in composition which result from the action, either of different kinds of matter upon each other, or of external forces upon one and the same kind of matter."

We repeat, we congratulate him on this emendation, and, doing so, we feel satisfied that the book will prove as useful as we have every right to expect it to be, from its own intrinsic merits, and from the high standing of its distinguished author. W. A. T.

The Students' Flora of the British Islands. By J. D. Hooker, C.B., M.D., D.C.L., LL.D., F.R.S., L.S., etc., Director of the Royal Gardens, Kew. London: Macmillan and Co. 1870. Fcap. 8vo, pp. xx. 504.

This book is, as might be expected from such an accomplished botanist as Dr. Hooker, one which will undoubtedly prove a most useful manual to students and others interested in the British Flora, and we may safely predict for it a wide and lasting success. Its object, as stated in the preface, is "to supply students and field botanists with a fuller account of the plants of the British Flora than the manuals hitherto in use aim at giving." In it will be found, as the result of the author's well-known extensive acquaintance with plants of all parts of the world, a much broader and more philosophic idea of genera and species than we might have met with if the work had been written by one whose attention had been more exclusively restricted to the flora of so limited an area as our own.

In the arrangement of the book the 'London Catalogue' of 1867 has been followed, and the well-known works of Syme and Watson have been freely consulted, but its great value arises from the fact that all the ordinal, generic, and specific characters of the plants have been rewritten by the author, and great care has been taken to render these descriptions as simple and perfect as possible.

From pages i. to viii. we have an excellent preface, followed by (ix. to xx.) a "Synopsis of the Natural Orders," instead of the usual artificial key, Dr. Hooker remarking that from experience he finds such artificial keys produce superficial habits amongst students; whilst diagnoses are more conducive to habits of observation. This change too is of advantage to the student's future studies in Botany, as it familiarizes him with the method always employed in more scientific works. Next follow the descriptions of the plants themselves, the names of the orders, genera, and species being in Egyptian type, rendering them at once distinct from the other letter-press. As an illustration of the book, we will quote from it the description of the sweet Violet.

"2. **V. odorata**, *L.*; slightly hairy or downy, runners very long, leaves broadly cordate, spur nearly straight, style hooked, stigma oblique. *Sweet Violet.*

"Hedgebanks and copses, wild in E. and S. E. England, naturalized elsewhere, perhaps native of E. Ireland; fl. March–May.—*Rootstock* short, scarred. *Leaves* deeply cordate at the base, sinus closed; stipules glandular. *Bracts* at or about the middle of the peduncle. *Flowers* fragrant, blue, white, or red-purple; lateral petals with or without a tuft of hairs; spur short, obtuse. *Anther-spurs* linear-oblong. *Capsule* pubescent, pedicels decurved.—DISTRIB. Europe, N. Africa, N. and W. Asia, to the Himalaya."

In the Umbelliferæ, in addition to the diagnosis, there is an analytical key. In some of the critical genera, Dr. Hooker has followed some well-known authority. The genera *Rosa* and *Rubus* have had the benefit of Mr. Baker's care, whose well-known accurate knowledge of them is fully recognized by British and Continental botanists.

In conclusion, we cordially recommend the book to students as a companion in their country rambles in search of

"These stars of earth,—these golden flowers."

A pastime at once healthgiving, intellectual, and mentally elevating and soothing.

Obituary.

SIR JAMES CLARK, BART., M.D., F.R.S.

We regret to have to announce the death of this eminent physician, which occurred on Wednesday, the 29th of June, at Bagshot Park, Surrey. The deceased baronet, who was the son of a farmer, was born in Banffshire, in 1788. He was educated at King's College, Aberdeen, and completed his medical studies at Edinburgh University, where he took the degree of M.D. Having passed some years in the service of the navy, he, in 1820, settled as a physician in Rome. Six years afterwards he returned to England, and practised in London. He was appointed physician to the Duchess of Kent and Princess Victoria, as well as to the late King of the Belgians, and on the accession of her Majesty to the throne, she made him her first physician, and conferred upon him a baronetcy. Sir James took a lively interest in the proceedings of the Pharmaceutical Society, especially at the time of its establishment, and for many years afterwards. He died at the advanced age of eighty-two.

We have also to announce the death of Mr. Thomas Salman, Cornwall Road, Westbourne Park, a much respected member of our Society. He died at his residence on the 12th of June, deeply and deservedly regretted by a large circle of friends.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

THE "AGE OF PROGRESS," AND THE PROVINCIAL MEMBERS.

Dear Sir,—In the last issue of the Journal, in the article entitled "An Age of Progress," you laudably endeavour to enlighten the benighted provincial members of the Pharmaceutical Society, and so philanthropic is your aim, that you kindly become the interpreter of a word, the subtle meaning of which you presume to think they have hitherto been unable to comprehend; in short, you attempt, though I apprehend without the least necessity, to show what the Pharmaceutical Council is, and what it is not.

I grant you that the Council is not "A Young Man's Mutual Improvement Association," I also grant you that it "aims at working out and protecting the interests of the Pharmaceutical Society," "which are grave," that its "talk" is "serious talk," and "thoroughly effectual as regards result;" but from the grave and effectual character of its proceedings I maintain that the "serious talk" which culminates occasionally in speech-making, when a "storm passes over its otherwise tranquil waters," is eminently *useful* for publication, and would do much to enlighten the provincials, and consequently would forward "An Age of Progress."

Of such vital interest have the proceedings of the Society become, since the passing of the Pharmacy Act, not only to the members themselves but to the entire trade, that nothing but dissatisfaction and want of perfect confidence will prevail, until the Council's proceedings are fully and faithfully reported.

No doubt there will be some slight disadvantage in publicity, but the greater weight of advantage will counterbalance all inconvenience. The only safe and simple plan is that of publicity, and whether the present Council will or not, that object will be attained.

If it be wished to have a good and reliable Council, composed of trusted and tried men, what better plan can be devised to enable the "provincials" to judge of their character and capacity than that which publicity would afford? If it be wished not to have another avalanche of "provincials," publicity may avert this great disaster.

I am sure I regret, and all will regret, that any gentlemen who have faithfully served us on the Council should be passed by. Still I cannot see how such an unfortunate result can be prevented at a time of excitement, like that preceding the recent election, when the trade, perhaps solely for the want of that information which fully reported proceedings would give, was rudely disturbed and unsettled by the premature and unwise attempt to interfere with patent medicines, and with the storage of poisons.

I trust, however, notwithstanding the free provincial admixture in the new Council, that it will be as useful and as zealous as any of its predecessors.

I am, dear Sir, your obedient servant,

ROBERT HAMPTON.

Manchester, June 20, 1870.

Sir,—Entirely agreeing with your article on the "Age of Progress," I beg leave to offer a few remarks upon the cause which, in my opinion, has elected a Council not well chosen to carry on the important duties of the Society.

Being one of the founders I speak with some experience, and although I have never taken an active part in its affairs, I have been ever ready to uphold the Council and strengthen their hands, whenever I have considered them unjustly attacked, as may be seen by reference to Vol. IV., First Series, p. 97, in a letter signed "A Town Member," and also in Vol. X., First Series, p. 210.

I believe that the Boards, as constituted from year to year, have done good service to the whole body of chemists, and that they have fairly earned our best thanks for the manner in which they have advanced our interest, in the broadest sense of the word; and therefore it was with the deepest pain I found the Council engaged, in the past year, in propounding a system of conducting business, as touching poisons, so extremely offensive, that I do not wonder it brought down a storm of indignation at the last annual meeting, which had the deplorable effect of depriving us of the valuable experience and services of many old members of the Council. Surely no man can have a greater influence to bear upon him, in the handling of poisons, than his own material interest.

As I have read in the Journal, from month to month, recommendations and propositions for the keeping of poisons, with the view of legal compulsion, I have felt perfectly ashamed of my calling. My own system being, to my mind, infinitely superior to any proposition I have seen, still I could not presume to recommend it to others, as every chemist must be guided by the construction of his shop, and other considerations.

I have hitherto forborne to make any comment upon the subject, believing it would all come to nothing, which the case now plainly shows.

I shall, at any time, feel much pleasure in showing my method of keeping poisons to any chemist,—not as being any wonderful contrivance, but for the simplicity which common prudence dictates. Doubting not most other chemists have a place equally good, and many perhaps better, nevertheless I have faith in my own, and should repel any interference.

If the Council will keep within their legitimate province, they will soon re-establish confidence, and, at the next election, have a due balance of experienced London members, who certainly are in the best position to render good service to the trade at large.

I am, Sir, your obedient servant,
John Beaton.

Kilburn, June 20th, 1870.

Dear Sir,—Will you kindly allow me to point out an error in the editorial article of the 15th instant? You speak of the provinces as being "omniscient," now that is just what they *are not*, and the desire for a greater amount of knowledge was the mainspring of their action in the matter of the election; had they been allowed to *know* a little more, they might possibly have *done* a little less; and had the statement of attendance on Committees been published *before* the election instead of *after*, the gentleman who has attended forty-four times would have stood higher on the list than he did. Further, we find from that statement that four members of the Council, who live within "omnibus ride from Bloomsbury Square" have attended just ten times amongst them, so that proximity to the Council-room does not necessarily produce attendance there.

Neither are we to be blamed for the "absence of names long held in reverence," seeing that those names were not even on the list of candidates; had they been so, they would hardly have been rejected. Even in the provinces there is *some* respect for Morson, Squire, and Deane, who have worked so long and so well, and whose names are an honour to British pharmacy.

Let us hope that the late storm will have the effect of clearing the atmosphere, and of bringing the Council and the members into better accord than has been the case for some time past, and there will then be no cause to regret our action in the matter.

Yours truly,
W. Wilkinson.

Manchester, June 20, 1870.

The Sale of Homœopathic Medicines by Pharmacists.

Sir,—It was not my intention to make any further remarks upon the above subject; but if you have no objection to carry the discussion into your new series, I should feel obliged if you will permit me to reply to Mr. Giles's second letter. In the first place, let me assure him that so far as I am concerned his letters have caused no annoyance whatever, and I believe he wrote them from a desire to benefit the trade generally.

I think that the real cause of the traffic in homœopathic medicines is to be found *not* "in the hardships under which pharmacy is often conducted," but in the fact that the public demands them. If there are any who "feel it inexpressibly painful" and "a degradation to themselves and their calling" to sell such medicines, to them are Mr. Giles's remarks very well suited, even if their "poverty and not their will consents." but I believe there are very few, if any, who feel thus.

Mr. Giles says, he *did not* represent the sale of homœopathic medicines as a "breach of trade honesty." Surely he must have forgotten his former statements, or does he desire to recall them, but knows not how to do so? What does he mean when he says, "They (the world) may possibly deduce another inference from this over-eagerness to make money all round, *obviously in defiance of conscience and consistency;* they may not unreasonably conclude that the pharmaceutist who humbugs one customer with his consent, may humbug the rest for his own profit, and that he who knowingly sells innocent sugar-plums for deadly aconite, may not scruple to sell cheap powdered slate for costly scammony"?

After such statements, I am surprised he should *deny* that he represented the sale of the above medicines as a breach of trade honesty. Does he mean to assert that if a chemist is open to a suspicion of supplying slate for scammony, he is not also open to the imputation of a breach of trade honesty? I maintain that if a chemist is suspected of selling slate for scammony, he may very reasonably be suspected of supplying rad. rhei ang. for rad. rhei E. I. elect., and if that is not "a breach of trade honesty," I should like to know what is?

Mr. Giles disowns Morrison's pills, but acknowledges Parr's pills "et hoc genus omne," and says that my argument is founded on an assumption. Well, Sir, I am agreeable to his substitution, or if he will, Perry Davis's Pain-Killer, of which it may be said—

"It matters not a pin,
Whether rubbed out or taken in,
Its effect is just the same."

My argument will then be founded *not* on an assumption, but on *an admitted fact*. He further states that he has a considerable respect for patent medicines (mark, *considerable* respect). I never before heard a chemist make such a statement, and I am inclined to think that Mr. Giles stands alone in this respect. But I am still more astonished when he says, "They are, at all events, based upon rational principles of therapeutics, such as pharmacy acknowledges." The principles on which patent medicines, as a class, are based (so far as my knowledge goes), are that one medicine is a remedy, or more frequently a specific for various diseases and disorders, differing materially from each other, and that, too, entirely regardless of differences in constitution and sex. And I was not aware before, that pharmacy acknowledged such principles.

If, however, such be the case, why do chemists adorn their shops with such a varied number of therapeutic agents when a few would answer the same purpose? Such an array is useless if Mr. Giles's statement is true. If he is inclined to dispute what I have said, I ask him to read a few of the many handbills that he receives from his wholesale house, and I think he will find that I have simply stated facts. With regard to the solution of camphor, it is undoubtedly an allopathic remedy; but it is only fair to state that homœopathy has brought it into such general use.

Again, with regard to Mr. Giles's prediction of the duration of homœopathy, he says that, according to his observation, it is already extinct as a form of medical practice. Mr. Giles has, I think, put his astrological telescope to the blind eye. I beg to inform him that "as a form of medical practice" it is far from extinct, as the rapidly increasing number of homœopathic physicians clearly shows. He says, too, that if left alone he "sincerely believes the present generation will outlive it." I suppose he means if left alone by chemists. Well, Sir, if it is left alone, I sincerely wish Mr. Giles a long life and a happy one. I quite agree with Mr. Swenden, when he says, "One thing is certain, that if homœopathy be destined to advance, and it certainly is gaining ground, the united opposition of the whole of the pharmacists in the country could not check it, for the motive of our opposition would be too apparent."

Mr. Giles is pleased to term homœopathy "*arrant folly,*" *ergo*, those who believe in it are arrant fools! including, of course, homœopathic M.D.'s. Really, how very complimentary we are! Permit me to remind him that homœopathic M.D.'s have to go through the same curriculum as allopathic M.D.'s before they can practise homœopathy. Again, he says, "Homœopathic practitioners do not now trust to homœopathic doses, etc.; they do not themselves use those absurd globules," etc. Here again, I think, Mr. Giles's observation is somewhat limited. Only very recently I asked a medical gentleman if he thought that pilules and globules were rarely if ever prescribed? and he replied, that he thought they were used quite as much as formerly, and I know he uses them largely himself.

In conclusion, permit me to remark, that I am as desirous as Mr. Giles to see our business raised to the rank of a profession, but I think he is going the wrong way to work to bring about such a result; at any rate, trying to clean the wrong end of the stick first. There are many things of far greater importance that want reforming in pharmacy before the sale of homœopathic medicines. Let him go to our country towns, large and small, and examine the class of business there, including Bristol, and he will find that 70 if not 80 per cent., or more even, is mixed up with the business of a grocer, hosier, cheesemonger, oil and colour merchant, or perhaps even all combined, and not unfrequently a genteel liquor traffic to boot. Let Mr. Giles endeavour to rid the business of such branches of trade, and I feel assured he will have the hearty co-operation of his *confrères*.

I am desirous, too, to see the business of a homœopathic and allopathic chemist kept entirely distinct; and I feel assured that homœopaths do not wish pharmacists, for their sake, to do anything that is "inexpressibly painful," or that they "feel to be a degradation to themselves and their calling." If the two businesses are kept so distinct, I firmly believe that homœopathy will make far greater strides than hitherto; and I hope that pharmacists will be more loyal to those "rational principles of therapeutics, such as pharmacy acknowledges," and to "scientific investigation" that the day may not be postponed when homœopathy shall have a "clear field and no favour" from pharmacists.

Apologizing for thus trespassing upon your space a second time,

I remain, yours respectfully,
ALFRED MARSHALL.

Highbury, June 16, 1870.

Sir,—As one of the offenders against whom Mr. Giles has directed his heavy onslaught in this month's Journal, may I be allowed to make a few observations?

I am pleased to recognize, and bow down to the lofty standard claimed by him for the pharmaceutical chemist, but what *is* the cause of the hot displeasure manifested by him towards homœopathy *in particular*, when he confesses that for Parr's pills, and other preparations from the *quack laboratory*, he has "considerable respect"?

At all events, homœopathy is practised by men of education and professional status, whose prescriptions the chemist must either literally follow or reject. Are we, as a body, prepared to adopt the latter alternative? But what shall we say of the *professional* standing of the pet quacks of Mr. Giles, and what of their scientific (?) preparations?

May not any ignorant pretender send as many nostrums *into the market* as he please, and impose, to any extent, upon public credulity through his mendacious statements, that he is allowed to publish with impunity? There is no guarantee of medical knowledge demanded of *him*. The law is strict *only* in enforcing the affixing of a stamp of proper value to every package he sends out.

May I use Mr. Giles's own word, and ask, can "humbug" towards a nation go further? It is needless, I am sure, to place before Mr. Giles a long list of the names of those who, entirely ignorant of medical knowledge and therapeutic skill, do not hesitate to blazon forth by every roadside, and through the universal press, their miserable medicaments, their lying protestations, but "luring to destroy."

I believe that very many pharmaceutical chemists, as well as myself, sell homœopathic medicines for the same reason that *we* sell quack medicines,—because the public demand them. We have no more credence in the practice than Mr. Giles himself, but, in fact, look upon homœopathy, from our stand-point, as one of the follies of the day, which now and then influence the public mind, to be displaced after a short season by some other novelty.

I should be glad to see a clean sweep made of all such medical myths from every pharmacy, and I doubt not many share in the feeling. With how much pleasure, then, should we have received Mr. Giles's avowal, had it been to this effect, that he not only abominated homœopathy but quackery *also!*

As an advanced man amongst us, he could venture (for the love of science) to take the initiatory step, since his business status could bear the drawback his yearly returns might show, and the pioneer's glory would perhaps be deemed by him a sufficient reward.

I have but just had my attention called to Mr. Giles's letter in the *April* number of the Journal, and am amazed at his forgetfulness of all proper courtesy towards *us*, especially in that portion of it, in paragraph 3, beginning "They may possibly," and ending "I know." I fear Mr. Giles wrote not only *calamo currente*, and therefore with little reflection, but also *atramento felleo*, hence his fierce and unwarrantable deduction.

I hope Mr. Giles does not assume that he himself is the only pharmaceutist influenced by high-souled honour in his calling. If he possess it, let him *rejoice* that others share that (to the pharmaceutist) precious treasure. We want *all* the help we can have to elevate our calling to its true position, but that can only be done by unity and good feeling; such advocacy as that of Mr. Giles, in the passage referred to, will effect nothing but disaster.

Mr. Swenden, in his letter of the 9th of April, has well referred to the business division of the matter in dispute. I will not, therefore, take up more of your space by any further remarks of mine. I could not, however, pass over *a swoop* so *relentless* and *uncalled for* without entering a protest against it.

I beg to remain, Sir, yours obediently,
THOMAS WITHERINGTON,
Local Secretary.

Worcester, June 16, 1870.

WORK FOR LOCAL SECRETARIES.

Sir,—Most of the Local Secretaries, whom I have known, seem to hold the office in vain; they do nothing for the benefit of their brethren, and the office gets no respect. Many of them cannot point to any work done, except, perhaps, that they have got some unauthorized neighbour into hot water for calling himself a "chemist," or some registered man fined because his printer accidentally slipped "pharmaceutical" into his address. Now, I would propose to Local Secretaries work profitable and pleasant, to make efforts to get the members of the trade together, and thus to form scientific and trade associations of which it will be an honour to be secretary; and one of the first subjects calling for their attention would be the prices of drugs, and for dispensing. It is a notorious fact, that many well-to-do chemists and pharmaceutists charge absurdly low prices—prices which, a little consideration would show, cannot pay in a business making such small returns as ours does. Some of our brethren forget to charge for skill, and want reminding of it. If a person presents a prescription to me consisting of—

Magnes. Sulphat. ℥j
Aquæ ℥viij,

I consider I am entitled to 1*s.* 6*d.* for dispensing it, and should make that charge, though I know many of my neighbours would charge 9*d.* or 10*d.* for it, and experience tells me that my customers like the medicine better at 1*s.* 6*d.* than at 9*d.* Our Local Secretaries may do great service to the trade by promoting amicable discussion and settlement of prices. There are probably but few in the trade who approve of low prices, but they adopt them because they fancy, or some unreliable customer tells them, that Mr. So-and-So is selling at low prices, and then, not to be outdone, they adopt Mr. So-and-So's fancied low scale.

If he can afford it, let the Local Secretary invite *all* his brethren to supper, or if he cannot, let him suggest such a meeting at some suitable place, and try to secure a good attendance; nothing brings men together and sets them at their ease like a supper, afterward discuss trade subjects, and let the Secretary be prepared to bring the talk to practical issue by resolutions, put into the hands of suitable men. The first meeting, well managed, would be sure to result in many other such being held. It seems most natural that men in the same trade should be friendly with one another, and should band together for mutual benefit. Will the Local Secretaries try?

QUINTUS.

EXEMPTION FROM JURIES.

Sir,—One would imagine when the Pharmaceutical Chemists were legally exempt from serving upon juries, that we had got rid of a very great nuisance, and so we should if we could only get our names properly erased from the Jury Lists, and so prevent ourselves from being summoned; but there is the difficulty.

You will be surprised to hear that since I have been exempt I have been summoned four or five times, and this has been done after my having taken the usual means to prevent it, viz. getting my name cancelled from the list. This would appear an easy matter, but it is not so; for I find the county select the jury from one list and the borough from another, and unless you annually trouble yourself in the matter your name is put upon the list, and when once summoned you are in duty bound to attend to claim exemption. This, of course, is a morning wasted. I thought this year I would be very particular in the matter, and you can, therefore, imagine my surprise on receiving another summons about a month ago. This I found was owing to my private residence being in the parish of Penn, and my name, unknown to me, being put upon another list altogether. This is very unpleasant, and the object of my writing to you is to ascertain if chemists in the larger towns are put to similar annoyance, and if not, the means they adopt to effectually prevent it. There is certainly fault to be found with the officials, who ought, by this time, to be aware of our exemption. I believe my neighbours have been troubled in a similar manner.

Yours truly,
W. Y. Brevitt.

Wolverhampton, June 24th, 1870.

Order of Merit at Examinations.

Dear Sir,—There is one part of our present system of examinations that I do not think is altogether right; for this reason I beg a portion of your space in the Journal. The point I wish to bring before you is this, "the arrangement of successful candidates *in order of merit*." That, Sir, I think is not quite justly carried out. For instance, a candidate presents himself for the Minor, and fails in three out of six tables, therefore is plucked, as it is commonly termed. He gets a note to say he is eligible to again appear in three months, when he will be re-examined in those subjects in which he previously failed. He is, at the end of that time, well up in those subjects; and the marks of the subjects he passed in at the previous examination are added to those acquired at the second examination. When the Journal is published, and the list appears, we find him perhaps second, or third, with several behind him, who have passed at their first attempt.

To the various readers of the Journal these facts are not shown, as no difference is made between those who pass first or second time, and often it makes those who have two examinations appear superior to one who passes the first time. This takes away the credit of passing without failure.

If to be placed in order of merit, I think they should be again examined in all the subjects, to entitle them to be arranged in the list as is now the rule.

Indeed, as matters are now, many will not mind failing first time, in order to get to the top of the list the second time. This is not written *simply* on my *own* account, but for the benefit of those who may follow.

Trusting others better able than myself will take up the subject,

I am, Sir, respectfully yours,
A Successful Minor Candidate.

Pendleton, June 21, 1870.

[We understand that an alteration has already been made in the mode of classifying successful candidates which will meet the writer's views.—Ed. Pharm. Journ.]

The Valisneria Plant and the Breeding of Leeches.

Sir,—In the April number Mr. Colton asks for information respecting the propagation of the Valisneria in leech aquaria, but observing no reply I venture to offer the following remarks:—

A mixture of sand, small stones, and shells is all that is required as *ground* for the root.

The plant should be placed lightly in and allowed to rest, and should not be rejected though apparently dead, as fresh shoots sometimes spring up when the leaves appear decayed.

The Valisneria does not appear to enjoy direct light, nor does it thrive in a dull corner. A good reflected light seems best suited for it, and the nearer to the open door of the shop the better; this I think is important.

By following these simple rules my stock of plants has, in less than three years, increased forty-fold. I shall be happy to send Mr. Colton one or two healthy plants, etc., if he will tell me *how;* and while on the subject of aquaria, which, as I think, are neither uninteresting nor out of place in our shops, may I ask him whether the breeding leeches are of the ordinary size, or, as I am told, much larger, and how his young brood is getting on?

Yours respectfully,
B.

33, *Norfolk Terrace, W., June* 24, 1870.

P.S. I should say the above are but jottings of my own experience; I do not give them as scientific facts.—B.

Anonymous Correspondence.

Sir,—I think it very desirable, and I hope it will be a point insisted on by the Editors of the new series of the Journal, that correspondents subscribe their communications with their names and addresses. Many letters lose half their value from want of attention to this. How much more valuable would the letters of "One who has known the drug trade more than thirty years," and that of N. H. in the supplementary number of the 15th of June have been, if the names and addresses of the writers had been given! A real *bonâ-fide* name is something substantial; but there is something shadowy and unreal in initial letters and fictitious names.

One correspondent who asks a question, relating to cough lozenges, that may be called "silly," because it has been so often answered, and has appended initials corresponding to my own, might, but for this denial, be mistaken for me.

I am, Sir, yours faithfully,
F. M. Rimmington.

Carbolate of Iodine.—Dr. Evans, of Dublin, has sent us a communication on this subject, in which, referring to Dr. W. G. Smith's note in our last number, he says, there was no controversy as to the fact, that ammonia will decolorize tincture of iodine, but as to the question, whether the so-called "carbolate of iodine" was decolorized in that way, which had been proved in the negative. This controversy must now be considered closed.

Barnsley Chemists.—A correspondent from Barnsley, who signs himself "Pipes and Tobacco," has written to vindicate himself and fellow-chemists from the imputations implied in the letter of "Spes," in the May number of this Journal. He says, "I feel persuaded, in my own mind, that our brother-tradesman (whoever he may be) has written upon first thought; for who would not fain think, that had he ('Spes') coupled kindness of heart with his intelligence, he would never have presumed to interfere with another man's business. After reading Spes's complaint over several times, I have come to the conclusion that the true cause of it is, in the fact of a customer having stood before him with a prescription dispensed by another chemist at a lower rate than he himself named; and by duly acknowledging this to be the true cause of his letter, and not what is sold, but how it is sold, the chemists of Barnsley will, I have no doubt, unanimously adopt the motto, 'Spectemur agendo.'"

Amateur wishes for a process by which he can prepare condensed milk.

Pepper's Ghost.—Mr. Pollard, of Rhyde, refers "Inquirer," on the above subject, to Pepper's 'Cyclopædic Science Simplified' (Warne and Co.).

"*Nemo*" (St. Andrew's) would probly find the filtration of the water through animal charcoal effect what he requires.

"*Minor Y. Z.*"—*Chloral Hydrate* and *Alcoholate of Chloral*. See Vol. XI. (n. s.) pp. 150, 721, and 846.

"*An Inquirer.*"—*Chloric Ether* and *Spirit of Chloroform.* See Vol. I. (n. s.) pp. 304, 343; Vol. III. (n. s.) p. 533; and Vol. XI. (n. s.) p. 662.

"*Major Maude*" (Watton).—The apparatus for preparing nitrous oxide gas may be obtained of Messrs. Ash and Son, Broad Street, Golden Square. When the gas is used largely, it may be stored in a gasometer with advantage.

S. G.—Dissolve the tannic acid in the glycerine, the sulphate of zinc in the water, then mix the two solutions. The resulting lotion should be clear.

Mr. Wilkinson's communication on the Regulations for Storing Poisons will appear next week.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W.*

PHARMACEUTICAL PROSPECTS IN CANADA.

BY J. BAKER EDWARDS, PH.D., F.C.S.

From some previous reports* your readers will be prepared to understand the present position of Canadian Pharmacy,—at least in Lower Canada, now best known as the province of Quebec. During the last session of the Local Legislatures, Bills were introduced to regulate the practice of Pharmacy both in the province of Quebec and in that of Ontario.

Both of these Bills, though diverse in character, and each supposed to be best adapted to the several localities, failed to pass into law, chiefly in consequence of medical opposition.

The Bill brought forward in Ontario closely follows the British Acts, and is likewise trammelled with poison regulations; that of Quebec, on the other hand, simply incorporated a College of Pharmacy, with powers of registration, examination, and penal statutes against offenders.

In Ontario no legislation at present exists touching Pharmacy, so that the Bill had to run the gauntlet of the free-traders. It was quietly shelved in Committee.

In Quebec, on the other hand, Pharmacy has had some recognition from the times of early settlement, and licences were required in order to practise it, which were obtainable from the Governor-General on presentation of satisfactory documents. This power, founded so far back as the 28th Geo. III. c. 8, in the year 1787, is probably the oldest enactment restricting British Pharmacy on record. A provincial medical board, appointed by the Governor, conducted the examination of candidates and granted licences to persons selling, vending, or distributing by retail, medicines in Lower Canada.† In 1847, the physicians and surgeons of Lower Canada obtained an Act of Incorporation, and assumed the functions of the Provincial Board; but the clauses in their Bill regulating the druggists and apothecaries were expunged, on the understanding and assurance that the chemists would incorporate themselves as a pharmaceutical society and make proper regulations for their own body. This they neglected to do, and, in 1864, the College of Physicians and Surgeons amended their Act, and obtained a clause requiring that no person should carry on the business of an apothecary‡ or chemist and druggist without a licence from the Board, to be granted after passing such examination as the Board may deem satisfactory. In 1865, the Board, by a bye-law, added the condition, "That the candidate for Pharmacy must also furnish proof that he has attended at some university, college, or incorporated school of medicine or of pharmacy within her Majesty's dominions, lectures on the following branches, viz. Chemistry, two courses, six months each; Materia Medica and Pharmacy, two courses, six months each; Botany, one course, three months." At present, although this curriculum has not been very strictly insisted on in individual cases, it is a legal barrier to the examination of competent persons already in business or of young men arriving from abroad. In the debates on the College of Pharmacy Bill at Quebec, the representatives of the Medical Board urged with great effect that many of the promoters of the Bill were persons who had neglected the existing regulations, and that the public had no proof of their competence; this objection was really of the most technical character, because the promoters were well known as leading members of the trade, both wholesale and retail, and most of them had been many years in business. To meet it, however, several presented themselves to the College Board at the next meeting, and applied for licences, but were informed that they must comply with the bye-law requiring attendance on lectures before the College could proceed to their examination. The present powers are, therefore, unsatisfactory to all parties, and probably both the chemists and the College will apply for further legislation during the next session of Parliament. Every such discussion tends to show how unsatisfactory is the attempt of the medical profession to legislate for or to attempt to regulate Pharmacy. This, the most thoughtful of the profession have from time to time acknowledged; and the worthy editor of the 'Canada Medical Journal'* supports this view in the following graceful terms:—

"With regard to the apothecaries and druggists obtaining an Act of Incorporation, we most fully endorse the views held by the late talented editor of the 'British American Medical Journal,' viz. 'We have long thought that, considering their number, their respectability, and the specific objects of their pursuits, they should be specially endowed with powers peculiar to themselves;' with this addition, that twenty-three years have more than quadrupled their number, and that the druggists and apothecaries of this part of the Dominion are, as a class, reliable, trustworthy, and thoroughly conversant with the details of their profession." . . . "It is in every way desirable that they should be incorporated, nor can we see what just grounds can be urged against their having the management of their own affairs."

On the other hand, an unthinking majority of the profession desire simply to retain power, and effectually resist reform measures.

In this respect, the French element is especially felt to be a great barrier to educational progress, being eminently conservative.

The debate in Committee at Quebec on this Bill was the most exciting and impassioned that has been seen or heard there for years. Some of the doctors, members of the Assembly, simply ignored all that had been done in Great Britain and America during the past twenty years; refused to recognize the examination of the Pharmaceutical Society; and rested their arguments entirely upon their own antecedents and "vested interests;" and the question assumes the aspect of a battle of races, with a large French majority, or a pitched battle between Montreal and Quebec, with French Canadians as umpires.

The French pharmaciens have generally complied with the law, but the English sturdily resisted it. In Quebec nearly all the druggists are licensed by the College, whilst in Montreal only four or five have complied with the law. The College has no penal clauses to enforce its laws, so that its powers may be set at defiance with impunity; but, upon the other hand, the unlicensed chemist has no power to recover a just debt, because he has placed himself *ultra legem*.

* See 'Pharmaceutical Movements,' vol. ix. p. 9; Montreal C. A. vol. ix. p. 104; 'Pharmacy in Canada,' vol. xi. p. 354.
† 'Canada Medical Journal,' vol. vi. no. 11.
‡ This term is generally adopted in America to denote a pharmacist, not a medical practitioner.

* Dr. G. E. Fenwick, C. M. J. vol. vi. no. 11, p. 526.

On the subject of a suitable pharmaceutical curriculum the medical mind is also quite at variance with pharmaceutical experience.

It has been abundantly proved that mere attendance on lectures will not educate the pharmaceutical student; and although it is an unquestionable advantage to the student to have his knowledge systematized by such means, yet habits of exact and exhaustive reading, of individual judgment and interpretation, of successful manipulation, and of self-reliance, are formed, not in the lecture-room, but in the laboratory and the library.

And there can be little question in the minds of those who have received its advantages, that synthetical and analytical manipulations in the laboratory are the only sound, true, and essential bases of an advanced pharmaceutical education. Chemical lectures, with merely flashy experiments and no laboratory instruction, and materia medica lectures, without museums, form but a poor curriculum, whatever be the number of "courses" prescribed.

In 1858, the College introduced a very stringent measure, which was successfully resisted. It demanded as a curriculum—*

A sound elementary education.

Certificates of good moral character.

One course of lectures on Medical Jurisprudence;

Two courses on Materia Medica;

Two courses on Chemistry;

Each of six months, at a MEDICAL college.

It also contained penal clauses for—

"Vending a spurious or adulterated medicine." Penalty, £5 to £10.

"Practising pharmacy for gain without a diploma." Penalty, £5 to £20.

"Sale of poison without certificate and registration." Penalty, £2.

"Poisons to be kept in a private and safe place, and in yellow bottles, legibly labelled." Penalty, £5.

"Visitation of governors to inspect shops." Penalty for resistance, £5.

In 1860,† a Bill was introduced to compel druggists to keep open from 6 A.M. to 9 P.M. from April to November, and certain hours on Sundays; it was rather an "early opening" than an "early closing" movement. This was also successfully resisted.

It is obvious that, unless pharmacists will legislate for themselves, they will be legislated for; and if they will not educate themselves, they will be educated more or less. It is highly desirable that the regulations adopted by British, Canadian, and American pharmaceutical bodies shall be, as far as practicable, assimilated, and the standards of education be consistent, if not uniform; and the more I see of the means of education available in various countries, the more confidently do I endorse the opinion of our lamented Jacob Bell, that our pharmaceutical students should avoid medical schools, and that it is our duty, wherever possible, to provide and encourage schools of practical chemistry and pharmacy, which are the true basis of pharmaceutical education.

ON SMOKE,—THE THEORY OF ITS FORMATION.

BY SHEURER-KESTNER.

It is well known that pure carbon, when burned even with an insufficient supply of air, never produces smoke. Thus wood-charcoal and coke produce none, while hydrocarbons, on the contrary, emit smoke when burnt with insufficient quantity of air, and some of them even cannot be ignited without yielding a smoky flame.

It is stated, in some works on chemistry, that the production of smoke, and therefore of soot, takes place in the following way:—A hydrocarbon being ignited, and taking fire, the hydrogen, being the more combustible body, is first oxidized, and there does not then remain enough oxygen for the combustion of the carbon, so that this is precipitated in the form of soot, and thus forms smoke. It is hardly necessary to insist on the unsatisfactory nature of this explanation, which I must say, however, is never advanced excepting as an hypothesis.

In fact, when a hydrocarbon is ignited, or, in other terms, when the first ignition is communicated to the molecules which should cause the oxidation of the whole substance, we cannot consider the hydrocarbon as a simple mixture of hydrogen and carbon; and still more, in saying that hydrogen is more combustible than carbon, we adopt a second hypothesis, for the hydrocarbon contains the vapour of carbon, and we know nothing of the more or less combustible nature of the vapour of carbon; it is, therefore, but one hypothesis used to solve another. We find a deposit, a separation of carbon, and we simply know this fact.

The investigations of M. H. Sainte-Claire Deville on dissociation, and those of Berthelot on the action of heat on hydrocarbons, induced me to endeavour, through some new experiments, to throw light on this hitherto obscure question.

M. H. Sainte-Claire Deville has shown that when a compound gas is brought to a sufficiently high temperature, the elements of which it is composed separate; that if the mixture resulting from this dissociation be quickly cooled, there will be found in the product a simple mixture in the place of the original compound; but if, on the contrary, the cooling has taken place slowly, the elements will be found to have recombined so as to form the original compound. Such was the first of the observations on which I rested my investigation.

On the other hand, M. Berthelot has shown that, on submitting certain compound bodies, and especially the hydrocarbons, to the action of a high temperature, it is possible to produce new compounds resulting from the elements of the first, and that this decomposition may be accompanied by a deposition of charcoal.

These two classes of facts being once admitted, the theoretical question of the formation of soot is almost solved. In fact, what occurs in a fireplace charged with coals? Let us suppose that the grate is covered with incandescent coal, that it only contains ignited coke: it emits no smoke. Let us now put fresh coals on the fire, and we soon find black smoke covering the mass and passing into the chimney. After a time the smoke diminishes, and finally ceases until the fuel has been renewed.

Here is what passes in this case. When the coal, composed of hydrocarbons, comes in contact with the incandescent fuel, the hydrocarbons soon become heated to a sufficient extent to cause their distillation. The vapours, coming in contact with the air, become immediately ignited, and consume the oxygen by which they are surrounded. If fresh quantities of air do not replace the oxygen already consumed,

* Pharm. Journ. Vol. XVIII. o.s. p. 44.
† Pharm. Journ. Vol. XI. N.S. p. 245.

the gas will pass up the chimney in the state in which it left the fire, that is, imperfectly burned; and thus we have hydrocarbons in the gaseous products of the combustion of coal. This is the first hypothesis I have to present.

The second hypothesis rests on the observation of M. H. Sainte-Claire Deville. At the moment when the hydrocarbons are disengaged, being brought to a very high temperature, they behave like a mixture of carbon vapour and hydrogen. If a sufficient quantity of air were supplied to this gas, its combustion would be complete; otherwise it would be imperfect, and we should have the result of a cooling more or less rapid. If the cooling should take place quickly, as would happen when it comes in contact with surrounding cold objects or cold air, a separation of carbon in the form of soot would occur, and free hydrogen would be left, which thus accounts for the presence of this element, as well as hydrocarbons, in the gaseous products of combustion, some of the hydrocarbons resulting from recombination of the elements, as explained by Deville.

Again, the third hypothesis rests on the observation of M. Berthelot. The hydrocarbons distilled from the coals are submitted to the heat of the fire, and decomposed. They form new compounds with deposition of charcoal, or, in other words, with the production of smoke. If there should arrive a sufficient quantity of air, the combustion of the whole will take place, but if there is a deficiency of air, the smoke will remain, together with the new hydrocarbon.

It is thus that smoke is produced. We have seen that there is always a deficiency of air as a necessary cause. This statement may appear extraordinary, as it has been found that the gaseous products of the combustion of coal always contain an excess of air. This, however, is not inconsistent with the previous statement, for in saying that there is a deficiency of air, what is meant is that this is the case in each volume or stratum of air in which combustion has taken place, but the gases which pass into the chimney may be regarded as a collection of such volumes mixed with others rich in oxygen, and these would be too much cooled to admit of their entering into combination.

It results from these theoretical considerations, that for the purpose of avoiding or diminishing smoke, it suffices to cause the intimate admixture of the gases the moment they quit the fire. In fact, this method has been practically applied with success. The first application of these principles was made by M. Harteg.*

The furnace of M. Harteg consists of two fireplaces, side by side, running parallel, and separated by a wall. The fires in these two fireplaces are fed alternately, and the currents of gas being directed one against the other at the back of the furnace, the strata are thus broken up and mixed so as greatly to diminish the amount of smoke.

M. Brix† diminishes greatly the amount of smoke or prevents it altogether, by introducing a little air in a minutely divided state behind the bridge of the furnace. This air supplies the required oxygen at the moment when the combustible gases are still sufficiently heated for them to become ignited, and the admixture is readily effected, but with some loss of combustible matter.

* Harteg, 'Sur la Combustion des Houilles de Saxe.'
† Brix, 'Sur la Combustion de la Houille de Prusse.'

Lastly, M. Thierry's process consists in introducing a jet of steam over the surface of the fire. The steam does not exert any chemical action, but operates mechanically by mixing the gases, and thus diminishes the amount of smoke.

The following experiment I have repeated frequently, and always with the same results:—If a metallic tube be introduced into the current of gases in the furnace by passing it through a hole in the brickwork, the following observations may be made,—when the tube is kept cold by an external current of cold water, a large quantity of soot will be deposited upon it, which will increase until the action of the cold water ceases. If the current of water be stopped, and the tube allowed to become hot, the soot will gradually disappear, and will not be again deposited under these circumstances but its formation may be at once determined by renewing the cooling process. After the explanation I have given of the production of smoke, the foregoing result is easily explained. The dissociated gases coming into contact with a cold surface, deposit the carbon, but at a sufficiently elevated temperature this combines with oxygen and passes off as carbonic acid.—*Répertoire de Pharmacie.*

ON DE LOSSEN'S OXY-AMMONIA.

BY M. E. FREMY.

In a previous communication on nitrous acid I announced the production of a body possessing reducing power in a high degree, and which is formed when nitrous acid or nitrites are submitted to the action of hydrogen, sulphuretted hydrogen, sulphurous acid, the alkali metals, zinc, tin, etc.

I was unable immediately to determine the nature of this body, and ascertain whether its composition was NH_3O* as thought to be the case by Maumené, whose publication on the subject has been of great use to me, because by the method I then adopted I obtained it in quantities insufficient for the purpose.

I have recently discovered a method of easily producing this derivative of nitrous acid, and have accurately determined its characters and nature. I have found that it possesses very marked basic properties.

I prepare it in the following manner:—I treat tin with concentrated hydrochloric acid, inducing chemical action by a slight elevation of temperature; when hydrogen is abundantly produced, I add to the liquor either nitrous acid or a nitrite, or, more simply, nitric acid; I precipitate the protoxide of tin with ammonia; evaporate the liquor to dryness by means of a water-bath, or *in vacuo;* and lastly, treat the dry residue several times with absolute alcohol, which dissolves the hydrochlorate of the base.

The circumstances under which this basic substance has been produced, and the way in which it is prepared led me to think that it is nothing else than oxy-ammonia, the important discovery of which is due to M. Lossen. The formula for oxy-ammonia, NH_3O, which might otherwise be written, $N_2H_4O.H_2O$, shows, among other things, that oxy-ammonia might be considered to be a hydrate of nitrous acid (nitrous anhydride) in which two atoms of oxygen are replaced by an equivalent quantity of hydrogen. Its production by the reducing action of hydrogen on nitrous acid or a nitrite, is thus perfectly intelligible.

But for the further elucidation of the subject, thus assuming so simple an aspect, two points remained to be determined.

* The notation in this paper has been changed from that used by the author to the new notation now used in this country.

The basic substance which I produced with nitrous acid and the nitrites is characterized by a very decided reducing power; the neutral and acid salts of this base produce the same effect,—thus, they immediately decompose permanganate of potash and iodic acid. The reducing power which the salts possess, is, however, greatly augmented when the base is set free by means of an alkali, and a liquor is thus obtained which reduces salts of copper, mercury, silver, and gold.

On the other hand, there is no mention made by M. Lossen, or in the publications of other chemists who have studied oxy-ammonia, of the reducing action of that substance.

Is therefore the base which I have obtained different from that of M. Lossen?

Assisted by a young chemist, M. Maudet, I have repeated M. Lossen's experiments, and prepared oxy-ammonia by the method he has described, causing a mixture of hydrochloric acid and tin to act on the nitric ether of wood spirit; and I have thus obtained a base with all the characters of that I produced with nitrous acid, and which, like it, possesses great reducing power. —*Répertoire de Pharmacie.*

ON THE PREPARATION OF SUBACETATE OF LEAD BY THE COLD PROCESS.

BY M. NERNING.

When this preparation is made with heat, the acetate of lead is liable to dissolve excess of oxide of lead, and insoluble basic acetate is thus produced, forming a white flocculent precipitate, which renders the liquid turbid. To obviate this inconvenience, M. Nerning proposes to operate as follows:—Put the water, litharge, and acetate of lead into a bottle, and let them stand, with frequent agitation, for twenty-four hours, then filter. The solution thus obtained answers all the purposes for which it is required in pharmacy, and, if kept in a well-stoppered bottle, it will remain clear even when kept for a long time.—*Journal de Pharmacie et de Chimie.**

MODE OF PREPARING THE CUTCH OF COMMERCE FROM THE ACACIA CATECHU.

BY CLAUDE DUMAINE.

Of this tree there are two varieties,—a white and a red kind; but the cutch or catechu is almost always prepared from the red kind, the white being seldom cut down. Cutch, or catechu, is prepared thus:—The tree is cut down to about 6 to 12 inches from the ground, and chopped into small pieces, the smaller branches and bark being rejected. The chopped wood is then taken to the place of manufacture, generally under trees in the open air, and placed over a brisk fire in mud jars, called *gharrahs*, filled with about two-thirds of water. This is allowed to boil down till, with the extracted matter, it forms a liquid of syrupy consistence. The contents of several jars are then poured into a larger jar and again placed over a brisk fire for a period of from two to four hours, and, when sufficiently boiled down, it is poured out over mats covered with ashes of cow dung and allowed to dry. The wood, when dry, is used for fuel.—*Journ. of Agr. and Hortic. Soc. of India, part iv. p.* 399. 1869.

* The editor, in a note, states with reference to this process, that it has long been adopted in the military hospitals, the following being the proportions of ingredients used:—Crystallized acetate of lead three hundred parts; litharge, in fine powder, a hundred parts; distilled water, six hundred and fifty parts. Put them into a bottle, shake them from time to time, and at the expiration of six or eight hours, filter.

THE PRESENT PROSPECTS OF THE SEWAGE QUESTION IN RELATION TO THE PUBLIC HEALTH.

BY HENRY LETHEBY, ESQ., M.B.

(*Read before the Metropolitan Association of Medical Officers of Health, May* 21, 1870.)

Hasty and inconsiderate legislation, promoted by those who, as the sequel will show, had no real knowledge of either the principles or practice of the subject with which they officiously meddled, together with the most mischievous charlatanism, has brought the whole question of the disposal of sewage into such a frightful mess, that the public are not only loud in their complaints of the injury inflicted on them, but are equally emphatic in their demands for a remedy.

A review of the parliamentary history of this subject would be instructive, and it would also be amusing, but for its serious results and its solemn prolixity; for it would show how Blue-book upon Blue-book, and report upon report, from the same officious hands, and in the same wearisome tone and bewilderment of facts and figures, had so perplexed the Legislature, that they were glad to dispose of the subject by hasty legislation, or by handing it over to some Royal Commission, not always discreetly chosen.

But bad as are the consequences of this, the prospects of the future are worse, for there is a well-grounded fear that the same incompetent school of sanitarians who have been concerned with our present difficulties, will also be concerned with the future, and that Parliament will again have to correct the errors of inconsiderate legislation. If this can be prevented it will be of vast importance to the public, and none are better able to assist in the matter than the health officers of this metropolis. It is with this object I draw your attention to it, and ask you to give it your serious consideration.

In the first place, let us inquire what is the nature of the thing we have to deal with. Sewage is at all times a very complex material, for it is composed not only of the solid and liquid excreta of the population, but also of the fluid refuse of every branch of industry, as the filth of kitchens, laundries, and dye-houses; the drainings from stables, slaughter-houses, and the public markets; the various liquid impurities of trades and manufactures; and the washings of streets and alleys. These, with the ejecta of the inhabitants, and a large volume of water, compose the sewage of towns. But each of these constituents has its specific influence on the composition of the general mass, and on the putrefaction to which it is subject. Every town or city, therefore,—in fact, every part of a city,—has its own peculiar quality of sewage, varying with the density of the population, the habits of the people, as to their diet, cleanliness, and trade pursuits; with the season of the year, the state of the weather, the day of the week, and even the hour of the day. This makes it difficult to obtain precise information of the nature and composition of sewage. Nevertheless, there are two ways by which the subject may be approached,—as by ascertaining the average amounts of solid and liquid matters contributed by each individual, and by the various branches of industry; and secondly, by making careful analysis of the sewage collected throughout the day at various seasons of the year.

Messrs. Lawes and Way in this country, and MM. Wolf and Lehmann on the Continent, have determined, with very nearly the same results, the average proportion of solid and liquid matters discharged daily from the human body. It varies, of course, with age and sex, but broadly it may be said that, taking a thousand individuals at all ages, as they are found in a population, they contribute about 2640 lbs. of liquid and moist excreta. In the dry state it would amount to about 141 lbs. This is at the daily rate of 42·25 oz. of moist, or 2·25 oz. of dry matter per head of the population. The washings of streets have been carefully examined by Professor Way, who finds that the liquid discharged into the gullies, after a heavy shower of rain, contains, in the case of granite roads, about 813·3 grs. of solid matter per gallon, and of this 276·2 grs. are dissolved, and 537·1 grs. suspended. In that of wood pavements it contains only about 39 grs. per gallon, of which 34 grs. are dissolved and 5 grs. suspended. The general average of the washings of several streets differently paved, and with various amounts of traffic, gave 262·6 grs. of solid matter per gallon, of which 113·3 grs. were dissolved, and 149·3 grs. suspended. The refuse of factories, etc., cannot be easily determined, and therefore we are obliged to rely for our results on the second method of investigation—namely, the analysis of the sewage at different times and places.

In this metropolis the sewage discharged by day contains about 94 grs. of solid matter per gallon, of which 38 grs. are suspended, and 56 grs. dissolved: of the suspended matters, 17 grs. are organic, and 21 grs. mineral; and of the dissolved, 15 grs. are organic, and 41 grs. mineral. The night sewage is not so rich in solid elements, for it contains only about 79 grs. of solid matter per gallon, of which 14 grs. are suspended and 64 grs. dissolved; and of these, 15 grs. are organic, and 64 mineral—the organic being distributed very evenly between the soluble and insoluble constituents.

Branch sewers, and those which are nearly stagnant, are generally very foul, for the sewage of them contains from 150 grs. to 500 grs. of solid matter per gallon, of which from 90 grs. to 250 grs. are suspended. The organic matter ranges from 20 grs. to 120 grs. in the soluble part, and from 20 grs. to 176 grs. in the insoluble.

Taking the average of all the results obtained in the examination of the metropolitan sewage by Dr. Hofmann, Mr. Witt, Professor Way, and myself, it may be said that it contains about 90·4 grs. of solid matter per gallon, of which about 29·8 grs. are suspended, and 60·6 grs. dissolved, there being about 15 grs. of organic matter in each of these constituents.

A storm of rain does not diminish the proportion of solid matter, for although it has a tendency to dilute the sewage, yet it washes away so large a quantity of filth from the streets, and disturbs so much of the sediment in the stagnant sewers, that the sewage after a storm generally contains more than the average proportion of solid impurity. Taking 90 grs. per gallon as the usual amount, it will be increased after a storm to 125 grs. per gallon, of which 64 grs. are suspended, and 61 grs. dissolved.

The physical properties of sewage are peculiar, for when examined under the microscope the clear liquor is found to contain a large quantity of amorphous organic matter, with filaments of various fungi, and it swarms with the lower forms of animal life, as beaded *spirulina*, *vibriones*, and *monads*; but soon after exposure to the air higher forms of infusoria appear, as *paramecium*, *vorticella*, *rotifera*, etc. The sedimentary matter consists of the remains of undigested food, as muscular fibre, husk and hair of wheat, the cells and starch of potato, and the tissues of vegetables, as cotton, cabbage, etc., and fibres of wool. It also contains the products of some of the secretions, as yellow biliary matter, intestinal mucus, and crystals of uric acid and triple phosphate; besides the *débris* of the streets, as particles of granite, flint, and carbonate of lime, with a large quantity of black amorphous matter.

(*To be continued.*)

THE "A B C" PROCESS FOR THE TREATMENT OF SEWAGE.

This process of purification, which has been adopted at Leicester and also on the south coast, at Hastings, and which is sometimes called "Sillar's process," was patented by Messrs. W. C. and R. G. Sillar, and W. G. Wigner. The process is described in the specification of the patent as follows:—

"We add to the sewage to be purified a mixture consisting of the following ingredients:—Alum, blood, clay, magnesia or one of its compounds, by preference the carbonate or the sulphate, manganate of potash, or other compound of manganese, burnt clay, otherwise known as ballast, chloride of sodium, animal charcoal, vegetable charcoal, and magnesian limestone. Of these substances, the manganese compound, the burnt clay, chloride of sodium, and magnesian limestone may be omitted, and it is not essential that both animal and vegetable charcoal should be used. If any of the ingredients named should from any cause be present in sufficient quantity in the sewage, it may, of course, be omitted from the mixture. The proportions in which the ingredients are to be used vary according to the nature of the sewage to be purified, as, for instance, if a large proportion of urine is present, we increase the proportion of clay; if the sewage is much diluted, we slightly increase the proportion of alum and blood; if it contains a large proportion of street refuse, we decrease the proportion of clay.

"For ordinary sewage the following proportions have answered well:—

Alum	600	parts.
Blood	1	"
Clay	1900	"
Magnesia	5	"
Manganate of potash . .	10	"
Burnt clay	25	"
Chloride of sodium . .	10	"
Animal charcoal . . .	15	"
Vegetable charcoal . . .	20	"
Magnesian limestone . .	2	"

"These substances are mixed together and added to the sewage to be purified until a further addition produces no further precipitate. The quantity required will be about four pounds of the mixture to one thousand gallons of sewage. In many cases it is preferable to mix the above compound with a small quantity of water, and add it in a liquid state to the sewage. The sewage must then be thoroughly mixed with the compound, and allowed to flow into settling tanks. The greater part of the organic and other impurities will be immediately separated in the form of large flakes, which rapidly fall to the bottom, leaving the supernatant water clear and inodorous, or nearly so. The water may then be allowed to flow away into a river, or be disposed of in any other way, and the sediment or mud allowed to accumulate at the bottom of the tank. In some cases it is preferable to add the compound of manganese to the water after the sediment produced by the other ingredients has been allowed to subside. The sediment will be found to possess the power of precipitating a further quantity of sewage; it must therefore be pumped or otherwise taken from the tank, and mixed with fresh sewage, the sediment being allowed to subside in the same way as before. The sediment may be used five or six times over in this way. When the sediment no longer possesses the power of precipitating the impurities in the sewage, it must be removed from the tank and allowed to dry; when partially dry a small quantity of acid, by preference sulphuric acid, may be mixed with it, which will retain all the ammonia in a soluble form. When dried, the sediment will be a valuable manure."

THE ECLECTIC INHALER.

This apparatus, which is made by Maw and Son for Messrs. Bullock and Reynolds, is described in the following terms by Dr. Morell Mackenzie, by whom it appears to have been designed.

A good inhaler should possess these properties:—

1st. It should be capable of containing a sufficient quantity of water, and also space for holding a sufficient quantity of steam.

2ndly. It should provide for the perfect medication of the vapour inhaled, by necessitating the passage of air through the liquid; or, in other words, it should allow the patient to inhale, NOT merely the medicated steam ascending from the hot liquid, but air which has passed through the liquid and become saturated with the volatile matter. This has been called the hookah or bubble-bubble principle, and has been *imperfectly* provided for in many inhalers.

3rdly. It should require very little effort on the part of the patient.

4thly. It should be capable of being kept at a uniform, or nearly uniform temperature.

5thly. It should be capable of being easily cleaned.

6thly. It should be capable of being used in either a sitting or recumbent position.

That the Eclectic Inhaler fulfils all these conditions will be now shown:—

a. It holds a pint of hot water, and has a larger air chamber above.

b. The perfect medication of the vapour is ensured by allowing air to pass through the medicated liquid on inspiration.

c. Absence of effort is secured by providing for the ample supply of air through the very numerous ingress holes (x and z), and for an easy passage of air through a large inhaling-tube and mouth-piece; and by being constructed in such a manner that the lower ingress-holes are only covered by about half an inch of the medicated liquids.

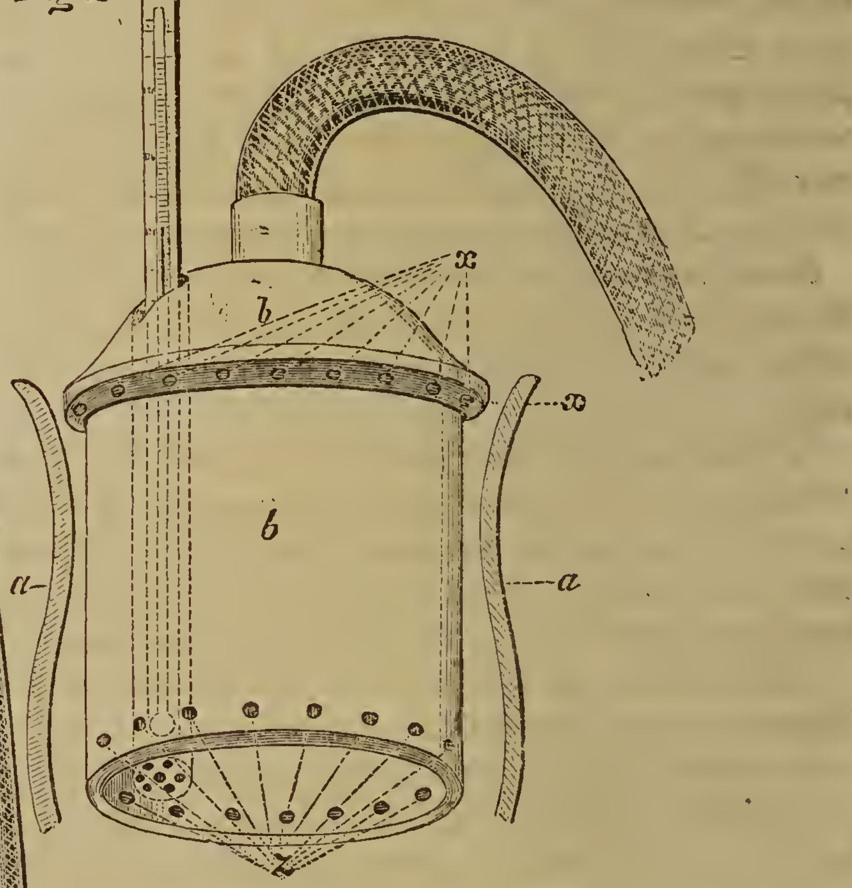
d. The temperature is maintained by a Clark's night-light, and regulated by a thermometer.

e. Cleanliness is provided for by the construction of the apparatus.

f. The use of the inhaler in any position is secured by the elastic inhaling tube, as in Curtis's.

Fig 1

Fig 2



DESCRIPTION.

The Inhaler consists of three parts—*a*, *b*, and *c*.

a is an open vase, and is essentially the containing vessel, into which the hot water and medicated solution are put. It is shown in Fig. 1, with a pint of water in it, and above the water-line is a large space for the steam.

b is a kind of lid, resembling an inverted tumbler. It is shown in Fig. 1, forming the lid of the containing vase, and in Fig. 2, with the sides of the vase drawn diagrammatically. The bottom of the tumbler forms the covering of the vase, and the sides of the tumbler dip down into it, leaving an air chamber between the two parts. When the vase has its proper quantity of water, the sides of the inverted tumbler or lid dip down only about half an inch below the water line. The circumference of the lid is perforated with small holes, as seen at x, and the circumference of what would be the rim of the tumbler is perforated in the same way at z. The apertures, both above and below, communicate with the air-chamber. When the patient inhales, air rushes through the various holes above at x, then through the air-chamber, again through the series of holes at z, and finally up to the mouth-piece, as shown by the course of the arrows. In the centre of the upper surface of the lid is a projecting nozzle, to which is attached a flexible tube, provided at its extremity with a double-valve earthenware mouth-piece. There is an opening in the lid, through which a thermometer registering high temperatures passes into the water.

c is a stand on which the vase rests, and is made hollow, so as to hold a night-light.

The Pharmaceutical Journal.

SATURDAY, JULY 9, 1870.

THE BETTS SUITS.

A condensed report of the proceedings before Vice-Chancellor James appears in page 32. Mr. Betts had filed twenty-five separate Bills in Chancery against retailers of capsuled articles; he sought injunctions, damages, and costs, and he has completely and signally failed.

Upon the testimony of Mr. Betts and his witnesses, and the arguments of counsel advanced in his interest, the Vice-Chancellor would have refused all that was asked, but when the defendant's case was entered upon, only so far as the reading of Mr. Betts's evidence under cross-examination, the Vice-Chancellor concluded to dismiss the Bills with costs, and remarked, "I must say this case seems to me about the most impudent case that ever came into Court."

Some passages in the cross-examination confirm the impressions which led to the formation of a Committee and to a subscription for defence; Mr. Betts says,

"I have no recollection of having had any conversation with Mr. Sandford in particular. I met a person of that name, amongst others, at the Pharmaceutical Society, when I do not believe the words twenty thousand pounds ever came out of my mouth."

"I told him, and I told them all together, as the Pharmaceutical synod, that with their vast numbers, their names being legion, a pound a-piece would put me straight in the matter; and if the numbers were few, five pounds a-piece would make an atonement for all that had passed."

"I think I said over thirty thousand pounds, but I did not in words say that I was resolved on being reimbursed; I said there must be something solid—something to eat."

The sentences quoted suggest whether, if all the twenty-five defendants had surrendered, the experiment of filing bills would not have been extended, and whether if £36,000, £30,000, or even £20,000 had as "something solid—something to eat," been provided by the Pharmaceutical Chemists of 1865, the cravings of Mr. Betts might not have expanded, and his operation extended far beyond the limits of the Pharmaceutical Society.

But who amongst the defendants, or the public, could have imagined that but one capsule, and that on a labelled bottle, would have been produced against each defendant, or that when Mr. Betts made affidavit that the capsules were not made by him, but were of foreign manufacture, there would be wrung from him, under cross-examination, evidence showing that they were made by his own Paris house; so that under his original oath there lurked the subtlety about Betts a Frenchman, and the same Betts as an English patentee, which led the Vice-Chancellor to say that he was shocked at such a mode of making an affidavit, and hoped never to see it again!

The extreme views contended for by Mr. Betts would, if successful, have added materially to the difficulties attending retail business; the Vice-Chancellor's remarks deal lucidly with the question, and will repay careful study; we see in them rules of conduct for the future, and thus good resulting from the litigation. Certainly the Defence Committee have been eminently successful, and deserve the best thanks of all interested in trade.

THE SCIENCE DEGREES OF THE UNIVERSITY OF LONDON.

The degrees of the University of London not only have acquired a high reputation on account of the stringency of the examinations through which they are obtained, so that they are looked upon as among the best tests of proficiency in the several departments of learning to which they relate, but they present to scientific men the peculiar advantage of including degrees relating mainly to scientific knowledge. The science degrees have become objects of ambition with scientific men, including chemists, geologists, and others, and we are very glad to observe that some of our members, associates, and students are becoming graduates in the University, and taking degrees in science. At the last examination, the result of which has just been published, we find that one of our associates, Mr. John Watts, obtained the highest degree in science, Doctor of Science, D.Sc., in the fourth branch, in which the subjects of examination were inorganic and organic chemistry, or mineralogy. Mr. Watts was a student in the Laboratory of this Institution about seven years ago; he was elected Junior Bell Scholar in 1863, and Senior Scholar in 1864. He has also passed the Major Examination of the Society.

THE POLLUTION OF RIVERS COMMISSIONS.

We alluded in our last number to the operations of a Committee appointed by the British Association, "to report on the treatment and utilization of sewage." The subject which this committee has undertaken to investigate has, in connection with other questions, occupied the attention of two commissions appointed by the Government, from whom three reports have already emanated; and one of those commissions being still in existence, further reports may be expected. The first Pollution of Rivers Commission was appointed by the Government in 1865, and consisted of Robert Rawlinson, John Thornhill Harrison, and John Thomas Way. That commission investigated the pollution of the Thames and the Lea, on which two reports were made. In 1868 the previously-formed commission was superseded by another consisting of Sir William Thomas Denison, Edward Frankland, and John Chalmers Morton, who have recently reported the results of their investigations on the Mersey and Ribble. These reports contain a large amount of valuable information relating to the past and present states of the rivers alluded to, the causes of the deterioration which has occurred in the waters of these rivers, the means which have been tried or suggested for mitigating the evils resulting from river pollution, and other subjects to which the attention of the Commissioners was directed by the terms of their appointment.

Many of the questions involved in this inquiry are of a purely chemical nature, and chemists are not agreed with regard to the solution of some of them. There are especially two views entertained of the influence of sewage on river-water. Some chemists contend that the deleterious matter communicated to rivers by the introduction of sewage, when the quantity is not very great, is soon destroyed by the natural process of oxidation, which is always occurring in running water, while others deny that this process of self-purification can be depended upon for rendering the water fit for domestic use. The Commissioners, with Dr. Frankland as their chemical guide, belong to the latter class; and Dr. Letheby, a good authority on such matters, may be taken to represent the former. We insert elsewhere the first part of a paper recently read by Dr. Letheby at a meeting of the Association of Metropolitan Officers of Health, in which his views are fully set forth.

UTILIZATION OF SEWAGE.

We understand that the authorities of Southampton, profiting by the example set them at Hastings, have determined to adopt the A B C process of utilizing the sewage of their town, and thus to preserve the local waters and beach from pollution. Any doubt that may exist as to the sufficiency of this process, a description of which was given in our last number, for purifying sewage-water so as to render it fit to be discharged into rivers, cannot apply to the waters discharged into the sea.

Transactions of the Pharmaceutical Society.

EXAMINATIONS IN LONDON.

July 1*st*, 1870.

Present—Messrs. Allchin, Bird, Carteighe, Cracknell, Davenport, Edwards, Gale, Garle, Haselden, Ince, and Southall. Dr. Greenhow was also present on behalf of the Privy Council.

MODIFIED EXAMINATION.

Thirty-eight candidates were examined; the following twenty-four passed, and were registered

As CHEMISTS AND DRUGGISTS.

Atkinson, Leonard	London.
Capell, Thomas	Steyning.
Chellew, William	London.
Dawney, Charles	Exeter.
Deane, Frederick Dawson	Jersey.
Garthwaite, William Humble	Liverpool.
Gillet, Daniel	Liverpool.
Hayward, George	Croydon.
Hume, William Andrew	Collingham.
Jenkins, David	Bridgend.
Morford, Thomas	Stoke Newington.
Moyle, Joseph	London.
Mundy, Alfred Octavius	London.
Organ, Edward	Bristol.
Pasco, George	London.
Rowell, John Childs	Reading.
Scott, Joseph	Worcester.
Smith, Charles William	Cirencester.
Smith, John Charles	London.
Squire, James	Lewes.
Stokes, Walter Edward	Sandgate.
Taylor, John	Oldham.
Taylor, Peter	London.
Wall, Alfred	Leamington.

FIRST, OR PRELIMINARY EXAMINATION.

One hundred and seventy-seven candidates were examined; the following one hundred and forty-five passed, and were registered as

APPRENTICES OR STUDENTS.

	Pank, Philip Durrell	North Walsham.
	Parsons, James	Sheerness.
	Peake, Arthur	Stalybridge.
	M'Jannet, James	North Walsham.
	Freeman, Ernest	Stourbridge.
	Lyddon, Richard	London.
Equal.	Cottam, William Procter	Lancaster.
	Parker, William	London.
Equal.	Goodacre, John William	Coventry.
	Kidd, Arthur	Broadstairs.
Equal.	Barry, Frederic	Bath.
	Marden, George	Fareham.
	Treweeks, Richard Harwood	Pembroke.
Equal.	Brookes, Frederick James	Selby.
	Daniel, John	Bromley, Kent.
	Mieklem, Austen	Reading.
	Hogg, Joseph Fawcett	North Shields.
	Fraser, Alexander	Liverpool.
	Lord, Frederick	Boston.
	Sherburn, Frederick	Keighley.
Equal.	Burder, Robert	Manchester.
	Gadd, William Fletcher	Oxford.
	Purse, Alfred Dodds	Sunderland.
	Dawson, Cantley	Stockport.
Equal.	Cooke, Edmund Herbert	Northampton.
	Pratt, Henry	Thirsk.
	Lewis, Edward	Sandown (I. W.).
Equal.	Burn, Henry	London.
	Butterworth, Albert	Sowerby.
	Farmer, William	Bilston.
	M'Cormick, Frank Henry	Cheltenham.
	Moore, Albert	Ashton-under-Lyne.
	Walton, William Henry	Croydon.
Equal.	Booth, William Grounds	Manchester.
	Tuck, Walter Barber	Eastbourne.
	Aitken, Henry, jun.	York.
Equal.	Slater, Jonathan	London.
	Taylor, Richard Eccles	Manchester.
Equal.	Robertson, George	London.
	Saunders, Thomas Bealby	Darlington.
	Sawyer, Henry	Carlisle.
	Turner, William Spencer	Hingham.
Equal.	Middleton, Christopher	Thirsk.
	Moss, Thomas Abbot	Carlisle.
	Pike, John	Great Yarmouth.
	Thompson, Frank Farrow	Cambridge.

	Plummer, Arthur	Reading.
Equal.	Dixon, Herbert	Retford.
	Johnstone, William, jun.	Nottingham.
	Holmes, Samuel	Hampstead.
Equal.	Fowler, George Bland	Bishop Stortford.
	Wilkins, Robert Elliott	Surbiton.
Equal.	Morse, Charles H. Stafford	Bishop Stortford.
	Nicholls, Arthur Lindley	Shanklin.
	Martin, William James	London.
Equal.	Buckle, James	Malton.
	Jackson, Richard	Carlisle.
	Leece, Frederick	Preston.
	Windle, John Thomas	Lower Norwood.
Equal.	Cuttle, Arthur Edward	Scarborough.
	Stables, William Skilbeck	Scarborough.
Equal.	Cox, George	Tewkesbury.
	Gardner, James Clarke	Newcastle-on-Tyne.
Equal.	Loadman, James	Liverpool.
	Morgan, Richard	London.
Equal.	Matterson, John Kitching	York.
	Shillcock, Arthur	London.
	Clifford, Richard Noon	Melton Mowbray.
Equal.	Savery, William Henry	Burslem.
	Scott, Thomas Alexander	London.
Equal.	Bolton, Felix Palmer	Dover.
	Eminson, Thomas	London.
	Richmond, William Wilkinson	Carlisle.
	Somerville, John	Carlisle.
	Spilsbury, James	Stafford.
Equal.	Farquhar, James	Aberdeen.
	Ord, Septimus William	Newcastle-on-Tyne.
	Rowcroft, Albert Edward	Gravesend.
	Turner, George Thomas	London.
	Sugden, Samuel	Newchurch.
Equal.	Emson, William Nicholls	Dorchester.
	Padwick, William Guy	London.
	Spence, Robert Davis	Harrogate.
Equal.	Matthews, Ernest	Royston.
	Sandwith, William Henry	Scarborough.
Equal.	Hemingway, Edward	London.
	Lynn, Edward	Blackheath.
Equal.	Twemlow, Francis Ernest Cassiani	London.
	Spencer, Alfred Barton	Burnham Westgate.
	Thompson, Harry	Norwich.
Equal.	Davies, Thomas Rhys	Swansea.
	Thompson, Thomas	Knaresborough.
	Worthington, William	Preston.
	Shackleford, Lewis John	Weston-super-Mare.
Equal.	Hall, Alfred Lee	Winchcombe.
	Wingate, John	Lincoln.
Equal.	Riach, Charles Beverly	Aberdeen.
	Wilson, Edward William	Nottingham.
	Bridger, Thomas	Fareham.
Equal.	Knowles, William Edward	Dewsbury.
	Mattocks, Charles Reynolds	Coventry.
Equal.	Brown, Walker	Retford.
	Carlton, Arthur	Horncastle.
	Tebb, Henry	St. Ives, Hunts.
	Smith, Walter James	Rochdale.
	Taylor, John	Carlisle.
Equal.	Goodlad, John Jonathan	Birmingham.
	Stevens, Nobbs	Swaffham.
	Glazier, Walter Henry	London.
Equal.	Chambers, Machin	Lincoln.
	Green, Frank	Cartmel.
	Shakerley, Benjamin	Liskeard.
Equal.	Pickup, John Arthur	Bacup.
	Saville, George	Wakefield.
Equal.	Lister, Joseph	Preston.
	Morgan, George Henry	London.
	Prust, Thomas William	Leeds.
Equal.	Cox, William	Lincoln.
	Steele, Stephen	Steyning.
	Wyborn, Samuel	Windsor.
Equal.	Cooke, William Kendle	Brighton.
	Sawden, Alfred	Filey.
	Willan, William	Preston.
	Evans, Ebenezer Richard	Cardigan.
Equal.	Banks, Edward	Salford.
	Gatenby, Robert	Beverley.
	Threlfall, Hugh	London.
Equal.	Adkin, Thos. Rennie Hutton	Pontypridd.
	Edwards, Thomas	Newport, Mon.
	Phillips, James Wilson	Broadstairs.
	Topham, Harry	Scarborough.
	Wellington, James	Oakham.
Equal.	Baker, Robert Southey	Battle.
	Barton, William	Preston.
	Bell, George, jun.	Hull.
	Churchman, James	London.
	Cordley, William Bains	London.
	Dodds, William	Hull.
	Hawley, William	London.
	Morson, Thomas Pierre	London.
	Platt, Jakeh Wright	Delph, Saddleworth.
	Salter, Thomas	Bradninch.
	Thompson, Mark Foggitt	Thirsk.
	Tucker, William Charles	London.
	Wardle, William	London.

The following is a list of the towns at which the Examinations were held, with the number of candidates examined at each town:—

Aberdeen	2	Liskeard	1
Bath	2	Liverpool	3
Beverley	3	London	43
Birmingham	1	Manchester	3
Boston	1	Merthyr	1
Bradford	1	Monmouth	1
Bridlington	1	Newcastle-on-Tyne	4
Brighton	2	Newport	2
Bristol	2	Norwich	8
Cambridge	3	Northampton	1
Cardigan	2	Nottingham	2
Carlisle	6	Pembroke	1
Cheltenham	2	Portsmouth	2
Chester	1	Preston	7
Congleton	1	Ramsgate	2
Croydon	1	Reading	2
Coventry	2	Retford	2
Darlington	1	Rochdale	3
Devonport	1	Ryde	2
Dewsbury	1	Scarborough	4
Doncaster	2	Selby	1
Dorchester	1	Stafford	1
Dover	2	Stalybridge	1
Fareham	2	Stockport	1
Hastings	1	Stoke-on-Trent	1
Hereford	1	Stourbridge	1
Horncastle	1	Sunderland	1
Huddersfield	1	Swansea	1
Huntingdon	1	Tewkesbury	1
Hull	2	Thirsk	3
Kendal	1	Wakefield	1
Kingston	1	Wednesbury	1
Leamington	1	Weston-super-Mare	1
Leeds	2	Windsor	1
Leicester	1	Wolverhampton	1
Lewes	1	Yarmouth	1
Lincoln	5	York	3

Total number of towns, 74.

The undermentioned, having presented to the Board a Certificate of Examination by the University of Oxford, was registered as an

APPRENTICE.

Ward, Edwin .... Cheltenham.

LOCAL SECRETARIES, 1870–71.*

Aberdare	Jones, John.
Aberdeen	Davidson, Charles.
Abingdon	Smith, William.
Altrincham	Holt, William Henry.
Andover	Madgwick, William B.

Yarmouth, Great	Poll, William S.
York	Davison, Ralph.

Provincial Transactions.

THE SHEFFIELD PHARMACEUTICAL AND CHEMICAL ASSOCIATION.

The last General Monthly Meeting of the winter session was held at the rooms on Wednesday evening, June 15th; Mr. Wilson, President, in the chair.

Mr. Burnell was elected a member, and Messrs. Clifton, Hutchinson, Liversidge, and Pickering, associates.

The President and Ex-President having kindly represented the Association at the recent Annual Meeting of the Pharmaceutical Society, this was deemed a favourable opportunity to receive from them a *vivâ voce* report of the Meeting and Conversazione; their remarks were listened to with great interest, and a lengthened conversation ensued thereupon, after which a cordial vote of thanks to the deputation was moved by Mr. Radley, seconded by Mr. Ward, and carried unanimously.

It being announced that on the following evening Mr. Ward would deliver the last of a course of twelve gratuitous lectures on the Chemistry of the British Pharmacopœia, Mr. Maleham, on behalf of the Council, proposed a hearty vote of thanks to Mr. Ward, and characterized the lectures as very valuable and instructive, having been carefully prepared at a great expense of time; he trusted they would be duly appreciated by the Associates who had enjoyed the privilege of listening to them.

Mr. Hudson, in eulogistic terms, seconded the motion, which was supported by Mr. Radley, who, judging from the report of some of the pupils, felt convinced that Mr. Ward had rendered the Association and the youths good service; carried with applause.

Mr. Ward briefly replied, expressing some disappointment that a larger number of the Associates had not availed themselves of the opportunity to attend.

A newly invented label-damper was presented by Messrs. Bourne and Taylor, which was handed round for examination, and appeared to possess considerable merit; this concluded the business of the meeting.

Meetings of Scientific Societies.

ROYAL INSTITUTION.

A lecture was delivered on Friday evening, June 10th, by Dr. Odling, F.R.S., Fullerian Professor of Chemistry to the Institution, "On the Ammonia Compounds of Platinum." The lecturer alluded to the discovery of ammonia gas by Priestley in 1774; to the characteristic property of this gas, H_3N, of uniting directly with hydrochloric acid gas, HCl, to form a solid deposit of sal-ammoniac, or hydrochloride of ammonia, H_3N,HCl; to the similarity of behaviour in many respects of sal-ammoniac with chloride of potassium, leading to the inference that sal-ammoniac contains a composite metal ammonium, H_4N; to the resemblance between chloride of potassium and sal-ammoniac in the way in which they are acted upon by a weak galvanic current, when a drop of mercury forms the negative pole, an amalgam of potassium, K_xHg_y, in one case, and an amalgam of ammonium, $(H_3N,H)_xHg_y$, in the other case, being thus produced; to the characteristic property of ammonia gas of freely dissolving in water and forming a liquid having many of the properties of aqueous potash, although differing from that, inasmuch as hydrate of potassium is a definite body, while hydrate of ammonium has an inferential existence only. He then said that the most interesting circumstance with regard to ammonia, was its property of serving as a type from which compounds of the most varied character may be derived by substitution. The general character of those substitution-changes was described, and the views of Laurent and others, with reference to the constitution of some of the ammonia compounds, and especially those with platinum, were referred to.

He said that his attention having of late been directed to the study of these compounds, he has succeeded in differentiating the simplest of the platinum sal-ammoniacs from several allied and isomeric bodies with which it had before been confounded; and in obtaining from it the corresponding hydrated base of the series. He has also obtained some reactions of interest with bodies belonging to the more complex series; and, as a general result of his inquiries, has ventured to put forward a new scheme of regarding the entire group of bodies. This scheme is based on the recognition of two principal facts or propositions:—

1. The different platin-ammonia compounds are produced, in the first instance, from platinous chloride, $PtCl''_2$; and just as the platinum of this compound possesses the property of taking up two additional proportions of chlorine, so as to furnish the platinic compound Cl_2PtCl_2, or $Pt''''Cl_4$, so also does the platinum of the different ammoniated bodies obtained from platinous chloride possess the property of taking up two proportions of chlorine, or its equivalent of other negative radical, so as to furnish platinic compounds corresponding to the original platinous compounds respectively. Hence the division of platin-ammonia compounds into the two classes of platinous and platinic, the compounds of the former differing in constitution from those of the latter class, just as platinic differs from platinous chloride, by a direct fixation of chlorine.

2. The monad residue, or radical amidogen, H_2N, is capable of becoming the monad radical ammon-amidogen, $H_2N.H_3N$, or H_5N_2, just as the monad radical methyl, H_3C, is capable of becoming the monad radical methylen-methyl, or ethyl, $H_3C.H_2C$, or H_5C_2.* Viewing sal-ammoniac, $H_3N.HCl$, as the analogue of methylic chloride, H_2CHCl, the difference is noticeable that, while the ammonia both of sal-ammoniac and ammon-amidogen is easily separable, the methylen both of methylic chloride and methylen-methyl is inseparable from the remaining constituents of the respective compounds. Hence the distinction between the two classes of amic and ammon-amic platinum compounds, the latter differing from the former by an actual addition of diad ammonia, much as ethylic differ from methylic compounds by a virtual addition of diad methylen. The parallelism is indicated in the under-written formulæ for methylic chloride and ethylic chloride, sal-ammoniac and ammonio-chloride of silver, respectively—

$$H_2CHCl \qquad \left.\begin{matrix} H_2C \\ H_2C \end{matrix}\right\} \begin{matrix} H \\ Cl \end{matrix} \quad \Bigg| \quad H_2N.HCl \qquad \left.\begin{matrix} H_3N \\ H_3N \end{matrix}\right\} \begin{matrix} Ag \\ Cl \end{matrix}$$

The group of platin-ammonia compounds is thus divisible into the two classes of platinous and platinic, and each of these again into the two classes of amic and ammon-amic compounds. To these four classes must yet be added a fifth subclass of di-platinic compounds, including the nitrate-chloride of Raewsky, and the subsequently-discovered nitrate of Gerhardt and chloride of Hadow. The scheme of the constitution of the entire group, in accordance with the writer's views, is exhibited in the accompanying table of the principal chloride, hydrate, nitrate, and nitrite compounds.

Platinum Bases and Salts (proposed scheme).

Platosamine.

Law Proceedings.

THE BETTS SUITS.

Vice-Chancellor James's Court, 28*th June*, 1870.

Betts *v.* Willmott, Betts *v.* Potts, *v.* Cleaver, *v.* Field, *v.* Brooks, *v.* Foster, *v.* Pratt, *v.* Stevenson, *v.* Smith, *v.* Hall, *v.* Hart, *v.* Ellis, *v.* Warin, *v.* Cooper, and *v.* Preston.

The suits were, in 1865, commenced against customers of Mr. Rimmel, and they now came on for hearing.

Mr. Willcock, Q.C., and Mr. Everitt appeared for the plaintiff, and Mr. Kay, Q.C., Mr. Eddis, Q.C., and Mr. Langley, for the defendant in each case.

Mr. Willcock, Q.C., opened the plaintiff's case, and was followed by Mr. Everitt, relying upon purchases of one bottle from each defendant, each bottle bearing Mr. Rimmel's labels and a capsule impressed "E. Rimmel, London and Paris, Perfumer," within a bead border.

The Vice-Chancellor, at the close of the plaintiff's case, said,—

In this case the plaintiff, Mr. Betts, has filed his bill against Mr. Willmott, asking an injunction to restrain the defendant from further infringing his invention, from using his invention in this country, and for the consequential damages. It is said, and said with truth, that according to the practice of this Court the *scienter* is not material, that a patentee has a right to file his bill against a person who has innocently infringed his patent, that he is entitled to take legal proceedings at all events. But I am not prepared to hold that every user of letters patent by a person necessarily entitles the patentee not to bring an action in the County Court, but to file his bill in this Court. I think one must look at the circumstances under which, and the extent to which the infringement has taken place, and the conduct of the plaintiff and de endant, before one sanctions such a bill. If it is to be carried to the strict length, it seems impossible to draw a line which would prevent a man being entitled to file his bill against every gentleman who, in this particular case for instance, has a bottle of wine accidentally covered with a capsule in his cellar; I think there is a difference between that case and the case of a person selling articles for profit. If this had been the case of a sale of these capsules for profit, it would have been a different thing, because, in that case, the person would have been selling the metal, and I should have been disposed to interfere, or if the person were using the capsules to a large extent himself.

But I understand all the evidence here is, that a person in the employ of the plaintiff went into the shop of the defendant, and bought there a bottle of a manufactured article, called Rimmel's Toilet Vinegar, the cork of which bottle was covered with a capsule. He bought only one bottle with a capsule on. The probability is, that the defendant had sold other bottles, perhaps he had sold a few dozen bottles in the course of his trade; but he says he had not the remotest idea he was doing anything in violation of the plaintiff's patent; that he bought this in the way of trade from the wholesale dealer, and sold it perfectly innocently; and the plaintiff was informed by the article itself who the person was from whom this innocent vendor obtained it. Under those circumstances, it appears to me, he ought to have given the defendant notice that it was an infringement, and told him not to do so any more; and if he found he was doing it afterwards, he might very well have filed his bill against him, or if the defendant had refused to discover from whom he bought the article. But, no doubt, this defendant would at once have told him, "I got this from Mr. Rimmel; and if Mr. Rimmel is wrong, I will not sell any more, I do not wish to run the risk of a Chancery suit with Mr. Betts." Probably that would have been the case if he had applied to him. But the application he received was this, which does not seem to me to be the right way of dealing with a case of this kind. He says, "I received from Mr. Kent, the plaintiff's solicitor, a letter dated 10th July, stating that he was instructed by the plaintiff to commence proceedings against me for an infringement of his letters patent, by the use and sale of metallic capsules on bottles, which capsules had not been made by the plaintiff, but of precisely similar materials." To which defendant writes:—"I have received a letter from you informing me that I have infringed the patent of Betts' Metallic Capsules. Now, as I have never capsuled, or caused to be capsuled, any bottle or pot in my establishment, perhaps you will have the goodness to let me know in what way I have infringed the patent." To which the answer is:—"I beg to state that the sale by you of the capsules on bottles is the infringement complained of. Any person supplying you is equally liable, and the time will come when you will be interrogated as to who has supplied you, when, and in what quantities." Thereupon, without any further intimations, upon the same 12th of July, on which that answer is made, the bill is served on this defendant. It does appear to me that that was a very violent and oppressive mode of proceeding against this defendant and the others. It is not justified by this observation that, unless you file bills against every retail dealer, you cannot maintain your patent. I do not know whether I should have been able to dismiss the bill with costs, though I think I should have tried to do so, if it had not been for what appears an equally unusual course on the part of the defendant,—instead of saying, "I really did it innocently; I do not wish to litigate your patent;" instead of relying entirely on the facts of the case, the defendant puts in an answer, in which he submits whether the patent is a good one or not. Relying on what he then supposed to be the then state of the law, he takes upon himself to litigate the thing, by raising upon a concise statement, which is almost a cross bill, the very fact of the invalidity of the patent, and he files that statement, and bases interrogatories upon it.

Under those circumstances, it appears to me that neither side has conducted himself in a way which entitles him to the costs of these proceedings; and the order I propose to make is, to declare that the patent having expired, and the Court being satisfied that the infringement by the defendant was innocent, accidental, and trivial, and not such as to have produced any substantial damage to the plaintiff, stay all further proceedings.

Mr. Kay.—Your Honour has not heard our evidence. We have proved distinctly there is no infringement.

The Vice-Chancellor.—Do you mean to say that this capsule is not made according to Betts' patent?

Mr. Kay.—Certainly; there is no evidence of it.

The Vice-Chancellor.—I think there is, unless you have strong affirmative proof that it is not.

Mr. Kay.—We have cross-examined him, and put the article into his hands, and he cannot say whether it is his or not.

The Vice-Chancellor.—He said he could not tell without a microscope.

Mr. Kay.—No; he could not tell at all.

The Vice-Chancellor.—Did you put the capsule into his hand which was bought?

Mr. Eddis.—Yes.

The Vice-Chancellor.—Was there any mark upon it?

Mr. Kay.—There was no mark upon it at all.

The Vice-Chancellor.—Is there the microscopical mark upon it? He swears distinctly it is not his metal, but made of the same material.

Mr. Kay.—If your Honour had heard the cross-examination, you would find it perfectly impossible to maintain any case of infringement. He does not know his own material, and he cannot distinguish between one made by him and anybody else, and he says there is no process which he knows of to enable him to distinguish the things made by him from those made by anybody else. The whole of his evidence has gone to an attempt to make out a case of infringement, which has failed *in toto.*

The Vice-Chancellor.—I did not know you denied the infringement.

Mr. Kay.—Yes, and I am perfectly ready to open the whole case to your Honour, rather than be saddled with our costs of this suit.

The Vice-Chancellor.—I think you must.

Mr. Kay then proceeded to read the plaintiff's cross-examination, but he had only in part done so when the Court rose. It contained passages—

"I have a manufactory in Paris, that is Espinasse's."

"I believe the Paris house supplied Rimmel with a great many capsules at one time."

"I will not swear whether the capsules supplied to

Eugene Rimmel by the house of Espinasse in Paris, either before or after I purchased the business, bore this inscription, 'E. Rimmel, London and Paris, Perfumer;' I may have sworn they did on some former occasion, and if so, it is true."

"I will not swear that each of the capsules on the 11 Exhibits, and on those numbered 211 and 401, was not made by my house of Espinasse, or that they were not sold and delivered by that house to Eugene Rimmel."

Question. In clause 5 of the affidavit of Sandford and another, filed the 18th of January, 1869, in this suit, it is stated that you told them "to the purport that you had been put to a great expense, £20,000, with regard to your patent, and must be reimbursed," whether or not is that true?

Answer. I have no recollection of having had any conversation with Mr. Sandford in particular. I met, I believe, a person of that name amongst others at the Pharmaceutical Society, when I do not believe the words £20,000 ever came out of my mouth. It would be more like at that time, with interest and compound interest, beyond £30,000; and I do not think I ever mentioned such a thing as £20,000. What transpired there I have given an account of in one of my affidavits. It is not true that I then stated, as is mentioned in the fifth paragraph of that affidavit, "that I would sue every retailer in the country who had sold articles capsuled until I had got that sum of money." I told him, and I told them all together as the pharmaceutical synod, that with their vast numbers, their names being legion, a pound a-piece from each would put me straight in the matter; and if the numbers were few, five pounds a-piece would make an atonement for all that had passed, namely, ten years' infringement that had been going on. The reply was that they had no money, and, if that is what you mean, it will be war to the knife. I know the difference between the Pharmaceutical Society and the Defence Committee. One grew out of the other. I did not insist on a payment by the Pharmaceutical Society or its members further than as my bills were filed against any member of that society.

Question. Did you not insist on a contract by the Pharmaceutical Society?

Answer. There were negotiations for peace after this interview, and there were plans suggested for an amicable arrangement of the matters by the Pharmaceutical Society insisting on the foreign merchants who had infringed and were importing their goods into this country dealing with me thenceforward. Certain terms were proposed by me to the Pharmaceutical Society and the Defence Committee, but they were not accepted.

Question. Did not the Pharmaceutical Society as a society always refuse to identify itself with this matter?

Answer. Certainly not. They advanced to me and pleaded guilty to the infringement of my patent from one end of England to the other. I believe that Mr. Rimmel, in my mind, appeared to be the cause of that meeting.

Question. Are you certain that you did not name £25 to any person as the amount to be paid by each?

Answer. I may have said that after they had paid £5 as a penalty to me, the taxed costs of the bill which was filed against them would come to somewhere about £15 or more, and I believe that was about the amount. I think those were the terms on which many were settled with. I thought I must fine them at least £5, so that they might tell the world that they had been so fined, and then it rested between them and my lawyer. I believe I told the people at the Pharmaceutical Society that I could not declare my rights without going at once to that expense of a bill to assert my rights, and therefore I said I could not assert them but at that cost to the one or other of us. I do not recollect whether I named the sum of £25 to be paid to me. I do not recollect whether I said that I had expended £36,000 in costs. I think I said over £30,000, but I did not in words say that I was resolved on being reimbursed. I said there must be something solid, something to eat.

Other material passages appeared in the course of the proceedings.

29th June, 1870.

At the sitting of the Court, the Vice-Chancellor said,—In this case, Mr. Kay, is there any evidence of the infringement except that of Mr. Betts himself?

Mr. Kay.—None, Sir, except the sort of corroborative evidence given in the same words by some of his servants. Mr. Betts himself says in his first affidavit that he firmly believes the capsules are made in infringement of his patent.

The Vice-Chancellor.—There is nothing about capsules in the patent. Where is the evidence that they were not made of metal bought of his Paris house?

Mr. Kay.—None.

The Vice-Chancellor.—What is the evidence of the infringement? What Mr. Betts verily believes is nothing.

Mr. Kay.—And what he says as to it is quite consistent with the fact that they were obtained from himself.

The Vice-Chancellor.—What evidence is there that these capsules are not made of lead purchased from Mr. Betts?

Mr. Willcock.—There is some evidence which my friend has not read. With reference to the actual houses at which it is suggested it may have been bought, we can only give negative evidence as to that. If they had chosen to call Mr. Rimmel, we might have cross-examined him.

The Vice-Chancellor.—What evidence have you given?

Mr. Willcock.—Your Honour will find it at page 7 of the depositions:—"Will you pledge your oath whether those capsules were or not manufactured by your house of Espinasse? *A.* I believe they are infringements, and that they are not of the house of Espinasse. I found this my belief on this, that Rimmel's dies in Paris do not correspond, as I have been informed, with the stamping on those, but I will not swear that they do not correspond exactly. I do not know whether it is the fact that Dupré's capsules supplied to Rimmel bore Dupré's name upon them. The Exhibit now produced and marked W. B. 24, appears to bear a Dupré capsule. It is a tin capsule, and Dupré puts his name on the tin capsules, but not on those made of the patent metal. I do not know whether every die used by Dupré for Rimmel's capsules contained in the inner circle the words 'Paris and London,' or '39, Gerrard Street, London.' It is not known to me that every capsule made by my house of Espinasse for Rimmel bore a bead border. It is not known to me that every Courdouzy capsule supplied to Rimmel bore a rope border. I will not swear that each of the capsules on the 11 Exhibits, and on those numbered 211 and 401, was not made by my house of Espinasse, or that they were not sold and delivered by that house to Eugene Rimmel."

The Vice-Chancellor.—That is not the way to prove infringement. You do not even pledge your belief that they are not made of metal bought from you.

Mr. Willcock.—We do not sell the metals.

The Vice-Chancellor.—It would be monstrous if everybody found with a bottle of this kind were to be considered an infringer. If these bills had been filed at the commencement of the patent, no one would have bought a single capsule. I should have taken the greatest possible care not to do it. I should have said, I am not going to be drawn into a Chancery suit by buying one of these things. Have you any other evidence of the infringement?

Mr. Willcock.—The plaintiff also says, "In answer to the 4th paragraph of the defendant's affidavit, I say that the capsule on the bottle purchased at his shop, as stated in my former affidavit, was not made by me."

The Vice-Chancellor.—It might be perfectly true that the capsules were not made by him. Your patent is not for capsules, but for metal.

Mr. Willcock.—We say we did not sell it.

The Vice-Chancellor.—I see evidence that you did not make the capsules, but I do not see a statement that it was not made of your material.

Mr. Willcock.—We do not sell the material to anybody.

The Vice-Chancellor.—There is no evidence of that fact. I have not seen a particle of evidence of the fact that you do not sell, or that your agents in Paris do not sell, the materials, or that the man at Bordeaux does not sell it.

Mr. Willcock.—I wish to suppose that your Honour is not satisfied of that, and that is why I was going to the other question, because that raises the point which I wished to call your Honour's attention to. The question is put to Mr. Betts, "When you say in your affidavit of April, 1869, that the capsules were not made by you, do you mean to swear that they were not made by your French house of Espinasse?" *A.* I hold that those made by my French house are not made by me as regards England most assuredly. *Q.* Suppose capsules were made at your manufactory at Bordeaux, should you swear that they were not made by you? *A.* Decidedly, in the sense in which I understand it. Unless they are of a certain kind, they have no business to come into this country, and hence would be ignored by me, and so with my Paris or any other house abroad. I explain it in this way. Betts as a manufacturer in France is a Frenchman. I sell capsules there to be used upon bottles, and such capsules may come into this country, but no capsules off bottles of any kind should I make or tolerate to come into England, to have one set against another. There is Betts, an Englishman, and there is Betts, a Frenchman, the one with English rights, and the other with French rights. Those which may come into England are those which bear my patent trade-mark, and my legend round it, and these must come on bottles. The Betts to whom I allude is myself." It is an odd way of putting it very likely, but, at the same time it stands thus. In France his right as a patentee had expired. He manufactures in France, but then what he manufactures in France and sells, the buyer has no right to bring into England. In England he is protected against the infringement.

The Vice-Chancellor.—If I buy from him in France, surely he cannot say that I have no right to bring them into England? Do you mean to say an English patentee can establish a manufacture abroad, and then say that the person to whom he sells cannot introduce the goods into this country?

Mr. Eddis.—If your Honour looks at the next paragraph, you will see these words, "When you have spoken of foreign manufactures, have you included in that phrase yourself as a Frenchman?" *A.* "Yes, in the sense in which I used it."

Mr Willcock.—I submit to your Honour that that evidence is sufficient to establish our case.

The Vice-Chancellor.—I have read the depositions carefully through, and I must say this case seems to me about the most impudent case that ever came into Court. A man says you have infringed my patent. I did not make the capsules which you sell; I am quite sure of that; they were made by foreign manufacture. Then he is asked, Do you include in the term "foreign manufacture" the goods made by your agents abroad? and he says, "I do." I am glad my attention was called to this, because it seems to me monstrous for a man to act in this way. I must say it is not creditable to the plaintiff, when he swears in his affidavit that these goods were not made by him, to divide himself into an Englishman and a Frenchman, and to say that he meant that these goods were not made by him in his English capacity, but that they were made by him in his foreign capacity. I dismiss the bill with costs.

Mr. Eddis.—That will apply to all the suits?

The Vice-Chancellor.—Yes. I am shocked at such a mode of making an affidavit; I hope never to see it again. Each bill is dismissed with costs.

Chapters for Students.

LIGHT.

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

1. Light is an agent which is, in many respects, analogous to heat, but there are one or two important differences between them. For example, heat passes through bodies by conduction, and is carried from place to place by convection as well as by radiation; light is known only in the radiant state.

2. Objects are visible only under two conditions:—*a*, when they are self-luminous, that is, when they generate light; or, *b*, when they receive light from some source, and throw it off again (reflect it) in such a way that at least some part of it strikes upon the nervous apparatus of the eye.

3. Bodies may be arranged in a rough way into three classes, according as they permit light to pass through them or not.

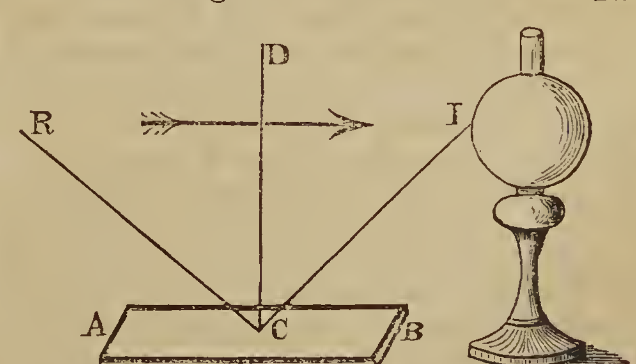
Transparent bodies, such as ordinary window-glass, are those which transmit light without sensibly scattering it. Objects are, therefore, visible through such media without alteration of outline.

Translucent bodies, for example, ground glass or fog, scatter the light which passes through them in such a way that the outlines of objects seen through them are confused or even obliterated.

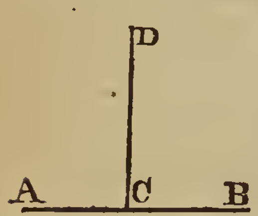
Opaque bodies are those which stop and absorb or reflect all the light which falls upon them.

There is no such thing as perfect transparency, for even air and white glass stop a part of the light incident upon them, and there is probably also no such thing as perfect opacity, for even metals, when they can be beaten thin enough, transmit a little light.

4. When a ray of light falls on a perfectly smooth surface, the whole or part of it is rejected, and it takes a new course, which is inclined at an angle to its former course. This is reflection. The law by which the direction of the reflected ray is regulated is expressed usually thus:—"The angle of incidence is equal to the angle of reflection." Suppose A B



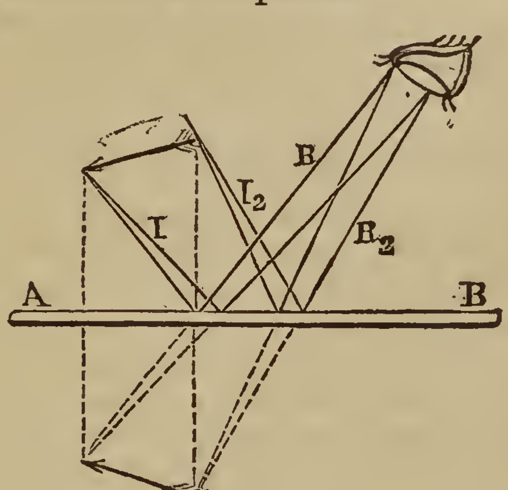
to represent the surface of a flat mirror; I, a ray coming through a small hole in the shade of the lamp, and "falling upon" the surface of the mirror, may be called the incident ray; R, the course into which it is "bent back," is the position of the reflected ray. If now a line, real or imaginary, be drawn to the surface of the mirror at the point C, the law tells us that the incident ray, I, will always form with C D the same angle that R forms with C D. And the three lines, I, C D, and R, will always be in the same plane; that is, if three rods attached to a board in the position of the lines in the figure, were used as a model, and the eye of the experimenter looked in the direction of the arrow, he would see the three coincident and appear as one.



In an experiment with a mirror he would see from this point a spot of light on looking down R, and in the direction of the arrow, he would see the hole in the lamp-shade. It will, of course, be understood, that the number of rays proceeding from the lamp are infinitely numerous. In a diagram, the course taken by one only of them can be shown with distinctness. But all of those which fall upon the mirror are reflected from their various points of incidence, according to the same law.

5. In the preceding experiment the spot of light would appear to proceed from behind the mirror. This is also the case with images of persons or things seen in ordinary looking-glasses. As a general rule, an object appears to be in the direction from which the rays which meet the eye last proceeded.

The experiment described makes use of a ray proceeding from a luminous point. The *image* of an object is the result of the association together of an infinite multitude of such points.



Suppose A B the surface of a mirror. The lines I and I_2 represent the paths of rays falling from the extremities of the arrow upon the reflecting surface. Between them there should be an infinite number of similar rays proceeding from the intermediate points. R and R_2 are the paths of the two rays represented after reflection. The arrow, therefore, seems to be in the position shown by the dotted lines, which are a continuation of R and R_2, and it appears to be at the same distance behind the reflecting surface that it is in reality in front.

In this diagram, again, it has been possible to represent only those rays which, after reflection, meet the eye. From every point of the object, however, it will be understood that rays proceed in every direction; those which are thrown downwards fall on the mirror and are reflected, and of these only a certain number, viz. those whose paths of reflection lie between R and R_2, are received in the eye.

6. Ordinary objects are visible from almost any position the experimenter may take up; the reason is, that the rays of light thrown off from objects in general are distributed in an infinite number of directions, owing to the irregularity of their surfaces. A beam of light entering through the shutter of a darkened room, and falling upon a sheet of paper, will do more to illuminate the room than if it fell upon a mirror. In the latter case, the light will be reflected in one beam, and will afford only one bright spot, instead of being distributed in all directions.

Reviews.

Manual of Qualitative Analysis. By Robert Galloway, F.C.S., Professor of Applied Chemistry in the Royal College of Science for Ireland. Churchill and Sons. 1870. Fifth Edition.

The title page of the volume before us informs us that we are presented with a fifth edition. This fact implies one or both of two things: either there is an extraordinary demand for treatises on qualitative analysis, or Professor Galloway's book is better done than others of its class.

Whilst we most willingly accord to the author of this work the large measure of praise which he undoubtedly deserves, we cannot withhold, at the same time, our opinion, that there is yet room for a good manual of qualitative analysis; we might say for two good manuals, for we should like to see every one of those already existing submitted to a process of sifting. For beginners we ought to have displayed all the most important principles deduced from just so many familiar facts as would serve to establish them in the mind of an intelligent school-boy or girl; they would then be in a position fairly to attack the subject as it is presented to them in the ordinary handbooks. When a child is first regularly instructed in writing or drawing he goes through a course of "pothooks and hangers," which, if they have no substantive value of their own, familiarize him with the nature of the work he has before him, and the tools he has to use; but in science, as generally taught, the unlucky juvenile is plunged, heels over head, into the waters of technicality, the shallows or the deeps of which he will be equally lucky if he escape. As an experiment, we should like to see some one subject, say botany, taught by the guidance of a gradational series of lesson books, similar in general principle to ordinary school "copy-books."

Professor Galloway has already made an attempt at something of this kind in his 'First Step' and 'Second Step' in chemistry, but we wish we could think he had done so with absolute success. His 'Qualitative Analysis,' which we have just most carefully examined, has given us the impression, however, that he has considerably improved with his experience in writing, and particularly in arranging. If he would now let the present volume stand as a *second* step, and would take the trouble to compile another about one-third of the size, and, not disdaining small matters, make it really suited to beginners, he would deserve the thanks of all chemical teachers.

Chemical analysis is an art; its success depends, in greatest measure, upon the judicious selection of the devices by which the characteristic properties of bodies are brought most prominently into view. One defect of the work before us is, that it fails to stamp with sufficient distinctness the diagnostic marks of each radicle and group of radicles. Unimportant properties and reactions are made as much of, except in the tables, as the most distinctive, and consequently the student finds none of those salient points to grasp at which ought to be ready to his hand. We feel bound to say, however, that there is evidence of very careful work. There are throughout, so far as we have been enabled to detect, no statements which are fundamentally incorrect.

We like the tables for contrasting the characters of the members of the several groups of basylous radicles, though we demur to the author's appropriation of all the credit due to the plan, for we find the same thing in a slightly different form in many other books.

There seems to have been great pains taken to give the latest information, and no process of importance is omitted.

Part II., devoted to the consideration of organic substances, contains a great deal of useful matter, which is generally rather shirked by writers on analysis.

Part III. includes a description of the common operations, solution, filtration, and the like, an account of Bunsen's flame reactions, and an enumeration of the reagents commonly required. Altogether, we have the groundwork of a very excellent guide for the student. If the author in the sixth edition, which he is pretty certain to reach, would consent to the excision of a considerable amount of matter, not incorrect, but foreign to the subject in hand; if he would carefully purify his pages of a number of trifling erudities and inaccuracies; and, lastly, by putting in a few good strong dashes of light and shade, make it less like a young lady's water-colour drawing, one tint all over,—he would bring his 'Manual' to a position of completeness and solid usefulness which would bid fair to double its already large circulation, and make it the leading text-book in our schools.

Index to the Native and Scientific Names of Indian and other Eastern Economic Plants and Products: prepared under the authority of the Secretary of State for India, by J. Forbes Watson, M.A., M.D., F.L.S., etc., Reporter on the Products of India. London: India Museum. 1868. Royal 8vo. Pp. viii., 637.

Though somewhat late, we now proceed to notice the above work, the publication of which we announced some time ago.

The trade which this country enjoys with India is so great in extent and in the variety of its articles, that such a book of reference as the above will be warmly welcomed by all connected therewith. To the economic botanist it will prove a valuable aid in the determination of the many new or rare products which from time to time find their way into the English markets.

These vernacular names are compiled from various publications on the botany, Materia Medica, and products of the East. Upwards of one hundred works, beside much manuscript matter, have been waded through to produce the present Index.

The work does not lay claim to be anything but a compilation. No critical examination of the orthography or correct bestowal of the names has been attempted; they are simply quoted as given by the authors from whose works they are taken.

Besides being a useful index, the book contains an immense amount of information. After the name, the language from which it is derived, and the plant to which it is applied, we have references to works where the word occurs and where information can be obtained respecting the substance; thus, under the various spellings of the fruit of *Ægle Marmelos*, as Bael, Bel, Bele, Beli, etc., we counted no less than seventeen references.

What we should very much like to see, would be a companion volume to the present one (and from the preface we are led to expect another), in which, under the botanical name, the various vernacular names are arranged, and concerning which the locality where used, synonymy, whether pure or introduced, derivation and meaning, whether collective or individual names, and whether applied to the plant as a whole or to its parts or products, would be stated.

In addition to the correct orthography of the name being given, they could be spelt as pronounced, according to Mr. Ellis's 'Glossic System,' which the English Dialect Society propose following in their 'Dictionary.' Of course this would entail much critical labour, but, with the resources at the command of the Indian Government, could undoubtedly be done; and such an Index, provided with copious references to works where the words occur, would be an immense boon to all scientific and commercial men, besides being of great philological value and interest. We say this not in any disparagement of the present work, but having felt the value of this, we long for a second, such as we describe, and which we are sure would meet with great success.

BOOKS RECEIVED.

The Unity of Medicine; its Corruptions and Divisions by Law Established in England and Wales, their Causes, Effects, and Remedy. By Frederick Davies, M.D., etc. etc. Second Edition, revised and extended to Ireland and Scotland. London: John Churchill and Sons, New Burlington Street. 8vo, pp. 302. 1870.

The Half-Yearly Abstract of the Medical Sciences. Edited by William Dornett Stone, M.D., etc. Vol. LI. January–June, 1870. London: John Churchill and Sons, New Burlington Street. 1870.

Philadelphia College of Pharmacy.—At a meeting of the College on the 27th of December last, the following gentlemen were elected corresponding members of the College:—Prof. John Attfield, London; Henry B. Brady, Newcastle-on-Tyne; John Abraham, Liverpool; T. B. Groves, Weymouth; C. R. C. Tichborne, Dublin; F. Crace Calvert, Manchester; John Mackay, Edinburgh; W. W. Stoddart, Bristol; J. C. Brough, London.

Society of Pharmacy, Paris.—We observe that Prof. Attfield and Mr. J. Collins have been elected corresponding members of this Society.

Suffocation by Carbonic Acid Gas.—An inquest has been held on the bodies of four men, John Smith, Edward Jones, Samuel Hassall, and Thomas Bedson, who were suffocated in a tube used to convey waste gas from the blast furnace to heat the furnace boilers at the North Staffordshire Coal and Iron Company's works at Talke. This waste gas, which is very light, is conveyed in a pipe 150 feet long by 4 ft. 6 in. diameter. It appears from the evidence that the works had been stopped for the purpose of cleaning the tube, and effecting some slight repairs, and Smith, the manager, with his assistants, Jones and Hassall, went to see to it. Shortly afterwards they were missed from the premises, and Bedson, in his search, entered the tube, where he also fell a victim to the gas. Attached to this tube is a large air-tube used to supply fresh air; and it seems that Smith, in his anxiety to get the repairs done, had omitted to take the precaution of clearing the tube of the gas.

Dr. A. Greatorex deposed that the cause of death was poisoning by carbonic acid gas, and the jury returned a verdict accordingly.

Dr. Percy, of the Royal School of Mines, in a letter to the 'Times,' referring to this lamentable accident, states that the poisonous ingredient of this so-called "waste gas from the blast furnaces" is carbonic oxide, the inhalation of which, whether pure or mixed with common air, rapidly destroys life. He observes that as the use of this "waste gas" for heating steam boilers is extending daily, it is important that managers of such works should be acquainted with its highly poisonous nature, and take every precaution to prevent their workmen from being exposed to its influence.

Ice.—The following singular formation of ice is recorded in the 'Central India Times,' as occurring in the Chanda district, at the village of Warrora. On the 23rd of February last, when an endeavour was made to empty a reservoir connected with a tank at that place, by opening the drainage pipe, it was found that the water would not flow. To ascertain the cause, the tank was pumped dry, when it was found that a solid mass of ice, some three feet in length, had been formed, completely choking the mouth of the pipe. When removed, it appeared opaque, somewhat similar to machine-made ice. The soil under which this phenomenon occurred is the common black loam of the Deccan (cotton soil), the piping of ordinary potter's clay, cemented at the joints with a composition of lime, linseed oil, and cotton, pounded up together, and the protecting masonry of the indigenous sandstone and mortar. The water in the reservoir and pipe had remained perfectly still for about six months previously, the pipe having been closed during that period. It is scarcely necessary to say, that the temperature at Warrora never at any time even approached freezing-point.

The Riga Pine.—M. Keller, of Darmstadt, writing in 'Cosmos,' says, that what is known outside Russia as the Riga Pine, and which has been praised for its specially good qualities, is unknown by any distinctive appellation at Riga, and is, in fact, nothing more than the ordinary *Pinus sylvestris.—Athenæum.*

The Treatment of Smallpox. — At one of the meetings of the "Vaccine Congress," in Paris, M. Jaffin brought forward not only a *specific* for smallpox, but one which he "has always found successful in every description of epidemic disease"! The remedy consists of a gramme of quinine dissolved in 120 grammes of an opiated vehicle, of which a tablespoonful is to be taken every two hours.

Obituary.

On the 27th of May, at Great Marlow, Mr. Robert Foottit, chemist.

On the 24th ult., at Shepherd's Bush, Mr. William John Beaton, son of Mr. John Beaton, of Kilburn, one of the founders of the Pharmaceutical Society.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the Editor, 17, *Bloomsbury Square.*

Betts's Suits.

Dear Sir,—I feel that I am only fulfilling my duty by at once returning my most sincere thanks to yourself and those kind friends who rallied round me with their advice and pecuniary assistance during the many years the suits 'Betts *v.* Willmott and others" have been going on.

I would at the same time congratulate the trade on the satisfactory termination of those suits as announced in your last issue.

I am, your obedient servant,
William T. Cooper,
Chairman of the Betts Defence Committee.

26, *Oxford Street, W., July 5th,* 1870.

Regulations for Storing Poisons.

Sir,—Now that the battle of the Regulations has been fought, and the danger of having vexatious restrictions imposed on our dealings with a large number of articles being over for the present,—it may be well to consider our future action in the matter. The subject has assumed an altered aspect since the Annual Meeting, for it now appears that the Privy Council, and not the Pharmaceutical Council, were the active parties in the scheme; and as it seems they require the adoption of *some* legal regulations for the keeping of poisons (the necessity for which I by no means admit), the opponents of the former proposals may perhaps be expected to assist in the endeavour to devise some plan that shall be practicable, and more likely to meet with general adoption. Not that I fear more onerous burdens being imposed on us without our consent; we have defeated "Poison Bills" before, and can do so again if need be, but perhaps it may be possible to discover some plan that shall effect all that is desired and satisfy the Government, without interfering too much with the arrangements of our shops or the requirements of our trade; and if the matter be well discussed in your columns, a more acceptable scheme may doubtless be arrived at before the next Annual Meeting.

It may, perhaps, assist in the discussion if the "Poison Schedule" be given *in extenso*, so that people may see what it really contains; and the following, I believe, will be found to comprise nearly, if not quite, every article that may fairly be included in the list:—

List of Poisons within the Meaning of the Act.

PART I.

Arsenic, Alb.	Morphiæ Acet.
„ Sulph. Flav.	„ Hydrochlor.
„ „ Rub.	„ Mecon.
Ferri Arsenias.	„ Sulph.
Liq. Arsenicalis.	Nicotine.
„ Arsen. Hydrochl.	Strychnia.
„ Arsen. et Hyd. (Donov.)	„ Liquor.
Scheele's Green.	Veratria.
Sodæ Arsen.	Cantharides.
„ „ Liquor.	Corrosive Sublimate.
Aconit. Extr.	Cyanide of Mercury.
„ Folia.	„ Potassium.
„ Linim.	„ Silver.
„ Rad.	„ Sodium.
„ Tinct.	„ Zinc.
„ „ Fleming's.	„ Potass. Solut.
Aconitia.	Emetic Tartar.
Atropia.	Ergota.
„ Liq.	„ Ext. Liquid.
„ Sulph.	„ Infus.
„ „ Liq.	„ Tinctura.
„ Unguent.	„ Liq. Secale Corn.
Brucia.	Prussic Acid, B. P.
Codeia.	„ „ Scheele's.
Conia.	Savin.
Digitalin.	„ Oil of.
Morphia.	

Fifty-three articles.

PART II.

Almond, Ess. Oil of.	Opii Extr. Liquid.
Belladonnæ Extr.	Linim. Opii.
„ Fol.	Liq. Opii Sed.
„ Linim.	Nepenthe.
„ Rad.	Pil. Ipec. c. Scill.
„ Tinct.	„ Plumbi c. Opio.
Canthar. Acet.	„ Saponis Co.
„ Liq. Epispast.	Pulv. Ipec. Co.
„ Tinct.	„ Kino Co.
Chloroform.	„ Opii Co.
Hyd. Bichlor. Liquor.	Tinct. Opii.
„ Lotio Flav.	Vinum Opii.
Morph. Acet. Liq.	Poppies, Ext. of.
„ Hydrochl. Liq.	„ Syrup of.
„ Mecon. Liq.	Oxalic Acid.
Opium.	Precipitate, Red.
„ Pulv.	„ White.
„ Extr.	Vermin Killers innumerable.

Thirty-six articles.

Being a total of 89 articles affected by the Pharmacy Act.

Now one of the chief objections to the late proposed "Regulations" was their application to every article in the above list, and it was felt not only to be impracticable to apply such stringent restrictions to so great a number of articles, but contrary to common sense to require the same rule to be adopted with articles differing so widely in their potency as they do.

A poison-closet, to be any element of safety, must be confined to a very limited number of the most powerful and dangerous articles. A cautious chemist would hardly like to put tartar emetic or morphia in the same cupboard with aconitia or strychnia, but would rather keep them as far apart as possible. Besides, it is nonsense to talk of shutting up such articles as cantharides, or ergot, or opium, or savin, or aconite, or belladonna, and many others, or even red precipitate or sublimate, in a poison-closet,—there is scarcely any one of these that could possibly be mistaken for anything else, except by the grossest carelessness or ignorance: and as to the idea that any one would attach a peculiar sanctity to such a poison-closet, or approach its doors with fear and reverence, we may be very certain that when he knows perfectly well that four-fifths of the articles contained in it can hardly be called either dangerous or deadly, the poison-closet would soon be considered of no more importance than any other part of the shop.

The same reasons hold good in regard to labelling with the word "poison," and the use of angular or other fanciful bottles. The word "poison" put on bottles containing tartar emetic, Dover's powder, syrup of poppies, tinct. belladonna, and others of like nature, would convey no warning to the mind of the druggist, and might probably create unnecessary alarm in that of the customer, whilst the use of angular bottles for such articles as those, would destroy their value (*if they have any value*) as safeguards for more dangerous substances.

In short, by far too many and too widely differing articles were affected by the proposed regulations, and if we *must* have regulations on the subject, they should be confined to a few of the more deadly and dangerous poisons and their names specified, if they are to be of any service and receive general adoption.

I am, Sir, yours sincerely,
W. Wilkinson.

Cheetham Hill, June 20, 1870.

The Late Election of Council.

Sir,—It appears to me that the constitution of the Society, rather than the judgment of its members, has been at fault in the late election of Council. I agree with Mr. Ince in thinking that there is too great a proportion of the country element in the Council, and for the reason, and only for the reason stated by him; in other respects a better selection of men could hardly have been made. On looking over the new list when it first appeared, I thought we had done well, and it was on reading the much but unjustly complained of leader in the supplementary number of the Journal, that I became fully impressed with the importance of studying something more than the quality of the men in arranging the composition of the Council. I am not so thin-skinned as Mr. Proctor appears to be, and was thankful that our attention had been drawn to this subject by an article likely to be read and pondered over; not written in the namby-pamby milk-and-water style to which Mr. Proctor would limit the editor of our Journal. In reading the article in question, and the comments upon it which have since been published, I have been anxious to form an impartial judgment, although perhaps with some of the prejudices of a provincial; but I can see nothing in the article to call forth the severe animadversions which have emanated from Newcastle. The discussion which has taken place may, however, raise the question, whether a journal, such as ours has become, is a suitable organ of communication in a Society, the members of which may be strongly opposed to each other on points affecting or supposed to affect their trade interests. It surely implies no small commendation of the editorial management of the Journal since it has been the property of the Society, that now, for the first time in eleven years, the judgment and impartiality of the editor have been called in question, and only now, when his position and influence had been previously weakened. But the circumstances by which the Society is surrounded are undergoing a change, and judging from recent manifestations, it is hardly to be anticipated for the future that there shall be that unanimity in the Council, and freedom from party spirit among the great mass of the members, which have characterized the past. Under such conditions the Journal may become a source of weakness rather than strength, and it behoves us well to consider upon what principles it is to be conducted. Let the Society either confine itself to the publication of its transactions as other scientific Societies do, or if it determines to seek influence through journalism, let it invest the editorial function with such a balance of responsibility and freedom from undue control, as may be at once consistent with the interests of the body at large, and with the spirit of honourable independence so essential to the efficient performance of editorial duties. I hope never to see the Journal of our Society become "the mere tool of the Council." One of the objects of the Journal should be to promote the temperate discussion of questions appertaining to the management of the Society, and among other important points to the composition of its Council. That provincial interests should be fairly represented is admitted by all; nor will it be denied that there is a large number of members in the Provinces, and in London also, in every way fitted to take part in the deliberations of the Council, who have never yet had a seat there. It is not desirable that the office of councillor should be permanent, or that the metropolitan element in the governing body should be so weak as to interfere with the efficient performance of the work to be done. The question is, how are we to provide for the election from year to year of a Council in which all the requisite conditions are maintained, in which town and country are sufficiently represented, in which old blood and new are duly mixed, and opportunities afforded for rising talent to manifest its abilities at the Council-board? In other Societies it is customary to have these things regulated by the bye-laws, but in our Society there is an absence of any such regulation. The consequence of this has been that that which is not officially done has been undertaken by those who, dissatisfied with the old system of following the stars, and being at the same time desirous of a change in the Council and an infusion of new blood, have sought to accomplish this through the influence of circulars, and other methods of canvassing. Now is it possible that the government of the Society should be satisfactorily conducted in this way? If committees at Manchester and Leeds are to influence the election of Councillors, why not others throughout the country? And what would be the result of this? Why, that party spirit would be fostered, and members of Council would be seeking to satisfy the requirements of those through whose influence they were elected, instead of studying the interests of the body at large. I say, then, the constitution of the Society is at fault, and the proper remedy for the defect will be the adoption of a bye-law limiting the number of provincial members of Council to (say) not more than ten, and limiting the period during which a Councilman can continuously hold office to not more than five years, but admitting him to election again after the lapse of a year.

Provincialist.

An Age of Progress.

Sir,—Of the two parts into which Mr. Ince's letter of last week is divided, the first, which has reference to the publication of the proceedings of the Council, possesses by far the more enduring interest.

It is much to be regretted that a man of his standing should have thrown the weight of his influence into the scale against publicity, from which progress is inseparable; and I would ask him in all sincerity, to consider well whether his reasons are not of the same character as those that have always been advanced, to be always in the long-run overruled by the opponents of wholesome publicity—from the case of proceedings in Parliament down to those in metropolitan vestries, and Boards of Guardians. Indeed, the analogy between the positions of members of Parliament and members of Council is too obvious to be easily overlooked; and how ridiculous would be the position of a constituency proceeding to elect its members in total ignorance of their opinions, and without the means of learning them, either by canvass, by address, or by speeches in the House! Mr. Ince, dwelling, as one may say, in the vortex of pharmaceutical life, and personally acquainted with the leading members of the Society, can have but little difficulty in selecting his candidates, but I question much whether he has realized, or indeed can realize, the difficulties of individuals less favourably situated; and I assert, without much fear of contradiction, that for the majority of members, and with the exception of a few well-known names among the candidates, a mere rule of thumb, which should lead to the striking out of alternate names or of the redundancy at the end of the list, would usually give results equally satisfactory with those at present obtained.

As a point of etymology, Mr. Ince's definition of the word Council must no doubt be accepted as correct, but examples are not difficult to find, in which it obtains a wider meaning; indeed, Mr. Ince has at this moment a notable opportunity for earning the gratitude of the Pope, and lasting renown for himself, by suggesting the means for banishing *discussion* from the great Council of the Church now sitting at

Rome—to which, by the way, the word *consilium* more especially applies.

Mr. Ince puts forward three objections to publicity. First, that most of the proceedings are of a conversational nature. So, frequently, are those of the houses of Parliament when in Committee—not to speak of vestries and such-like, which are reported without difficulty every day; nor is it to be supposed that *verbatim* reports are required. Secondly, he is afraid of not being recognized as the father of his own offspring, from the circumstance that he has sometimes made a mouthpiece of another member. I reply that he has the remedy in his own hands, and can by no possibility be worse off in that respect than he is now. His simile of the signpost is a good one, but he would hardly wish to destroy such signs because *one* had sent him in a wrong direction. His third reason is even more unsatisfactory. Why the debates which occasionally arise must of necessity be of a personal nature I do not know, though I am bound to accept his statement; but of this I am certain, that if any member can so far forget himself as to make use of personalities, or make statements the publication of which will "sow an abundant harvest of ill-will, misunderstanding, and estrangement," it is highly desirable that he shall be known to the Society at large. Nor is a feeling of uncertainty as to who may next suffer under the tender mercies of the Council likely to make us less desirous of the safeguard of publicity, of the necessity for which Mr. Ince has now himself supplied us with conclusive proof.

Charles Eve.

Hampstead, July 4th, 1870.

Sir,—May I be allowed space for a few remarks on the "Age of Progress"?

In common with many others, I feel annoyed that every now and then the Journal of our Society should be made the medium for propagating strictures and remarks which are quite uncalled for, and reflect injuriously on large numbers of the Society's friends.

The members of the Society last month elected in the usual way a new Council. Immediately on this being done, there appeared in the Journal a somewhat extraordinary leader, commenting very freely on the matter, and hinting, in no indistinct manner, that the Society had done a very foolish thing in electing such a Council. The grammatical peculiarities of the leader sufficiently indicated its author, and Mr. Ince has since acknowledged it. Had it appeared at the end of the Journal among the "Correspondence," it would probably have been regarded as representing the opinion of an individual member, and have called forth no comment; but, appearing with the editorial sanction, it was looked on, and naturally so, as representing the opinions and feelings of those who conducted the Journal.

Now, Sir, comments of the kind contained in that leader could only have been excusable had they appeared at the end of the new Council's year of office, and after, on its part, twelve months of gross mismanagement and neglect of the interests of the Society. Coming as they did, at a time when neither Mr. Ince nor any one else could have had the slightest reason for judging it, or supposing that it would prove incompetent or indifferent, they must be considered to have been quite uncalled for, and to have had no ground, either in justice or good taste.

The present Council has been chosen by the Society in the regular way, and to prejudge its action, to condemn it before trial, is a proceeding quite without parallel. Imagine the Geographical and Geological Society electing its Council, and then allowing its principal journal to speak of that election as Mr. Ince has spoken of ours. Should the Council prove incompetent, the Society will be able, at the proper time and in the proper way, to intimate its disapproval, and take proper action with regard to it. It is not wise to jump to the conclusion that, because its members are scattered over the country, they will be unable properly to attend to their duties, and that, therefore, the Society has done a very foolish thing in electing them.

I am sure that others, as well as myself, have derived both instruction and pleasure from much that Mr. Ince has written, and I regret that he should ever employ a pen—so capable of benefiting the Society, and adorning the pages of the Journal—in writing articles that causelessly rouse hostile feeling, and tend to produce that discord which already constitutes our principal weakness.

York Town. A. H. Claypole.

Sir,—I hail with satisfaction the first weekly issue of the 'Pharmaceutical Journal,' and gladly accept as an omen of impartiality the juxtaposition of Mr. Proctor's and Mr. Ince's letters. It will astonish most of your readers to learn the authorship of "An Age of Progress," and the unsatisfactory explanation will but increase the surprise. Rightly or wrongly, I have been wont to attribute to Mr. Ince a remark I read some years since in recommending the study of French (in which I fully concur), that devotion would suffer little by an occasional attendance at a French service. But if "An Age of Progress" is an example of the effect of studying French, I imagine the advantage is more than doubtful: style will not be much improved, while moral tone will be certainly lowered. Possibly the recollection of the common French adage, "Qui s'excuse, s'accuse," would have prevented Mr. Ince's letter in your last; but, in recollection of many interesting and valuable contributions from the same pen, we shall be glad to forget this last infirmity.

I trust, Sir, that you will not insist, as one of your correspondents suggests, upon the name and address of every writer. Great names are wont to carry more influence than they merit at all times; while anonymous communications are more likely to be estimated at their intrinsic worth. "We want measures, not men." There are some subjects, too, to which it would be highly undesirable to subscribe one's name. Such a subject is the appointment of local secretaries. I have an ardent desire to see the secretaryship of my own neighbourhood more worthily filled; but I should be extremely sorry to offend a neighbour, who is very worthy in many respects, by indicating my name or residence, neither would I thus put myself forward as a candidate. We want men as local secretaries who are not merely the "fathers of the trade" in age, but who are comprehensive enough to study the interests of the trade at large, whether in or out of the Society,—men, who not only collect members' subscriptions, and make an annual appeal on behalf of the Benevolent Fund, but who are in harmony with the spirit of the times, and have at least some sympathy with the measures and objects of the Pharmaceutical Society. I regret the apathy of chemists in this matter. I thank "Quintus" for his suggestions, which I, for one, should be glad to see carried out, as well as many others that might be made.

I enclose my card, and am, Sir,

Yours truly,
Henricus.

July 5th, 1870.

A. W. (Lowestoft).—*Unguentum Sulphuris Hypochloridi Compositum.* The formula will be found in Vol. X., page 66; but, for the convenience of those who may not have the early volumes, we repeat it here.

℞. Sulphuris Hypochloridi ʒij
Potassæ Subcarbonatis gr. x
Adipis purificati ℥i
Ol. Amygd. Essent. ♏x. M. ft. unguentum.

B. N. (Northampton).—We are not acquainted with Startin's 'Treatise on Diseases of the Skin.' A course of lectures on 'Chronic Diseases of the Skin,' by Mr. Startin, were published in the 'Medical Times and Gazette,' vols. xiii. and xiv.

W. L. W. (Torquay).—We believe there is no such law.

H. S.—There is no such name registered in or near London.

I. T., *H. S.*, and *A Lover of Fair Play* have sent us communications on the "cutting" system adopted by some chemists, with lists of prices charged, from which we may quote the following:—Seidlitz powders, 1*d.* each; children's powders, 1*d.* each; castor oil, 2*d.* per ounce; blue pill and black draught, 4*d.*, etc.

Aspirant should apply to the Secretary of the Apothecaries' Company.

W. P. Parry (Hammersmith) thinks that chemists ought to meet and consider what steps should be taken to counteract the injurious effects produced by co-operative stores.

A. P. S.—An Associate who has passed the Modified Examination is not entitled to call himself "Pharmacist."

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W.*

THE CHEMISTRY OF THE ATMOSPHERE.

BY J. ALFRED WANKLYN.

A first glimpse at the minute but potent constituents of the atmosphere, is afforded by Dr. Angus Smith's reports under the Alkali Act passed in the year 1863. As is doubtless known to many of our readers, it is the business of the Government Inspector under this Act to take upon himself the office of Conservator of the Atmosphere in the manufacturing districts, and in the discharge of his duty the Inspector has had before him the task of distinguishing between polluted and non-polluted air. His results, especially those just published in the report for the year 1869,* appear to us to be of the highest interest.

That the air of a close room is different from the air of a well-ventilated room; that air indoors is different from air outside; that the air of a town is different from the air of the country, and that the air of one country-place is not quite the same as the air of another country-place,—all this is matter of common observation. But wherein these differences consist has been, up to the present time, involved in the greatest obscurity, and is now, for the first time, becoming intelligible.

Towards the close of last century, immediately on the discovery of the main composition of the atmosphere, viz. that it consisted of a mixture of nitrogen and oxygen, and that the important processes of combustion and respiration consisted in chemical action of the latter on the combustible burnt or on the tissues of the animal which breathed,—the idea arose that the differences between one atmosphere and another depended on richness or poorness in oxygen. This idea, in itself so plausible, was fostered by the irregular character of the analytical results furnished by the method of analysing air, which was in vogue at that early period in the history of chemical analysis.

Many of these early measurements of the quantity of oxygen in the air were made by observing the contraction which a volume of air underwent when subjected to the action of nitric oxide. Very accurate results are possible when this process is properly performed (Cavendish got excellent results with it), but sources of error, which we understand at the present day, though they were not understood when it was in use as an analytical process, prevented the general attainment of accurate results at that period. Thus it was that great variations in the proportion of oxygen in the atmosphere were regarded as having been found by chemical analysis, and to this source may be traced those curious errors which have survived to the present day in the discourse of the itinerant lecturer, and even of the medical practitioner (in foreign countries as well as at home) who opens the window *to let in oxygen*, and is *oppressed by the excessive accumulation of carbonic acid.*

With the modern improvement in the methods of eudiometric analysis, the truth became apparent, that the proportion of oxygen in the air is very nearly constant,—Regnault, Bunsen, and all modern chemists who have examined the composition of the atmosphere, being unanimous on this point. The following determinations may be quoted:—

	Oxygen per cent.
Air from sea-shore, Scotland	20·999
,, the summit of hills, Scotland	20·980
,, suburb of Manchester . . .	20·980
,, ,, . . .	20·960
,, St. John's, Antigua	20·950
,, a close sitting-room	20·890
,, pit of a theatre, 11 P.M. . .	20·740
2 Feb. 1866. Court of Queen's Bench .	20·650

The air of a crowded room therefore contains very nearly as large a proportion of oxygen as the air of the open country. Furthermore it has been shown that great variation in the proportion of oxygen may be made without any corresponding physiological effect being produced on animals breathing such an atmosphere.

For the essential distinctive characters of different atmospheres we cannot, therefore, look to the relative percentages of oxygen in different specimens of air, but must look to other criteria. In truth, the sanitary chemistry of the atmosphere is very much like that of water; being, like the latter, concerned with very small quantities of impurities present in very large quantities of the main material. Pursuing this analogy, which may be of service in conveying a just idea of the character of atmospheric impurities, the carbonic acid present in air may be likened to the total solids contained by waters. In 100,000 volumes of average air there are about 34 volumes of carbonic acid. In 100,000 parts of average Thames water, as supplied to the metropolis by the water companies, there are about 28 parts of total solid residue. Moreover, the slight percentage of carbonic acid in the air is just as harmless as the main bulk of the total solid residue of water, and the extent of variation which actually obtains in the amount of carbonic acid in badly ventilated rooms is quite too small to be of physiological importance.

The following numbers will serve to give an idea of the actual quantities of carbonic acid which occur in different specimens of air.

100 volumes of air	Vols. of CO_2.
From the hills in Scotland contain	0·0332.
From surface of Thames (London)	0·0343.
Neighbourhood of middens contain	0·0774.
Worst parts of theatres ,,	0·3200.

The proportion of carbonic acid in the worst of these specimens of air, and probably a far higher proportion of carbonic acid, would be without physiological importance.

It is not the carbonic acid, but matter existing in air in far smaller quantity, which determines the physiological character of different atmospheres.

Referring to the report just issued, it will be seen that Dr. Angus Smith has recognized atmospheric pollution by acids, salts, and nitrogenous organic matter, the latter having been detected and measured by the ammonia-process.* The absence of vegetation in the northern manufacturing towns, and in the neighbourhood of many kinds of chemical works, is ascribed, in great part, to the presence of free acids, such as sulphuric and hydrochloric in the atmosphere; and the possibility is suggested, that to the presence of traces of different saline substances in the air of seaside watering places, may be due some of the sanitary effects which attend a sojourn in places of that description.

* Sixth Annual Report of the Inspector under the Alkali Act of 1863. London: Eyre and Spottiswoode.

* Journal of Chemical Society, 1867, vol. v. p. 445.

In reference to the nitrogenous organic matter, it is established, in a general way, that open country air contains very little, and that town air, especially that of unhealthy towns like Glasgow, contains comparatively much; also, that the air of close rooms and of privies contains comparatively much. The air of open places in London stands this test well; and, as is so well known, London is remarkably healthy.

A curiously close parallelism may be traced between the "organic character" of air and that of water.

Thus, from the data to be found in the report, it appears that one kilogramme of air collected in different parts of Chelsea (London), gave 0·035 milligramme of free ammonia, and 0·085 milligramme of albuminoid ammonia.

It is known that one kilogramme of average London water, such as is supplied by the Thames water companies, gives 0·01 milligramme of free ammonia, and 0·08 milligramme of albuminoid ammonia.

The range of variation in atmospheric air when it has been polluted is much like the range exhibited by polluted water. Thus the analysis of air from a "midden" showed—

In one kilogramme of air,
0·26 milligramme of free ammonia;
0·32 milligramme of albuminoid ammonia.

Chemists who are in the habit of using the ammonia process will recognize these numbers as being such as are given by bad well-water.

In conclusion, and to complete the parallel, the remark may be made that the daily amount of water drunk by the human subject and the daily amount (by weight) of air passed through the lungs are commensurable quantities.

CULTURE AND DISEASES OF THE SILKWORM.

Pasteur has recently investigated some of the diseases which attack the silkworm, and has published the results of his labours in a work entitled 'Sur la Maladie des Vers à Soie.' The disease, called pébrine, which has been very prevalent and destructive of late years in various parts of France, has especially engaged his attention.

Pébrine derives its name from the black specks which occur on the silkworm suffering from it, and it consists in the development of peculiar parasitic corpuscles which invade the eggs, the blood, and all the tissues of the silkworm. One of the observations of M. Pasteur is, that the corpuscles are very easy of detection in the moth of the silkworm, whilst in the earlier stages of silkworm development, *i. e.* in the stage of the egg and of the worm, the detection of the pébrine corpuscles is difficult and often impossible.

Moths, which are recognized as sound, produce sound eggs, whilst unsound moths produce unsound eggs, which, although themselves showing no sign of the disease, cannot develope into healthy worms.

Pasteur's practical advice to the silk cultivator was to examine the moth, and to make sure that healthy moths were started from. The mode of procedure in vogue before Pasteur's investigation of the subject was to examine the eggs. Pasteur remarks, that the culture of the silkworm ought to become a profitable industry in many of the colonies of Great Britain.

MUSCARIN, THE ALKALOID OF THE FLY FUNGUS.

From Wittstein's 'Vierteljahresschrift,' bd. xix. heft 2 (1870), it appears that Koppe and Schmiedeberg have extracted an alkaloid from the fly fungus (*Amanita muscaria*), and have given to it the name Muscarin. The process of preparation is very complicated and tedious, including the pressing out of the juice of the fungus, subsequent concentration by evaporation, and precipitation by means of alcohol. The alcoholic solution is evaporated, and then purified by means of sugar of lead and ammonia, which remove some insoluble matter from it; it is then dried up with powdered glass. From the dry mass a tincture in absolute alcohol is made. The evaporation and precipitation by means of ammonia and acetate of lead is repeated. The lead is subsequently removed by means of dilute sulphuric acid. To the sulphate of the new alkaloid there is added the double iodide of potassium and mercury, which throws down a precipitate containing the alkaloid in question. From this precipitate it is to be extracted by means of baryta water, etc.

Muscarin forms a crystalline mass, which is very deliquescent, fusing to a syrup on exposure to the air. It is tasteless and odourless; reacts strongly alkaline; is insoluble in ether, little soluble in chloroform, very soluble in alcohol and ether. When exposed to the action of heat, it first becomes brownish (at 80° C.), and at 100° C. is a solid, but fuses at higher temperatures; strongly heated, it evolves a smell of tobacco and burns. It is not alterable by boiling with weak solution of potash or dilute sulphuric acid. Heated with solid potash, it evolves a smell of fish, and, on further treatment, disengages abundance of ammonia.

It is a powerful base, precipitating oxides of iron and of copper from their solutions in acids. With carbonic acid, it yields a tolerably stable carbonate, and, with sulphuric acid, it gives crystalline salt, which is deliquescent.

Tannic acid precipitates it only from concentrated solutions; picric acid, chloride of platinum, and ferrocyanide of potassium give no precipitate.

The toxic effects of muscarin resemble those of the Calabar bean.

ACCIDENT DURING THE RECTIFICATION OF ETHER.

An accident, which it is difficult to account for, is described in one of the French journals, 'Répertoire de Pharmacie,' as having occurred to a chemist, M. Adrian, while engaged in the distillation of ether. The assistant who had charge of the apparatus having left the laboratory for a short time, M. Adrian observed that the ether was coming over too rapidly, and proceeded to reduce the jet of steam by which the retort was heated. While he had his hand on the steam-cock for that purpose, he saw a flame in the middle of the laboratory, on the floor, travelling towards the receiver attached to the condenser. In an instant the liquid in the receiver caught fire, the vessel broke, and some of the burning liquid was projected over M. Adrian, finally setting his clothes on fire. He suffered severe injuries from the accident, and had great difficulty in escaping with his life. The most remarkable part of the case is this, that the process was being performed by the use of steam as the source of heat, in a room from which fire was strictly excluded. Whence came the flame which was first seen in the middle of the laboratory, travelling towards the liquid, which it ignited? No doubt the vapour formed a train along the floor, and it is possible that this extended to another apartment, where it took fire.

ON COCA.

BY E. H. FOURNIER.

One of the most remarkable phenomena which claim the attention of the physiologist is the action of stimulants on the human organism. It is a well-ascertained fact that they are capable of supporting the organism in the absence of food; and, whatever the inclinations of individuals may have been, or still are, with regard to their use, it is certain that nations of the past and present cannot, or, at any rate, do not exist without them. Von Bibra, in his preface to 'Die Narkotischen Genuss-Mittel und der Mensch,' assumes the following:—"Coffee leaves, in the form of infusions, are taken by 2,000,000 of human beings; Paraguay tea is consumed by 10,000,000; coca by as many; betel is chewed by 100,000,000; chicory, either pure or mixed with coffee, by 40,000,000; cacao, either as chocolate or in some other form, by 50,000,000; 300,000,000 eat or smoke haschish; 400,000,000 use opium; Chinese tea is drunk by 500,000,000; coffee by 100,000,000. All known peoples of the earth are addicted to the use of tobacco, chiefly in the form of smoking, otherwise by snuffing or chewing." He adds that, with the exception of cacao, perhaps none of these substances has any direct nutritive power. In corroboration of the above figures, stand the reports concerning production, consumption, and taxation of these articles, from which a fair inference can be easily drawn by anybody doubting Von Bibra's accuracy.

In the present article the action of coca will be considered, as described by various travellers in South America. The substance itself is little known in Europe, but it has received considerable attention lately, and a proposal has been made, or at least hinted at, by Dr. Abl, of Zara, to introduce it here. He says,—"Coca, in the hands of cautious captains, will very probably put a stop to the much more disgusting habit of chewing tobacco, and would certainly diminish the number of those who, after shipwreck, perish from want of food." The descriptions given by Pöppig and Weddell* are not likely to stimulate the desire for the importation of the Peruvian herb. They describe the *coquero* as a sickly, tottering being, with hollow eyes, pale lips and gums, black marks at the corners of the mouth, and greenish and stumpy teeth,—a somewhat hideous counterpart to the inveterate drunkard of our own regions. Von Tschudi† mentions a case of a somewhat different character. He says, "A cholo of Huari, named Hatun Huamang, was employed by me in very laborious digging. During the whole time he was in my service, viz. five days and nights, he never tasted any food, and took only two hours' sleep nightly; but, at intervals of two and a half or three hours, he regularly masticated about half an ounce of coca leaves, and he kept an acullico continually in his mouth. I was constantly beside him, and therefore had the opportunity of closely observing him. The work for which I engaged him being finished, he accompanied me on a twelve days' journey of twenty-three leagues across the level heights. Though on foot, he kept up with the pace of my mule, and halted only for the chacchar. On leaving me, he declared that he would willingly engage himself again for the same amount of work, and that he would go through it without food, if I would but allow him a sufficient supply of coca. The village priest assured me that this man was sixty-two years of age, and that he had never known him to be ill in all his life."

* 'Voyage dans le Nord de la Boline.'

† 'Peru. Reiseskizzen.' Translated by Ross.

The *Erythroxylon Coca* is a shrub about six feet high, with bright green leaves and white blossoms. The latter are succeeded by small scarlet berries; the former are described as shaped similarly to the leaf of the cherry-tree. In the tables accompanying Von Bibra's work, some specimens are shown in nature-print (*Naturselbstdruck*). They appear to be considerably smaller than cherry leaves, although in shape not unlike them. The coca is raised for the seed, in garden beds, called almazigas. It requires humidity; therefore maize is sown between the *matas*, or young shoots, to screen them from the too great influence of the sun. When the leaves are ripe—that is to say, when, on being bent, they crack or break off—the gathering commences, and they are stripped from the branches, a task usually performed by women. The plant, thus rendered leafless, is soon again overgrown with verdant foliage. The colour of the leaves when dried is a pale green. The drying demands great care and attention, for, if they imbibe damp, they become dark, and then a lower price is obtained than when they are green. Coca is not believed to improve by keeping; the inhabitants find it unpalatable at a year old. Von Bibra estimates the yield of one acre (German) at 800 lb. of dried leaves; and he calculates that 30,000,000 lb. are annually produced.

The Indians masticate the coca generally in combination with some alkaline substance, which they carry in a small flask gourd, called the *ishcupuru*; a pouch, called the *huallqui*, or the *chuspa*, contains a supply of coca leaves. Unslacked lime pulverized is usually taken with the herb. In Cerro de Pasco, and in places still further south, the Indians use, instead of this, a preparation of the pungent ashes of the quinine. This preparation is called "llucta" or "llipta."

The flavour of coca is said to be rather pleasant. It is slightly bitter, aromatic, and similar to the worst kind of green tea. When mixed with the ashes of the musa root, as in some of the Montana regions, it is somewhat piquant, and more pleasant to European palates than it is without that addition.

In Dr. Mantegazza's prize essay* the whole subject is carefully reviewed and ably treated. Abstracts thereof are contained in the leading pharmaceutical journals. From experiments made repeatedly on himself and on other individuals, Dr. Mantegazza draws the following conclusions:—1. The leaves of the coca, chewed or taken in a weak infusion, have a stimulating effect upon the nerves and stomach, and thereby facilitate digestion very much. 2. In a small dose, coca increases the animal heat, and augments the frequency of the pulse, and consequently of respiration. 3. In a medium dose (three to four drachms) it excites the nervous system in such a manner that the movements of the muscles are made with greater ease, after which it produces a calming effect. 4. Used in a large dose, it causes delirium, hallucinations, and, finally, congestion of the brain.

An inveterate coquero, or coca-chewer, says Von Tschudi, is known at the first glance. His unsteady gait, his yellow-coloured skin, his dim and sunken eyes encircled by a purple ring, his quivering lips, and his general apathy, all bear evidence of the baneful effects of the coca juice when taken in excess. Such an individual is treated as the opium-eater is treated in Java and the East in general. Intemperance is an evil which springs from the love of self-indulgence; and the means for its gratification are, in some form or other, everywhere to be found.

Von Bibra looks upon the chewing Indian as upon an adder, quick to the touch, and resenting with demoniacal hatred an interruption of his feast and his dreams.

* Pamphlet, Milan, 1859. See 'Oesterreichische Zeitschrift für praktische Heilkunde,' Nov. 4, 1859.

Intoxicated sometimes for several weeks, the debauchee hides in the deepest forest. There, stretched upon the ground, he indulges, unmindful of flood, storm, or wild beast, fascinated by, as Bibra has it, one of his components. "Whoso," he says, "has experimented upon himself with narcotics, knows how long one is able to take stock of one's state while under their influence. It seems as if there were two individuals present, the one experiencing all the effect of stupefaction, the other conscious of that state in the one."

Dr. Weddell asserts that the Indians who accompanied him chewed coca all day long, and sat down to their suppers with a double appetite. He believes that the moderate use of coca enables a man to overcome the feeling of hunger for a longer period. The exalting effect which it produces calls out the power of the organism without leaving afterwards any sign of debility. This is proved by experiments, and a number of cases treated by Dr. Mantegazza. The Inca, who lives at a height of from 7,000 to 15,000 feet above the level of the sea, and whose meagre fare consists principally of maize, some dried meat, and potatoes of bad quality, believes that he can sustain his strength solely by the use of coca. The porter who carries the mail, and accompanies the traveller over the roughest roads at the quick pace of the mule, invigorates and strengthens himself by chewing coca. The Indian, who works half-naked in the silver and quicksilver mines, looks upon this plant as ambrosia capable of imparting new life, and of stimulating to new exertions.

Tschudi says, "It is a well-known fact, confirmed by observation and experience, that the Indians, who regularly masticate coca, require but little food, and, nevertheless, go through excessive labour with apparent ease. They therefore ascribe the most extraordinary qualities to the coca, and even believe that it might be made entirely a substitute for food." Setting aside all extravagant and visionary notions, the moderate use of coca is not merely innoxious, but it may even be very conducive to health. There are numerous examples of longevity among Indians who, almost from the age of boyhood, have been in the habit of masticating coca three times a day, and who, in the course of their lives, have consumed no less than 2700 lb., yet, nevertheless, enjoy perfect health. There are cases of individuals in Peru, by no means singular, who have actually attained the age of 130. Supposing these Indians to have begun to masticate coca at ten years old, and calculating their daily consumption as a minimum at 1 oz., the result is the consumption of 27 cwt. in 120 years.

In experimenting upon himself, Dr. Mantegazza states that an infusion of coca will increase the action of the heart to four times its normal standard; while cocoa, tea, coffee, and warm water only double it. By taking an infusion prepared from 3 dr. of the leaves, a feverish condition was produced, with increased heat of the skin, palpitation of the heart, flashes, headache, and vertigo; while the pulse rose from 70 to 134. A peculiar, roaring noise in the ear, a desire to run about, and an apparent enlargement of the intellectual horizon, indicated that the specific influence upon the brain had commenced. A peculiar, hardly describable feeling of increased strength, agility, and impulse to exertion follows; it is the first symptom of the intoxication, which is, however, quite different from the exaltation produced by alcoholics. While the latter manifests itself by increased but irregular action on the muscles, the individual intoxicated by coca feels but a gradually augmented vigour, and a desire to spend his newly-acquired strength in active labour. After some time, the intellectual sphere participates in this general exaltation, while the sensibility seems to be hardly influenced; the effect is thus quite different from that produced by coffee, and resembles in some degree that of opium. Dr. Mantegazza could, in this excited condition, write with ease and regularity. After he had taken 4 dr., he was seized with the peculiar feeling of being isolated from the external world; and, with an irresistible inclination to gymnastic exercise, he jumped upon the writing-table, moving about with ease, without breaking the lamp or other objects upon it. In his normal condition, the learned doctor is by no means given to gymnastic exercise. After this, a state of torpidity came on, accompanied by a feeling of intense comfort—consciousness being all the time perfectly clear—and by an instinctive wish not to move a limb during the whole day, not even a finger. During this sensation sleep sets in, attended by odd and rapidly-changing dreams. It may last a whole day without leaving a debility or indisposition of any kind. Dr. Mantegazza increased the dose to 18 dr. in one day; his pulse rose in consequence of it to 134. Three hours of sleep sufficed to set him right again, so that he was able to follow his daily occupation without the least indisposition, on the contrary, even with unusual facility. He had abstained for forty hours from food of any kind, and the meals then taken were very well digested. During the last stage of intoxication, and in the moment when the delirium was most intense, he described his feelings to several of his colleagues, who were watching him, as being most exquisite, ten years with coca being preferable to a million of centuries without. The description was given in writing by Dr. Mantegazza, thus:—"*Io preferiscata una vita di 10 anni con coca che un di 1,000,000 secoli senza coca.*"—*From the 'Food Journal.'*

NAVY DISPENSERS.

Admiralty, W.C., 7th July, 1870.

Sir,—I herewith transmit for the information of the Pharmaceutical Society twenty copies of the new regulations for the appointment of dispensers and assistant-dispensers in her Majesty's naval hospitals, and I have to request you will be good enough to give publicity to the same.

I am, Sir, your obedient servant,
(Signed) A. Armstrong, *Director-General.*

Elias Bremridge, Esq.,
Secretary and Registrar,
Pharmaceutical Society,
17, *Bloomsbury Square, W.C.*

Admiralty, 24th June, 1870.

Regulations relative to the Appointment of Dispensers and Assistant-Dispensers in Her Majesty's Naval Hospitals at Home and Abroad.

The Lords Commissioners of the Admiralty are pleased to direct that the following regulations relative to the qualifications of Candidates, and the pay and allowances of Dispensers and Assistant-Dispensers of her Majesty's Naval Hospitals at home and abroad, shall in future be adopted:—

1. That a Candidate for entry as Assistant-Dispenser shall make a written application to that effect, addressed to the Secretary of the Admiralty.

2. As vacancies occur, Candidates will be ordered to attend at the Office of the Director-General of the Medical Department of the Navy, observing that no person can be admitted as an Assistant-Dispenser unless he possesses the Minor qualifications of the Pharmaceutical Society; but Dispensers or Assistant-Dispensers in charge of stores must possess the Major qualifications of the Pharmaceutical Society.

3. The age of Assistant-Dispensers on entry not to be less than 20 years, or more than 25.

4. The daily pay of Assistant-Dispensers will be as follows:—

Under 5 years' service.	Under 8 years' service.	Under 11 years' service.	Under 14 years' service.	Under 17 years' service.	Under 20 years' service.
5*s*.	5*s*. 6*d*.	6*s*.	6*s*. 6*d*.	7*s*. 6*d*.	8*s*. 6*d*.

and for every additional year an addition of 6*d*. per diem, till 10*s*. a day is reached.

5. When in charge of stores an additional allowance will be granted, viz. at Haslar and Plymouth Hospitals 2*s*. per day, with the title of Dispenser; and at other Home and all Foreign Hospitals 1*s*. per day.

6. An allowance of 6*d*. per day, in lieu of fuel and lights, will be granted to all Dispensers and Assistant-Dispensers, and they will be provided with quarters.

7. Superannuation will be allowed in accordance with the Superannuation Act of 1859, and a Certificate of Qualification will be required from the Civil Service Commissioners, under the terms of the Order in Council of 4th June, 1870, published in the 'London Gazette' of the 7th June, 1870.

8. Assistant-Dispensers will be liable to serve in any of her Majesty's Naval Hospitals at home or abroad, to which they may from time to time be appointed.

By command of their Lordships,

Vernon Lushington.

ON THE COMBINATIONS OF CARBONIC ANHYDRIDE WITH AMMONIA AND WATER.

BY EDWARD DIVERS, M.D.

The following paper contains an account of some investigations that I have made on the chemical reactions and combinations of carbonic anhydride, ammonia, and water with each other. The properties and relations of such bodies as these being of primary importance in the theory of chemistry, they have indeed already received a large share of the attention of chemists; and therefore, besides much that has come to be known concerning them, of which it would be impossible now to ascertain the discoverers, several valuable memoirs have been written upon them. Nevertheless, I think it will be generally admitted that the combinations of these bodies are still felt not to conform in a clear manner to the ammonium theory, the theory of the general constitution of salts, and even the theory of combining proportions.

In attempting to arrive at a more satisfactory knowledge of these combinations, I have made out much that I believe will be found to be new, both to chemical literature and the traditions of the laboratory, and of service in helping to decide as to the normal character of these combinations.

General History.—The first contribution to a knowledge of the chemistry of the carbonated compounds of ammonia must be considered to be that of Black* in 1756, pointing out the difference between solution of ammonia and the solid carbonate of commerce. After this we find Priestley making out the difference between ammonia and its carbonate in his 'Experiments and Observations relating to Alkaline Air' in 1774.†

The first recorded quantitative analysis of a compound of carbonic anhydride and ammonia, as far as I can discover, is that by Bergmann, in 1774.‡

The variable composition of the compounds of carbonic anhydride and ammonia was pointed out in 1799 by Sir Humphry Davy,* but the results he obtained proving to be erroneous, his statements were untrustworthy. The fact of the existence of different carbonates was afterwards confirmed by Berthollet, Dalton, and others.

The Ammonium Carbonates.—I. Normal Ammonium Carbonate.

There are certainly three combinations of ammonia and carbonic anhydride, into the formation of which water enters in sufficient relative quantity to allow of their being represented as ammonium salts of carbonic acid,—the normal, the half-acid, and the acid carbonate.

Since writing the note on the preparation and composition of the first-named of these in the 'Philosophical Magazine,' I have ascertained several interesting particulars in the chemical conduct of this substance, so that the facts there communicated form only a small part of the history of this salt I am now able to give.

History.—The want of the normal carbonate of ammonium was only felt after Berzelius had promulgated his ammonium theory; until then the carbonate, $CO_2(NH_3)_2$, had been considered to be this body.

Berthollet,† in 1806, by distilling a solution of the acid carbonate, obtained a weak solution of normal carbonate ("subcarbonate") as the distillate. But Dalton was the first to describe a solid carbonate, neutral in composition, in 1813.‡ He ascertained that the carbonate of commerce did not contain two atoms of ammonia to one of carbonic anhydride, and prepared a hydrated compound of these bodies in this proportion.§

This compound contained, according to him, one atom of water, and would therefore be represented by the formula,

$$CO_2OH_2(NH_3)_2.$$

The percentage number which he gives for the ammonia is indeed very incorrect in itself; but then he determined it by using standard solution of sulphuric acid, and, as we all know, the equivalent number he adopted for ammonia is wide of the true one. But then he clearly established that in the acid carbonate the acid is only *half* saturated with ammonia, and that in the normal carbonate discovered by him the acid is *fully* saturated. He was, however, also wrong in representing the normal salt to contain, like the acid salt, but one atom of water to one atom of carbonic anhydride instead of two, as his analytical results really indicated. The following is his statement of the composition of the two salts:—

‡ Works, translated by Cullen, vol. i. p. 29. Of the "Aerial Acid," paper read in 1774.

* Works, vol. iii. p. 47.

† 'Journal de Physique,' vol. lxiv. p. 168. Troisième suite des Recherches sur les Lois de l'Affinité. Extracted from the 'Mémoires de l'Institut de France' for 1806.

‡ 'Experiments and Observations on the Combinations of Carbonic Acid and Ammonia.' Mem. of the Lit. and Phil. Soc. of Manchester (2), vol. iii. p. 18; 1819.

§ So far as I can ascertain he has never received credit for this, or for the real excellence of his paper, in spite of the errors it contains. Indeed Henry, in his 'Life of Dalton' (Cavendish Society's Publications), speaks very disparagingly of this paper. The circumstances that seem to me to have contributed to this result are:—(1.) The paper was published five years after it was read, in a journal which probably had a very limited Continental circulation. (2.) The calculations of the results of his analysis are erroneous, in consequence of the atomic weight—6—he adopted for ammonia. (3.) It contains some decided errors, among which, unfortunately, is that of denying the correctness of Gay-Lussac's researches on the proportion by volume in which ammonia combines with carbonic anhydride. (4.) It was severely criticized by Thomson, in his 'Annals of Philosophy' (vol. xv. p. 137), who, nevertheless, besides erring himself in his correction of Dalton's remarks on Gay-Lussac's researches, also misstates another conclusion at which Dalton had arrived.

	Acid carbonate ('carbonate').	Carbonate ('subcarbonate').
Carbonic Anhydride . .	58	41
Ammonia	18	25+
Water	24	34
	100	100

These results show that the normal salt he examined contained two atoms of water to one of carbonic anhydride. For by accepting the percentage numbers he gives for the acid carbonate, and calculating from these the numbers for the normal salt with two atoms of water, we get just those which he gives. Thus:—

Carb. A.		Am.				Carb. A.		Am.
58	:	18	×	2	::	41	:	25·4.
		Water.						Water.
58	:	24	×	2	::	41	:	33·9.

Or putting it in another way: if we apply to his numbers for the normal carbonate the correction we know to be necessary for those he found for the acid carbonate, we get almost exactly the numbers expressing the composition of the normal carbonate with two atoms of water. The calculated numbers are—

	Acid carbonate.	Norm. carb. with $2\,OH_2$.
Carbonic anhydride .	55·70	38·60
Ammonia	21·52	29·82
Water	22·78	31·58
	100·00	100·00

He prepared the normal carbonate in two ways, of which one was by distilling the commercial carbonate, and collecting the first product of the distillation before it had been exposed to the air; and the other, by adding to a warm saturated solution of the commercial carbonate sufficient ammonia to raise the proportion to the proper degree, when, on cooling, the normal carbonate was copiously precipitated.

Sir Humphry Davy obtained, in 1799, a salt that seemed to be, according to him, the most ammoniacal carbonate, and by the first of the methods afterwards employed by Dalton, but he did not determine its composition.

Dr. Thomson, in the seventh edition of his 'System of Chemistry'* (1831), stated that a normal carbonate $CO_2O\,H_2(NH_3)_2$, could be formed by mixing together one volume of carbonic anhydride, two volumes of ammonia, and one volume of water-vapour. It is very doubtful, however, whether the product thus obtained is a single substance, as will be seen by the later part of the present paper.

In 1834 John Davy† repeated his brother's experiments, apparently ignorant of what in the meantime Dalton had done, and ascertained the substance obtained by Sir Humphry to be a hydrated compound of two atoms of ammonia to one of carbonic anhydride. He also confirmed the above statement of Thomson.

Hünefeld, in 1836,‡ obtained a neutral combination of ammonia and carbonic anhydride by distilling the commercial carbonate with aqueous alcohol, but he did not determine its state of hydration.

Next, in 1839, Heinrich Rose§ also examined the most remote part of the first product of the slow distillation of the commercial carbonate, and found it to contain two atoms of ammonia to one of carbonic anhydride; but, according to him, there was associated with these only half an atom of water, so that it was not a true ammonium carbonate, its formula being—

$$(CO_2)_2O\,H_2(NH_3)_4.$$

He obtained the same compound also by distilling a mixture of sal-ammoniac and sodium carbonate.

Lastly, in opposition to the general statement to the contrary, I myself announced in a paper in the 'Philosophical Magazine' for 1868* that a normal ammonium carbonate having the formula

$$CO_2(O\,H_2)_2(NH_3)_2$$

could readily be obtained.

I have already mentioned that Berthollet obtained a solution of normal carbonate at an early date. Then, the year before Rose's paper appeared, Scanlan† pointed out that the action of water upon more of the commercial salt than it can dissolve furnishes a solution containing the ammonia in much greater proportion to the carbonic anhydride than is in the commercial salt. Dalton, however, claimed to have anticipated Scanlan in this observation, and the latter admitted the justice of the claim. Rose, in his paper the year after, showed that this solution was one of the normal carbonate, with only a little acid carbonate, and gave two other methods for obtaining a solution of normal salt. One is to boil a solution of the commercial carbonate; the other is to heat the commercial carbonate very gently in a retort, having its beak dipping under mercury, continuing the heat until a great part of the carbonate has volatilized and the rest become wholly liquefied, then setting aside the liquid in a closed vessel to crystallize (which it continues to do for some days), and then decanting the mother-liquor, which is a solution of normal carbonate free from acid carbonate. That a solution of the normal salt can be obtained by distilling sal-ammoniac, pearlash, and dilute spirit together, was known to Phillips, and perhaps others before him.

Lastly, normal ammonium carbonate, in combination with magnesium carbonate as a crystalline double salt, was prepared by Fourcroy many years ago, and afterwards by Bucholz.‡

THE PRESENT PROSPECTS OF THE SEWAGE QUESTION IN RELATION TO THE PUBLIC HEALTH.

BY HENRY LETHEBY, ESQ., M.B.

(*Read before the Metropolitan Association of Medical Officers of Health, May* 21, 1870.)

(*Continued from p.* 25.)

When sewage has a very offensive odour, and is evolving marsh gas and sulphuretted hydrogen, it rarely exhibits much sign of animal life, but when it is diluted with water and exposed freely to the air, the bad odour quickly disappears, and the higher forms of infusoria are rapidly developed. This is proof of the salutary influence of air and water in promoting the less hurtful kinds of decay. I have often noticed that where the sedimentary matters of sewage accumulate and putrefy, without free access of air, foul gases are evolved, and little or no organic life, except of the very lowest kind, appears. This was formerly the case with the mud upon the banks of the Thames, where the only living things were *monads*, *vibriones*, and *fungi;* but in the middle of the stream, where there was abundance of air and water, the highest forms of infusoria abounded. This may be noticed in every river of the kingdom which receives the sewage of a large town. At first, the sedimentary matters deposit and putrefy; but the supernatant water, containing all the soluble constituents of the sewage, passes on, and rapidly becomes clearer and clearer, until its organic matter is appropriated by living beings, or destroyed by oxidation. This process is not only indicated by the marked improvement in the appearance and odour of the water, but it is actually demonstrated by the character of the vegetation, which passes successively from the simplest and lowest forms of fungi to *conferva*, *calothrix nivea*, *vaucheria*, etc., until at last *anacharis*, *nasturtium*, *veronica*, etc. abound; and when these are clean and healthy we may be assured that the sewage, in its noxious condition, is no longer in existence, and that the most refined skill of the chemist will fail to discover it.

I have, on a former occasion, fully discussed this important question, and I should not again refer to it if it had not been made a special subject of comment, and apparently* of experimental inquiry, by the Rivers Pollution Commission; for at page 18 of their recent report they say, "It has often been stated, but so far as we know without proof, that the organic matter contained in sewage, and other similar polluting materials, is rapidly oxidized, during the flow of a river into which such materials are discharged. Thus, it has been asserted (Report of Royal Commission on Water Supply, p. 79) that if sewage be mixed with twenty times its volume of river water, the organic matter which it contains will be oxidized, and completely disappear whilst the river is flowing 'a dozen miles or so!'" Now, I think it is right to state that the quotation is not fairly made, and that the sense and substance of my evidence herein alluded to are not fully expressed; for on referring to the page from which the Rivers Pollution Commissioners have quoted, it will be found that I spoke of oxidation as only one of the agencies concerned in the destruction of organic matter in a running stream. My words are these: "Considering the powerfully oxidizing influence of water upon sewage, the many agencies which are at work destroying it, the power of precipitation, the using of it up by vegetable and aquatic plants, and by fish, and above all by the power of oxidation, I think none of the sewage discharged into the Thames can, at the present time, be discovered at Hampton;" and when I am asked how far it would have to flow before it would be broken up into other chemical compounds, I answer thus: "I have made a great number of chemical experiments to determine that. I have examined most of the rivers in England, and this is the conclusion that has been come to, not only in my mind, but in the minds of all the engineers† who have devoted their attention to the subject—that if ordinary sewage, containing, we will say, nearly 100 grs. of solid matter per gallon, such as London sewage, out of which probably something like 14 grs. or 15 grs. are organic, be mixed with twenty times its bulk of the ordinary river water, and flows a dozen miles or so, there is not a particle of that sewage to be discovered by any chemical process."‡ I ought perhaps to have said by any *reliable* chemical process; for I will not answer for the results of such processes as are used by Dr. Frankland for the determination of "organic carbon" and "organic nitrogen," processes that I have already criticized, and which others have declared to be so faulty, that the range of error embraced by them is greater than the range of possible truth. It is curious, however, that even with these processes the Thames at Hampton, according to Dr. Frankland, is purer than the Thames at its source, notwithstanding that it has received the drainage from all the towns on its banks.*

But to return to the subject, the Pollution Commissioners say, "We thought it very undesirable that a subject of such vital importance to our inquiry should any longer rest upon mere opinion, and we have therefore determined to submit it to careful experimental investigation." Their investigations were of two kinds—namely, an examination of the Mersey, the Irwell, and the Darwin, at different parts of their course, choosing the winter time,† when most of the agencies to which I have referred were dormant; and, secondly, by examining air and sewage contained in a bottle. Both of these investigations were of the most unsatisfactory kind; for from what I know of the rivers in question, there is no part of their course so free from the access of impurities as to furnish even remotely the sort of evidence upon which we can rely. The evidence, however, which they do furnish is that, notwithstanding a continued access of impurity, there is a continued improvement of their condition; and as for the experiments with sewage in a bottle, they are so absurdly ridiculous, as a means of testing so important a question, that I am ashamed to refer to them. The proper way in which such an inquiry should be conducted is an appeal to the large facts of nature; for everywhere the rivers of England are receiving the sewage of towns, and yet they are everywhere undergoing a rapid self-purification. If this were not so, their condition would be frightful,‡ and we should expect a universal pestilence. In this metropolis, for example, the water which we drink is taken from the Thames after it has received the sewage of thousands of people, and yet, to use the words of Dr. Frankland, "it is purer and better adapted for domestic purposes at Hampton," where it is taken, "than at any other part of its course.§ And how has this been effected but by oxidation, and by the operations of animal and vegetable life? When Dr. Miller was asked by the Royal Commissioners on Water Supply, whether he had made any experiments on the power of water, in a given course, to oxidize organic matter, he said, "I ascertained a remarkable result in 1859 upon the river: I took specimens of the water at Kingston, at Hammersmith, at Somerset House, at Greenwich, at Woolwich, and at Erith on the same day, and examined the quantity of oxygen which the water contained at all these different points. I found that the quantity of oxygen at Kingston was the ordinary or normal proportion; at Somerset House it was much diminished, at Greenwich the whole of the oxygen had disappeared, at Woolwich it was in much the same condition, and at Erith the water was very much improved, showing that this diminution of oxygen had been produced by its action upon the water contaminated with

* The Commissioners have given a full account of the experiments and data on which they base their conclusions. (See *Report of Commission on the Pollution of Rivers*, pp. 18–22.)

† Apart from the consideration that this, being a chemical question, cannot be decided by engineers, it has been pointed out by the Royal Commissioners (Report, p. 22) that engineers and superficial observers have been misled as to the self-purifying power of flowing water. They have also pointed out the circumstance which has led to the erroneous impression. Mere clarification of water is no proof that it has been purified sufficiently to be wholesome, and we are not aware that Dr. Letheby has anywhere published chemical evidence to support his views. It is, however, essential that in a matter of such importance this should be done; for no mere assertion, however authoritative will suffice.

‡ Dr. Letheby's influence in regard to sanitary matters is so great, that it is necessary to say the result which he has arrived at is directly at variance with all chemical probability, and with the general opinion of chemists. It is also inconsistent with the direct evidence of facts bearing on the subject.

* Dr. Frankland clearly shows that the water of the Thames is purer near the source of the river, but he says that, *from Lechlade downwards*, it is purer at Hampton than elsewhere.

† The experiments were made between March 10th and June 11th.

‡ The condition of some rivers *is* frightful.

§ Dr. Frankland and Dr. Odling have shown in their Report on Water Supply to the Royal Commission, that the greater purity of the Thames at Hampton is, in great measure, due to admixture of tributary water.

the sewage of the London district, and that, as it passed lower down, the oxygen was again absorbed from the air, and again it became diluted with a large volume of water from below, from other sources—the Lea, the Ravensbeurne, and other tributaries—and in this manner the water had again become oxidized. I look," he says, "upon this as *a direct proof of the effect of oxygen in destroying those organic contaminations which are thrown into the river.*" Dr. Odling, also, in reply to a question from the Royal Commissioners, as to the self-purifying power of water said, "You see in many rivers, even sluggish rivers, having sewage discharged into them, that for a mile or two the appearance of the river is affected by the sewage, but beyond a certain distance there is no recognizable effect at all—the weeds are perfectly clean and perfectly healthy;" and he instances the river Soar, at Leicester, which is black and very foul from the refuse of the town; but "three miles from the town its appearance is such that you could not tell it had been contaminated, for it was running clear, with fish swimming in it, and the weeds were clean." That, he said, was simply from a process of self-purification. Again, Dr. Taylor, of Guy's Hospital, in his examination before a Committee of the House of Commons on the Metropolis Water Supply Bill, states, when speaking of the effect of water on sewage matter, that "all such substances are very rapidly decomposed and destroyed; the nitrogen is converted into nitric acid, and the sulphur into sulphuric acid, so that those fetid and putrid substances which go into the Thames from London, when rolled about by the action of the water, containing an enormous amount of air, *are all oxidized and destroyed; within a certain limit they may be found, but still, after a very short passage, they are very soon indeed destroyed.* I believe," he says, "it is the opinion of every chemist who has considered the subject, that sewage matter does not remain as sewage matter in well-aerated water, but all phosphorus, sulphur, and nitrogen are speedily destroyed by the oxygen of the water. Every 1000 gallons of water contain 46 gallons of oxygen, and that oxygen destroys all such putrescent effluvia. With water not exposed to the air, and not containing air, it is most offensive and unwholesome; but with water containing air, like the Thames, and exposing an enormous surface to the air in its daily motion, the effect is completely to obliterate every trace (of sewage matter) that a chemist can detect. In the Thames, and other water, the air is in a state of solution, the matter in a state of diffusion, and thus the air and this fetid matter are in the very condition to combine together and form an innoxious compound; it requires time and motion, but still it does take place with very extraordinary rapidity." And he concludes his remarks by saying, "The supposition that the drainage of London, which goes into the river about the bridges, remains the drainage of London all up the river, is contrary to all chemical experience; it is contrary to every chemical fact, and every chemical analysis."*

In a former communication to you I spoke of the investigations of Dr. Angus Smith on the polluted water of the Clyde, which were to the same effect. Engineers also, who have been largely concerned in such inquiries, have always spoken of the remarkable self-purifying power of water. Mr. Hawksley, whose experience of this matter renders him a very high authority on the subject, said, in answer to a question from the Rivers Commission, as to the quantity of water, compared with the volume of sewage discharged into it, as necessary for the purpose of breaking up the sewage into inoffensive compounds, that generally 20 to 1 was sufficient; but if the water flows rapidly, and is very much disturbed, so as to be continually receiving fresh oxygen, a smaller quantity—even 12 to 1—will effect the process; and if it proceeds very tardily it may take a little more, but 20 to 1 is abundant. "I could," he adds, "give you very remarkable instances of it. Take Sheffield. Nothing can be fouler probably than the state of the water at Sheffield, whereas if you go down to Doncaster (about twenty miles below Sheffield), the water is supplied by the water-works, and is actually drunk in the town." Again, says Mr. Hawksley, "Take the river Irwell (the very river which Dr. Frankland has been examining). After leaving Manchester it receives the Irk, the Matlock, and all the refuse of the manufacturing population for a great many miles; when it travels down only eight or nine miles to Warrington it is perfectly changed; it ceases, or nearly ceases, in that short distance, to be an offensive river." "At Leicester, likewise," to use his words, "the water was as black as ink—nothing would live in it, and the smell was abominable; but by the time it had got to Loughborough (which is about twelve miles below Leicester) it was entirely restored to its pristine condition. You could stand on the bridge there and see the fish swimming amongst the beautiful reedy and other plants growing in the water, just as in the purest stream. You could see every pebble at the bottom; that is an instance of oxidation." You may remember the instance which I gave you last year of the river Trent, which receives the sewage and manufacturing refuse of some of the largest, busiest, and dirtiest towns in the kingdom, with an aggregate population of more than a million and a half of persons, and yet when it arrives at Nottingham it is not only clear, pellucid, and inoffensive, with abundance of fish and aquatic plants, but is actually used for the domestic supply of the town. But why need I multiply such instances, or dwell upon such self-evident empirical facts, when they are within the common knowledge and experience of everybody? for even Dr. Frankland is ready to admit, in the case of the London water supply, that "by gradual oxidation, partly in the pores of the soil, partly in the Thames and its tributaries, and partly in the reservoirs, filters, and conduits of the company, this sewage contamination had been converted into comparatively innocuous organic compounds before its delivery to consumers."

"I believe," said Dr. Frankland, in his evidence before the Royal Commission on Water Supply, "that the noxious part in sewage is that which is held in mechanical suspension, not that in solution;" and no doubt the sedimentary matters of sewage are capable of producing an offensive condition of the rivers, for when they are discharged into a sluggish stream they quickly subside, and form accumulations of persistently putrefying mud. This is the chief cause of complaint wherever sewage enters a river.

At the time of the inquiry into the state of the Thames, in 1858, it was admitted on all hands that the filthy mud-banks of the river were the great source of annoyance; and Dr. Hofmann and Mr. Witt, in their report of the matter to the Government referees, declared emphatically that the formation of this mud-deposit in the bed of the river appeared to them to be by far the most serious evil which results from the discharge of London sewage into the river, and they strongly urged this point upon public attention. Dr. Odling, in his report to me on this subject, for the information of the referees appointed by the Metropolitan Board of Works, said that "any means which would prevent the deposition of organic mud in the bed, but more particularly on the exposed banks of the river, would effect an amply sufficient purification of it." The same was my own opinion, for in reporting to the referees I stated that the mischief produced by the discharge of sewage into the river "was not occasioned, as I once supposed, by the soluble matters of the sewage, but by the mud or insoluble constituents which settle and putrefy upon the banks of the river." These constituents being in a solid form, and not easily accessible

* The supposition here referred to is an imaginary one, that no chemist would entertain. Whatever change sewage may undergo after its discharge into rivers, there is no evidence to show that it is destroyed so rapidly or to such extent as to be harmless; and that is the real point to be considered.

to atmospheric oxygen, continue to putrefy for a considerable time. In my laboratory operations I have found that they will keep up a persistent decomposition, with a constant evolution of offensive gases, for many months, the air being excluded from them. I am therefore of opinion that the chief point to be aimed at in the purification of sewage is the rapid and effectual separation of its suspended matters, leaving the soluble matter to mix freely with proper proportions of running water, in which it will be quickly appropriated by infusorial life, or be destroyed by atmospheric oxidation; and this leads me to consider the means whereby this may be effected.

One method of accomplishing it is to keep the solid matters out of the sewage, as is practised, with more or less success, in Manchester, Salford, and other towns of Lancashire. In Salford, according to the report of the medical officer of health, Dr. Syson, the most satisfactory results have been obtained with a modification of M. Goux's plan, whereby the soil is received at once into tubs lined with some refuse absorbent; and the advantages of the plan, according to Dr. Syson, are that the manure becomes of great commercial value; that the excrement of the whole town can be readily removed at least once a week; and that in case of fever or contagious diseases the whole of the excrements can be readily and economically disinfected; besides which the plan is simple and economical. Earth-closets are not so manageable, as they require about 3½ times their weight of earth to the excreta, and the difficulties of carrying the material to and from the closets are not manageable on a large scale, although I have seen them in satisfactory operation in factories, as they may be in military camps, where the organization of labour is easy. Instead of earth, Mr. Stanford recommends charred seaweed, which is not only an excellent deodorizer, but does the work of three times its weight of earth. In Edinburgh, in olden times, there were no closets in the poorer houses, but there were numerous public privies, which still exist. These are provided with from eight to forty compartments, beneath which there is placed by the scavengers, every morning, a tin can, like the modern milk-can on the railways, and the can of the previous day, with its contents, is taken away. The soil is mixed with ashes and road-sweepings, and sells for about £7000 a year, which is half the entire charge of the scavenging of the older part of Edinburgh. Nearly everywhere on the Continent some such method is adopted for the collection of the refuse and excreta, and they are profitably utilized. How far an improvement of this condition of things, instead of the present water-closet system, may have met the requirements of hygiene and the demands of agriculture, is an important question. The Pollution Commissioners, however, condemn this plan *in toto;* and so far are their views disturbed by the medium of their prejudices, that they cannot perceive any difference in the quality of the sewage of a place retaining its solid matters, and of another which lets them flow into the public sewers. Liverpool, for example, which collects and disposes annually of about 139,000 tons of privy soil; Manchester, 74,000 tons; Salford, 46,000 tons; Oldham, 50,000 tons; Preston, 30,000 tons; and Bolton, 22,500 tons,—furnish in each case as much sewage, and of the same composition, as the towns which discharge everything into the sewers. The inconsistency of the thing is so striking that it creates most serious doubts of the accuracy of the analyses, and of the reliability of the determinations of organic carbon and organic nitrogen.

And now let us turn to the pet scheme of the Pollution Commissioners—the disposal of sewage in all places and under all circumstances by irrigation. Fortunately for us, the thing has been tried, and is now being done in many places, so that we can test it by its practical results, and examine it by the light of something more than that of abstract speculative chemistry.*

To begin with its absolutely required conditions. You must have a soil that is sufficiently porous to allow the sewage to filter through it, and this soil must be well drained to carry off the subsoil water. The situation of the farm must be convenient as regards the flow of sewage to it by gravitation, and the discharge of water from it by drainage. It must not be within reach of danger from atmospheric miasms, or the pollution of wells by the subsoil drainage. It must have a ready market for the disposal of its only merchantable produce, green Italian rye-grass; and lastly, there must be an area of not less than two acres for every 100 people, one of these acres being in use while the other is resting to recover itself.

These conditions cannot always be secured, but even if they could, let us see if the objections to the process, on sanitary grounds, are not conclusively against it.

1. In the first place, the land irrigated with sewage is always a fetid, swampy morass of the most offensive description. Nowhere, of all the places which I have visited, is there an exception to this condition of things. At the Craigintinny meadows, near Edinburgh, which I have often seen, the stink from them is hardly endurable; —to use the words of Dr. Ligertwood, who was stationed at the neighbouring barracks, "the stench is sometimes quite sickening." At Norwood and at Beddington it is a subject of serious complaint by those who reside in the neighbourhood of the farms. I have myself experienced it on several occasions, and have been surprised at the statements of Dr. Carpenter, of Croydon, whose pet thing it is, that nobody complains of it. Mr. Creasy, the surgeon at the Female Orphan Asylum, at Beddington, tells a different story, for he says it so damages the value of the neighbouring property that villas near the farm do not let so well as others, nor at so high a rent.

At Aldershot, which is frequently referred to as a well and successfully managed sewage farm, I ascertained, on a recent visit with Mr. Hawksley, Mr. Eggar, and Professor Ansted, from the occupants of the few cottages which skirt the farm, that the stench is frequently unbearable and most sickening. At Banbury there is but one house upon the estate; it is a public-house called the Bowling Green, and the landlady described to us, in very graphic terms, the nuisance she was obliged to submit to.

2. But these miasms are not alone offensive, they are also dangerous to the public health; in fact, the early proceedings of those who have brought about this condition of things were devoted almost entirely to the proof of their morbific action, and it was this apparently clear proof which was made the lever of their parliamentary movements, and was the main cause of our present difficulties. Now, however, they will tell you that the emanations from acres of land sodden with putrefying sewage are neither offensive to the senses nor injurious to the health.† I put it to you, gentlemen, as a simple matter of common medical experience, whether you are of such an opinion; for, if so, where is the necessity for all our elaborate and expensive machinery for getting rid of these matters from our houses, and for preventing the escape of such offensive emanations? Why feel, in fact, the least concern for an untrapped drain or an overflowing cesspool? One of the highest medical authorities on the subject of fevers, Dr. Murchison, has traced a particular fever to this particular source, and has devoted a large portion of his classical work to the proof of sewer gases being the primary cause of what he has termed *pythogenic* or enteric fever. It is true that he has some doubts, like Dr. Christison, of the effects of the diluted gases; but time will prove whether these doubts are well

---

* The cases where sewage irrigation has been practised can scarcely be regarded otherwise then as cases of getting rid of sewage; its utilization is still a problem to be worked out in all that relates to profit and health.

† It is the concentration of noxious gases by confinement that is hurtful; but in irrigation sewage need not be putrid, moreover it is subject to the disinfecting influence of the soil and atmosphere.

founded. Already enough has been seen to show that they are not so harmless as many suppose. Mr. Creasy, to whom I have before alluded as practising at Beddington, said very recently, before a committee of the House of Commons:—I know the sewage farm belonging to the Croydon Board of Works, at Beddington, and have had experience in my professional capacity of what condition of health is around those flats, for I have known the district ever since it was a sewage farm. The first case of typhoid fever occurred in the place in 1867, and from that time to this there has been typhoid fever in every cottage on the estate; and I find around it that almost every disease assumes a particular type, accompanied with what we call a sewage tongue."

In the spring of last year I was inquiring into the condition of a stream called the Hebble Brook, which receives the sewage of Halifax, and I was informed that at a place near the outfall of the brook into the Calder, some of the sewage was distributed upon the land, and that it caused such a serious outbreak of typhoid fever in a neighbouring model village, belonging to Mr. Ackroyd, that it was found absolutely necessary to discontinue it.

Again, in the autumn of 1862, I had an opportunity of witnessing, on a very large scale, the morbific effects of sewer gases in the town of Shaftesbury, and the adjacent village of Enmore Green. The town had been recently drained by a gentleman of no great practical acquaintance with the subject, and he carried the sewage into the ponds and ditches around the town. It was an experiment of a very instructive kind, for soon the people were attacked with enteric fever, and in less than a year one-eighth of the whole population was down with the disease; for out of about 3500 persons, 448 were attacked. I am afraid, therefore, that these miasms, even when diluted with air, are capable of producing serious mischief, and that such facts are more conclusive than the statistics of Dr. Carpenter, which seem to show that the people of Beddington and Norwood have actually been better in health since the sewage was brought to them than before.

3. I would remind you that the efficacy of sewage irrigation is entirely dependent on the percolation of sewage matter, and the distribution of it through the subsoil water. It cannot but be, therefore, that this water is polluted to such an extent as to endanger the neighbouring wells. Many instances of this have already come under my notice; and it would seem, from the remarks of Dr. Carpenter, that Dr. Frankland had himself stated that the chalk well at Croydon, from which the public supply is obtained, is actually polluted with the soakage of foul matters from the irrigated grounds at Beddington. The morbific effects of such water are but too frequently observed, as the annual reports of the medical officer of the Privy Council abundantly testify; and then, again, if the doctrines of Professor Von Pettenkofer, of Munich, be correct, as they certainly seem to be, that fluctuation in the level of ground water charged with sewage is the most active agent of fever and cholera, the consequences of irrigation may be most serious.

(*To be continued.*)

*** The subject of which this paper treats is important in its general bearings, and so urgently forced upon the consideration of municipal authorities throughout the kingdom, that it has been deemed necessary to add some notes in reference to the opinions and assertions put forward by Dr. Letheby with great decision, and with some aspect of plausibility, though they are far from being regarded as sound or judicious by sanitary authorities either here or abroad. It is probably in any case premature to pronounce so decisively as Dr. Letheby does that sewage irrigation is an unmitigated evil; and, in spite of the positive declarations made by those who act with him, three sewage irrigation bills have passed both Houses of Parliament this session. Those who can distinguish between what is termed "scientific evidence" and that evidence which is recognized in science, will probably fail to share Dr. Letheby's shame, or to participate with him in his appreciation of what he declares "absurdly ridiculous."—ED. PH. J.

CRYSTALLIZED HYDRATE OF SODA.

According to a communication made by O. Hermes to the Chemical Society of Berlin, crystals containing 30·09 per cent. of anhydrous soda (Na_2O), and having the formula $2\,NaHO + 7\,H_2O$, are deposited when a concentrated aqueous solution of caustic soda, sp. gr. 1·365, is exposed to the action of intense cold. The crystals form rhombic prisms, and are perfectly transparent and colourless; they begin to melt at 6° C. A point worthy of being remembered is, that impure solutions of soda, contaminated with chloride, sulphate, and carbonate, are capable of depositing these crystals in a state of tolerable purity.

The occurrence of errors respecting the composition of these hydrated crystals in some of the newest treatises on chemistry induced the author to bring the subject before the Chemical Society of Berlin.

ON THE TIME FOR COLLECTING THE LEAVES OF DIGITALIS.

BY F. SCHNEIDER.

The pharmacopœias and text-books direct to collect these leaves of the flowering plant. I had the leaves annually collected in the Black Forest during the latter part of May or beginning of June, requiring always some flowering stems. In appearance I had a beautiful drug, but rarely could I get a satisfactory reaction by tannin and ferrocyanide of potassium in the infusion. In 1869, a botanical friend, formerly apothecary, offered to supply Digitalis, which he collected near the end of August and beginning of September, as he had done during his long pharmaceutical practice, from the rosulate leaves of plants, flowering the following year. The Digitalis yielded a deeply-coloured infusion of strong odour and taste, and gave with tannin at once a dense precipitate; with ferrocyanide of potassium, after twelve to fifteen minutes, a strong turbidity. The leaves should, therefore, be collected not in the flowering season, but late in summer.—*American Journal of Pharmacy*, from *Schweiz. Wochenschr. f. Ph.*

APPLICATION FOR BALDNESS.

Take of

Rum		500 parts.
Rectified Spirit } Distilled Water }	each	75 ,,
Tincture of Cantharides		3 ,,
Carbonate of Potash		3 ,,
Carbonate of Ammonia		5 ,,

Mix the liquids, then dissolve the salts, and filter. After having saturated the bald part for some minutes with this liquid, wash the head with water.—*Journal de Pharmacie et de Chimie.*

Indelible Ink.—The following receipe is given by Puscher:—Dissolve 4 parts of anilin black in 16 parts by weight of alcohol, with 60 drops strong hydrochloric acid, and dilute the dark blue solution with 90 parts by weight of water, in which 6 parts of gum arabic has been previously dissolved. This ink is said not to act upon steel pens or to suffer any alteration by alkalies or acids.—*Deutsche Industriezeitung.*

Poisoning by Corrosive Acids. — On Monday, June 27th, a man was found in Richmond Park, lying on the ground apparently in great agony. Near him was a small bottle, labelled "spirits of salts." He was conveyed to the infirmary, where he lies in a dangerous state. A few days previously, a man, a plumber and glazier by trade, in a fit of temporary insanity, swallowed a quantity of fluoric acid; he was conveyed to Middlesex Hospital, where he died almost immediately.

The Pharmaceutical Journal.

SATURDAY, JULY 16, 1870.

NAVAL DISPENSERS.

We congratulate the Pharmacists of Great Britain that a step has been taken towards the recognition of the claims of pharmacy by the national Government, as implied by the communication from the Admiralty to the Secretary of the Pharmaceutical Society given in another part of this Journal.

The Admiralty now requires that its dispensers shall know their business, and that department has become alive to the fact that theirs is a business requiring to be learned. Now the dispensers and assistant-dispensers in charge of the Government stores must be educated men; not, as formerly, pensioners with a turn for dispensing, or persons needing to be provided for in some way, but having no kind of natural aptitude for anything.

Quoting from the official communication just referred to, "No person can be admitted as an assistant-dispenser unless he possesses the Minor qualifications of the Pharmaceutical Society; but dispensers or assistant-dispensers in charge of stores must possess the Major qualifications of the Pharmaceutical Society."

When we reflect that the Admiralty is slow to change, and how discipline and necessary subordination (as a kind of makeweight to their acknowledged advantages) entail reticence, and a casting into the shade of such mishaps as the administration of a poison in place of medicine, we shall be prepared to realize the full significance of this last order, transmitted by the Admiralty to the Secretary of our Society.

THE "AGE OF PROGRESS."

In the belief that the calm which proverbially succeeds a storm has now become established, we refrain from inserting a number of letters that have reached us on this subject. The views of all parties have, we think, been adequately expressed, and further correspondence would probably have the effect of supplementing mere difference of opinion with the acrimony arising from controversial disputes.

If the recent Council election be the index of a "period of transition" rather than of an "age of progress," as suggested by one of our correspondents, it would seem to follow that its advantages or disadvantages would be better dealt with as matters of history than as subject for prophecy.

The desire of provincial members to be more largely represented in the governing body of the Society has been attained, and it now remains for them, not only to bear their victory with becoming dignity and forbearance, but also to sustain and justify their claim to a representation in the Council proportionate to their numbers.

On these grounds alone we think it would be advisable to let this matter rest, and we trust this view will be so far appreciated by our correspondents that they will regard it as a sufficient reason for the non-publication of their letters.

ANONYMOUS WRITING.

A number of letters have been received in which the propriety of anonymous correspondence is disputed and maintained. As the provision of a medium of communication is an important function of this Journal, this question deserves serious consideration, and there is much to be said on both sides. Wherever the subject-matter of a letter has a personal bearing, it is desirable that the name of the writer should appear, and in many cases the statement of facts, or even opinions, will gain weight by the signature of a name. At the same time there are cases in which expression of opinion, argument, and criticism, would be restricted by the necessity of publishing a writer's name, and the best safeguard of propriety is to be looked for in that exercise of judgment and regard for principle which are admitted to be characteristic of the English press.

On the Continent, as many of our readers doubtless know, it is customary for every leading article to bear the signature of the writer, and in this country the same practice has been adopted by the 'Fortnightly Review,' to some extent by 'Nature,' and by other publications. It is, however, at least doubtful whether we should or not follow these examples, and conform to Continental usage.

THE NEW LIBRARIAN OF THE LONDON INSTITUTION.

The office of Librarian of the London Institution was once filled by the celebrated Greek scholar, Porson; afterwards it was held by Mr. Thompson, and then by the late Mr. Brayley, who died a short time ago. The choice of the managers of the Institution has now fallen on Mr. J. C. Brough, who has just been elected to the librarianship. Mr. Brough is well known to our readers from his connection with the 'Chemist and Druggist,' of which he was editor until quite recently. The short-lived and much regretted 'Laboratory' was, as many of our readers will also recollect, edited by the same gentleman. Great satisfaction has been expressed with Mr. Brough's election: the managers of the Institution could hardly have hit upon a better man for the office.

ON SULPHOCARBOLIC ACID AND THE SULPHOCARBOLATES.

BY T. OMAR GUY.

These chemical combinations have quite recently come before the medical world as new therapeutical agents, but have not been thoroughly investigated. There having been no satisfactory process given for their manufacture, the subject was presented to me several months ago for investigation; since which time I have experimented with various combinations, and find the following to give the most satisfactory results:—

Sulphocarbolic Acid.—This is first formed by combining, by aid of heat, sulphuric and carbolic acids, in the proportion of 49 parts by weight of the former to 94 parts by weight of the latter, or one equivalent of each.

The mixture is put into a glass flask with a narrow top, into which is inserted a thermometer, and covered over by means of a paper diaphragm, in order to keep the fumes from escaping. It is then placed on a sand-bath, and heat gradually applied, until the acid is raised to the temperature of 290° F., and kept at this point for ten or fifteen minutes, and then allowed to gradually cool.

At first this forms a thick syrupy liquid of a rich wine colour, which, in time, passes into a crystalline mass, composed of small rhomboidal crystals, having a reddish-brown appearance. These again become liquid at or about 80° F.

When the two acids are first mixed, heat is evolved, the temperature being raised to 190° F. Fumes are given off, which are again condensed on the sides of the vessel. These have an odour similar to carbolic acid, though differing in some respects.

Sulphocarbolic acid reddens litmus; with the sesquichloride of iron, also, with the solution of the pernitrate of iron, it produces a beautiful purple colour, which fades when exposed to the sunlight for a short time. With chloride of barium, nitrate of baryta, and the acetate of lead, it produces a slight opalescence, which is probably owing to a little free sulphuric acid.

Its taste is at first strongly acid, leaving a slight empyreumatic taste upon the tongue. It also has a strong empyreumatic odour, resembling, to some extent, carbolic acid. Its sp. gr. is 1·288; boils at 540° F., and is decomposed at 560° F. into a black, shiny, amorphous mass, having lost all of its odour; soluble in water and alcohol, and gives a decided reaction with the soluble barium and lead salts.

The acid is soluble in any proportion of water, alcohol, and ether. It dissolves iodine, and the solution will combine with water without throwing the iodine out of solution.

When heated to 400° F. it becomes of a bright red colour, and when cooled forms an almost semi-solid mass. If nitric acid is added to a portion of sulphocarbolic acid, it is immediately decomposed with violence, nitrophenic acid being formed—a black, oily liquid, giving off a peculiarly disagreeable odour, entirely different from that of carbolic acid.

In forming the sulphocarbolic acid, I used the chemically pure sulphuric acid, sp. gr. 1·823, and Calvert's No. 2 carbolic acid.

The interchange of elements which takes place when sulphocarbolic acid is formed may be represented by the following reactions:—one equivalent of carbolic acid $= C_{12}H_6O_2 = 94$; one equivalent of sulphuric acid $= SO_3HO = 49$; then $C_{12}H_6O_2 + SO_3HO = C_{12}H_6O_2 SO_3HO = C_{12}H_5O, SO_3, 2HO$, which might be considered sulphophenic acid, or a hydrated sulphate of the oxide of phenyl.*

Sulphocarbolic acid has been experimented with in regard to its disinfectant properties, and found to be much more efficient than carbolic acid alone.†

* These formulæ are somewhat doubtful and antiquated.—Ed. Ph. J.

† *Vide* 'Pharmacist,' Chicago, September, 1869.

With salifiable bases it combines and forms salts, which have been called sulphocarbolates. These have a faint odour of carbolic acid, and are supposed to have its therapeutical properties combined with its respective bases, without its causticity, rendering it suitable for internal administration.

In heating the acid great care should be used not to heat it too suddenly. There is apt to form at the bottom of the vessel a black liquid, caused by too great a temperature, resulting in the decomposition of the acid.

Sulphocarbolate of Soda.—This salt is at present considered the most important of the series. It may be produced by taking one volume of sulphocarbolic acid, adding six volumes of water, and completely saturating with carbonate of soda in crystals. The solution is then filtered and evaporated slowly over a sand or water bath until a slight pellicle is formed, when it is set aside to crystallize. When the crystals are all formed, the mother-water may be still further evaporated, and a new crop of crystals obtained.

Should they contain colouring matter, or the crystals not be well-formed, a re-solution and crystallization will produce a beautiful salt, free from colouring matter, and of well-defined rhomboidal prisms, soluble in five parts of cold water at 60° F., and in two-thirds its weight of boiling water; soluble to a slight extent in alcohol, but insoluble in ether.

Sulphocarbolate of soda is a nearly colourless salt, possessing a slight pinkish tinge. It has a somewhat saline, bitterish taste, and a faint odour of carbolic acid; neutral to test paper; produces no precipitate with chloride of barium, nitrate of baryta, or the acetate of lead. With the sesquichloride of iron and the liquor ferri nitratis, it produces a beautiful purple colour, characteristic of the sulphocarbolic acid.

The crystals should be well dried by exposing them to the air in a warm place on filtering or porous paper.

The reactions which take place when the salt is formed may be represented by the following equation:—$NaO, CO_2 + C_{12}H_5O, SO_3 2HO = NaO, C_{12}H_5OSO_3HO + CO_2$.

In heating this salt to a high degree, it loses thirty per cent. of its weight, and falls into a greyish-white powder, giving a white precipitate with chloride of barium, nitrate of baryta, and acetate of lead; with the sesquichloride of iron and the solution of ternitrate of iron, it produces a deep reddish colour. If the heat is continued to redness, it takes fire and burns without flame. Nitric acid, added to a solution of the salt, gradually acquires a reddish-brown colour.

The therapeutical properties of sulphocarbolate of soda have not been thoroughly investigated. It has been used in phthisis with marked success; also in zymotic diseases with favourable results. It has been given in doses ranging from ten to sixty grains.*

Several physicians of this city have used the sulphocarbolate of soda in the treatment of disease. Among the number the following have been reported. One case was that of Anna E——, having suffered from ozena for several years. The sulphocarbolate of soda was used, varying the strength from two to eight grains to the fluid ounce of water. It was used twice daily, with Thudichum's nasary douche, with the most flattering success.

It was also used as a topical application in a case of syphilitic sore-mouth with good results. In this case the strength of the solution used was ʒi to f℥iv of water.†

As a dressing for fetid leg ulcers the solution of the sulphocarbolates possesses one advantage over the carbolic acid; the acid in oil or paste is at first generally too stimulating, but soon volatilizes, leaving the oil or paste inert. The sulphocarbolates being less volatile, but at the same time possessing the antiseptic qualities, a more uniform application is obtained.

* 'London Practitioner,' July, 1869.

† Cases reported by Dr. Collins.

This salt was used in several cases of severe tonsilar ulceration, which all rapidly recovered without the occurrence of suppuration.

It was also employed in several severe cases of scarlet fever, every case of which recovered in a less period of time than under any treatment which had previously been employed in similar cases.*—*American Journal of Pharmacy.*

Transactions of the Pharmaceutical Society.

MEETING OF COUNCIL,

July 6th, 1870.

MR. SANDFORD, PRESIDENT, IN THE CHAIR.

MR. HASELDEN, VICE-PRESIDENT.

Present—Messrs. Abraham, Atherton, Bottle, Bourdas, Brady, Brown, Dymond, Evans, Groves, Hanbury, Hills, Mackay, Reynolds, Savage, Stoddart, Sutton, and Woolley.

The minutes of the last meeting were read and confirmed.

The following letter from the Privy Council was read, and ordered to be entered on the Minutes:—

"*Medical Department of the Privy Council Office, June 9th*, 1870.

"Sir,—In answer to your letter of the 3rd instant, submitting, on the part of the Pharmaceutical Society, for the approval of the Lords of Her Majesty's Council the names of certain Pharmaceutical Chemists proposed to be Examiners for the Society for the ensuing year, my Lords direct me to inform you that they approve the appointments submitted to them.

"I am, Sir, your obedient servant,

"JOHN SIMON.

"*The Secretary, Pharmaceutical Society.*"

In consequence of the increasing number of candidates for examination in Scotland, it was considered desirable to extend the Board of Examiners to eight, as provided under the Bye-laws; and the following Pharmaceutical Chemists were thereupon appointed, subject to the approval of the Privy Council:—

Henry C. Baildon .... Princes Street, Edinburgh.
Alexander Noble .... Circus Place, Edinburgh.

Letters were read from—

The Science and Art Department, South Kensington, acknowledging the receipt of the votes of thanks passed at the last meeting of the Council.

Professor Roscoe, expressive of his appreciation of the honour conferred on him in being elected an Honorary Member of the Society.

Mr. Schacht, of Clifton, consenting to deliver the sessional address in October next.

The report of the Finance Committee was presented, showing, on the General Fund Account, a balance in the Treasurer's hands of . . . . £1862. 11*s.* 3*d.*
And submitting for payment accounts, law costs, salaries, etc., amounting to . £1469. 11*s.* 9*d.*

On the Benevolent Fund Account a balance of £458. 12*s.* 1*d.*

The Finance Committee, as requested at the last meeting of the Council, having taken into consideration the funded capital of the Society with a view to its more advantageous investment, further reported,—

"That this Committee is of opinion that the funded capital of the Society might be more advantageously employed if invested in good freehold ground-rents, or freehold landed security; and the Committee recommend that a portion of the capital be so employed at the earliest opportunity."

Moved by Mr. Mackay, seconded by Mr. Brown, and

Resolved—That the Report of the Finance Committee be received, but the Council deem it more prudent to continue the present investment of the funds of the Society in Government Securities.

Resolved—That the Treasurer be requested to pay to the several annuitants (10) their quarter's annuities in advance to Michaelmas next.

The Report of the House Committee Meetings of June 5, 10, and 17, having been read, it was resolved that the Report be received: that the matters recommended relating to office-fittings, house-cleaning, painting, etc., be referred back to the Committee to carry out.

Resolved—That the Report and recommendations of the Library, Museum, and Laboratory Committee be received and adopted.

On the Report and recommendations of the Parliamentary Committee, it was

Resolved—That the list of Local Secretaries for the ensuing year, now presented, be approved, and that the said list be published in the ensuing number of the Journal.

Resolved—That the Registrar be instructed to consult the Society's Solicitors, in reference to proceedings to be taken in certain cases reported by him of infringements of the Pharmacy Acts.

On the Report of the Special Journal Committee, the Council proceeded to the election of an Editor for the 'Pharmaceutical Journal.'

Mr. Watts having withdrawn his application, the remaining candidates were

Dr. Redwood, Dr. B. H. Paul, and Dr. J. Baker Edwards.

Ballot having been taken, the following was the result:—

BENJAMIN H. PAUL, PH.D., F.C.S.	12
THEOPHILUS REDWOOD, PH.D., F.C.S	7
JOHN BAKER EDWARDS, PH.D., F.C.S.	0

Dr. Paul was therefore declared elected Editor.

The election of a Sub-Editor was left to a committee, consisting of the President, Vice-President, Messrs. Dymond, Mackay, and Reynolds, subject to confirmation by the next Council.

Moved by Mr. Abraham, seconded by Mr. Mackay,

That Professor Redwood be re-appointed Professor of Chemistry and Pharmacy at a salary of £400 per annum.

Amendment—Moved by Mr. Brown, seconded by Mr. Woolley,

That Dr. Redwood be re-appointed Professor of Chemistry and Pharmacy at a salary of £300 per annum.

Mr. Brady demanded that the voting should be by ballot.

Ballot—*For* the Amendment, 11. *Against*, 7.

The Amendment, having been put as a substantive Motion, was carried.

Moved by Mr. Hanbury, seconded by Mr. Mackay,

That, in recognition of the long and varied services of Dr. Redwood, an annuity of £100 be in future paid him.

Amendment—Moved by Mr. Brady, seconded by Mr. Brown,

That no notice having been given of the proposed annuity to Dr. Redwood, the consideration of the subject be delayed for a month.

For the Amendment—

Messrs. Atherton, Brady, Brown, Dymond, Reynolds, Savage, Sutton, and Woolley.

* *Vide* 'London Practitioner,' July, 1869.

Against—
Messrs. Abraham, Bottle, Bourdas, Evans, Haselden, Hanbury, Hills, Mackay, Sandford, and Stoddart.

Mr. Groves did not vote.

The Amendment being lost, the original Motion was then put, when another Amendment was moved by Mr. Sutton, seconded by Mr. Atherton,

That Dr. Redwood be allowed £50 per annum.

Mr. Reynolds demanded that the voting should be by ballot.

Ballot—*For* the Amendment, 8. *Against*, 10.

The original Motion was carried.

Professor Bentley was reappointed Professor of Botany and Materia Medica for the ensuing year.

Professor Attfield was reappointed Professor of Practical Chemistry, and Director of the Laboratories, for the ensuing year.

William Augustus Tilden, B.Sc., was reappointed Demonstrator in the Laboratories for the ensuing year.

John Moss was reappointed Assistant-Demonstrator for the ensuing year.

On the consideration of the resolution passed at the last Annual Meeting,

"That this meeting is of opinion the means hitherto adopted by the Society to supply the educational wants of its members are no longer adequate to the necessities of the times; and it respectfully urges upon the new Council the desirability of considering some scheme by which the resources available for such purposes may be more generally distributed,"

It was moved by Mr. Reynolds, seconded by Mr. Hanbury, and

Resolved—That the following be a Committee to inquire into the existing facilities for Pharmaceutical Education in the Provinces, and that they be desired to offer suggestions for the aid and extension thereof:—The President, Vice-President, Messrs. Atherton, Brady, Dymond, Groves, Mackay, Reynolds, Stoddart, Sutton, and Woolley.

The consideration of the resolution on the Sale and Keeping of Poisons, passed at the Annual Meeting, "That the subject be taken into consideration by the incoming Council, and that a further report be made to the next Annual Meeting," was deferred.

A letter was read from Messrs. Churchill and Sons, containing suggestions in reference to the publication of the Journal, etc., and was referred to a Committee.

REPORT OF THE BOARD OF EXAMINERS FOR ENGLAND AND WALES.

June 15,	Major Examination,	5 candidates,	4 passed.
"	Minor "	28 "	19 "
"	Separate "	1 candidate,	1 "
July 1,	Modified "	38 candidates,	19 "
"	Preliminary "	176 "	144 "
		248	187

Preliminary Examination, certificates approved, 4.

Resolved—That the following, being duly registered as Pharmaceutical Chemists, be respectively granted a Diploma stamped with the seal of the Society:—

Duncan, Joseph .... Glasgow.
Finlay, James .... Edinburgh.
Fryer, Charles .... Guildford.
Furmston, Samuel Chambers .. Wycombe.
Horsley, Thomas Wood ...... Manchester.

Resolved—That the following Pharmaceutical Chemists be and are hereby elected Members of the Society:—

Cadman, Daniel Charles ...... Folkestone.
Duncan, Joseph .... Glasgow.
Goulden, Edward Baker ...... Uckfield.
Meadows, Henry .... Gloucester.
Paffard, Walter Haideen .... Niagara.
Reeler, John William .... Cape Town.
Tuck, William Henry .... Surbiton.
Williams, Richard .... Brixton.

Resolved—That the following Registered Chemists and Druggists be elected Members of the Society:—

Barnitt, Francis .... Bath.
Foster, James Alfred .... Birmingham.
Fowke, Thomas Edward ...... Stafford.
Harvie, George .... Helensburgh.
Hodkinson, John .... Macclesfield.
Longhurst, Edward .... Matlock Bath.
Malden, William Walter .... London.
Stevens, John Ashley .... Trowbridge.
Sykes, Thomas Hindle ...... Southport.
Wright, George .... Burton-on-Trent.

Moved by Mr. Woolley, seconded by Mr. Brown,—

That Elizabeth Leech, Munster House, Fulham, Registered Chemist and Druggist, be elected a member of the Society.

For—
Messrs. Abraham, Bourdas, Hanbury, and Woolley.

Against—
Messrs. Atherton, Brady, Dymond, Groves, Haselden, Hills, Mackay, Reynolds, Sandford, Savage, and Stoddart.

Mr. Evans did not vote.

The motion was therefore lost.

Resolved—That the following, having passed their respective Examinations, be elected

ASSOCIATES IN BUSINESS.

MINOR.

Peake, Henry Felix .... Twickenham Green.

MODIFIED.

Goodwin, Medmer .... Plymouth.
Hackney, William Francis .... London.
Jones, Owen .... Llanrwst.
Morris, Frederick Robert .... Lowestoft.
Waterworth, Alfred .... Preston.

Resolved—That the following, having passed their respective Examinations, be elected

ASSOCIATES OF THE SOCIETY.

MINOR.

Appleby, Calvert .... Retford.
Botterill, George Thomas .... Boston.
Davison, Anthony .... Kidderminster.
Griffin, Thomas .... Bromley.
Hill, William Edward .... Leicester.
Homer, Frederick George .... Birmingham.
Horton, Walter Charles ...... Windsor.
Howie, William Lamond .... Edinburgh.
James, George .... Haverfordwest.
Masson, George .... London.
Osborne, James .... Ashbourne.
Pick, Richard .... Hull.
Powell, Thomas Henry ...... Hornsey Rise.
Vincent, Philip, jun. .... Fulham.
Wallis, Herbert Boyd .... London.
Warren, William .... Chertsey.
While, William John .... Cheltenham.
Wing, Lewis .... Torquay.
Wonfor, Herbert Ison .... Southampton.

MODIFIED.

Burgess, Frederick Augustus .. London.
Floyd, John .... Liverpool.
Gowen, Albert .... Stratford-on-Avon.

Hill, Edward .... Barnstaple.
Turner, John .... Ramsgate.
Matthew, Josiah .... London.

The Secretary presented a list of members who had paid their subscriptions since the 30th April last.

Resolved—That they be severally restored to their former status on payment of the nominal fine of one shilling.

A request having been made by the Sunderland Chemists' Association that the Journal of the Society be supplied to them, it was resolved that the requisition be complied with.

EXAMINATION IN LONDON.

July 13th, 1870.

Present—Messrs. Allchin, Bird, Carteighe, Cracknell, Davenport, Gale, Garle, Haselden, Ince, and Southall. Dr. Greenhow was also present on behalf of the Privy Council.

Twenty-five candidates presented themselves for examination,—twelve Major and thirteen Minor; the following passed and were duly registered

MAJOR (As PHARMACEUTICAL CHEMISTS).

*Webb, Edward Alfred .... Clapham.
*Bland, Thomas Fredrick ...... Stourbridge.
*Thompson, William Milner .. Thirsk.
*Raffle, William .... South Shields.
Pitts, Phineas Reynolds ...... Hingham.
Walton, Jonathan Sparke .... Haydon Bridge.
Adams, Frank .... Stoke-on-Trent.
Mason, Robert William ...... Rugby.

MINOR (As CHEMISTS AND DRUGGISTS).

*Sherburn, Thomas .... Harrogate.
*Sumner, Benjamin Tindale .... Horncastle.
Clark, Walter Beules .... Leicester.
Page, William Henry .... London.
Storey, Edward Henry ...... London.
Margetts, George William .... Fakenham.
Green, Marryat Hahnemann .. London.
Thomas, Evan Medeni .... Pantyrodyn.

The above names are arranged in order of merit.

* Passed with honours.

Chapters for Students.

CHEMICAL NOTES TO THE PHARMACOPŒIA.

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

ACIDUM CARBOLICUM. *Carbolic Acid.—Synonyms:* phenic acid; phenic alcohol; hydrate of phenyl; phenol. When coal-tar is distilled, the first portions which come over constitute crude *coal naphtha*, and contain benzol, C_6H_6. The next portion collected in the receiver is *heavy coal oil* (being heavier than water); it boils at 300° F. and upwards, and contains carbolic acid. Later in the process the oil which distils contains a good deal of solid matter (naphthaline, etc.), and the black residue in the retort forms pitch. Carbolic acid is separated from the heavy oils by distilling them fractionally, that is, by collecting the constituents which pass over at different temperatures in different receivers. The details of its successful preparation on the large scale, are only known to a few manufacturers.

It melts at 95° F., and boils at 370° F.; sp. gr. 1·065. Formula HC_6H_5O.

It resembles creasote in many respects, but differs from it in having no action on polarized light, and being easily crystallizable by cooling. An aqueous solution also gives a blue colour with perchloride of iron, which creasote does not. Carbolic acid is an important antiseptic. [§ A slip of deal dipped into it, and afterwards into hydrochloric acid, and then allowed to dry in the air, acquires a greenish-blue colour. It coagulates albumen.] Although called an acid it has no acid reaction upon litmus-paper, and is given off unchanged by heating any of its compounds with bases.

By treating it with nitric acid it gives, according to the strength of the acid and time allowed for reaction—

Mononitrophenic $HC_6H_4(NO_2)O$,
Dinitrophenic . $HC_6H_3(NO_2)_2O$,
Or trinitrophenic $HC_6H_2(NO_2)_3O$ acid.

The last is important as a yellow dye, it is called picric or carbazotic acid.

By dissolving carbolic acid in oil of vitriol, sulpho-carbolic or sulpho-phenic acid is obtained, and by diluting this, and neutralizing with various metallic oxides or carbonates, the sulpho-carbolates are formed. These salts have been recently introduced into medicine. The sodium salt is $C_6H_5NaSO_4$, H_2O; the zinc salt $Zn''(C_6H_5SO_4)_2, H_2O$.

ACIDUM CITRICUM.—Citric acid is found in greater or less proportion in the fruits of all the orange tribe. It is prepared practically from lemon-juice or from lime-juice, by boiling with chalk until the acid is neutralized, collecting the insoluble citrate of lime thrown down:—

$$\underbrace{2H_3C_6H_5O_7}_{\text{Citric acid.}} + 3CaCO_3 = \underbrace{Ca''_3 2C_6H_5O_7}_{\text{Calcic citrate.}} + 3(H_2O, CO_2).$$

Suspending this in water and digesting it with a sufficient quantity of sulphuric acid:—

$$Ca''_3 2C_6H_5O_7 + 3H_2SO_4 = 2H_3C_6H_5O_7 + 3CaSO_4.$$

The addition of the chalk to the juice causes effervescence, from the escape of carbonic acid gas; the citric acid is wholly precipitated upon boiling in the form of citrate of lime, leaving behind, in solution, the other substances (mucilage, sugar, etc.), which are mixed with it in the juice. The sulphate of lime formed in the second part of the process is almost wholly insoluble, and is therefore filtered off.

Citric acid crystals are soluble in three-fourths of their weight of cold, and in half their weight of boiling water; they are easily distinguished from those of tartaric acid, by being much shorter and, as it were, rounder, and by giving no precipitate when added in excess to solution of acetate of potash, nor when added in moderate quantity to cold lime-water. Alum or bisulphate of potash would be detected in it by giving a white precipitate with chloride of barium. 7 grams of the acid are neutralized by the addition of 100 cubic centims. of volumetric solution of soda.

Citric acid is tribasic; out of the 10 atoms of hydrogen which it contains altogether, 3 atoms can be expelled by the action of metals by way of double decomposition. For instance:—

$$\underbrace{H_3C_6H_5O_7 . H_2O}_{\text{Citric acid crystals.}} + 3NaHO = Na_3C_6H_5O_7 + 3H_2O + H_2O.$$

If, then, 1 molecule of the acid is neutralized by 3 mols. of soda, $\frac{1}{3}$ mol. of the acid will be satisfied by 1 mol. of soda:—

$$\begin{array}{rl} C_6 &= 12 \times 6 = 72 \\ H_{10} &= 1 \times 10 = 10 \\ O_8 &= 16 \times 8 = 128 \\ & \overline{3)210} \\ & \overline{70} \end{array}$$

70 grams of the acid would then be neutralized by 40 grams of soda, or, which is the same thing, by 1000 c.c. of the vol. sol. of soda: therefore, 7 are neutralized by 100 c.c.

Crystals of citric acid, exposed to the temperature of boiling water, lose 1 mol. of water, which is merely water of *crystallization*, and can be taken up again. Heated more strongly, the residual dry citric acid again loses a mol. of water and becomes transformed into an acid, which is chiefly interesting on account of its identity with the acid of the aconite and of various species of the equiseta. It is soluble in ether, whilst citric acid is not:—

$$\underset{\text{Citric acid.}}{H_3C_6H_5O_7} - H_2O = \underset{\text{Aconitic acid.}}{H_3C_6H_3O_6}.$$

Acidum Gallicum. *Gallic Acid.*—Obtained by exposing crushed galls, in a moist state, to the air during a month or six weeks; then pressing out the black residual liquid and boiling the cake in water, which extracts the gallic acid from it. On cooling, the acid crystallizes out from the solution.

There is some difference of opinion as to the nature of the change which gives rise to the gallic acid in this way; it is probable, however, that under the influence of the "moulds" which form upon the mass, the tannin present is broken up into gallic acid and glucose, and that the latter, as it forms, is almost entirely oxidized to CO_2 and H_2O:—

$$\underset{\text{Tannin.}}{C_{27}H_{22}O_{17}} + 4\,H_2O = \underset{\text{Gallic acid.}}{3\,C_7H_6O_5} + \underset{\text{Glucose.}}{C_6H_{12}O_6};$$

and then—

$$C_6H_{12}O_6 + 6\,O_2 = 6\,CO_2 + 6\,H_2O;$$

possibly in a manner analogous to that by which the vinegar-plant promotes the oxidation of the alcohol in vinegar making.

Minute silky needles, soluble in three times their weight of boiling water, but only in 100 of cold. In dispensing gallic acid, hot water should not, therefore, be employed to dissolve it, or the acid crystallizes in large tufts on cooling. The aqueous solution gives a deep bluish coloration with ferric salts, but, when pure, it does not precipitate the vegetable alkalies nor gelatine as tannin does. [§ The crystalline acid when dried at 212° F., loses 9·5 per cent. of its weight.] This is only water of crystallization; but when heated to between 410° and 420°, it is wholly resolved into carbonic acid gas and pyrogallic acid, which sublimes in shining plates:—

$$C_7H_6O_5 = C_6H_6O_3 + CO_2.$$

Acidum Hydrochloricum.—A solution of real hydrochloric acid, HCl, in water.

On heating chloride of sodium (common salt) with sulphuric acid, it yields a colourless gas, which, if expelled into the air, forms a steamy fume, owing to the presence of moisture. This gas dissolves rapidly and readily when passed into water, forming the solution usually known as hydrochloric or muriatic acid, or spirit of salt. The sp. gr. of the official liquid is 1·16, and it contains 31·8 per cent. of HCl. The residue left in the flask or retort is acid sulphate of sodium.

$$NaCl + H_2SO_4 = NaHSO_4 + HCl.$$

Hydrochloric acid and all other soluble chlorides give, with solution of nitrate of silver, a curdy white precipitate, consisting of chloride of silver, AgCl, soluble in excess of ammonia, but insoluble in nitric acid.

[§ 11·48 grams mixed with half an ounce of distilled water, require for neutralization 100 c.c. of the volumetric solution of soda.]

$$1 \text{ mol. of } HCl\ (= 36{\cdot}5) + 1 \text{ mol. of } NaHO = NaCl + H_2O.$$

36·5 grams of hydrochloric acid gas would neutralize 1000 c.c. of the vol. sol. of soda, which contain 40 grams or 1 mol. of NaHO. 3·65 grams of HCl, or 11·48 grams of the liquid, will, therefore, neutralize the same amount, viz. 100 c.c. of the vol. sol. of soda. 11·48 of the liquid contain accordingly 3·65 of the gas:—what do 100 parts contain?

$$11{\cdot}48 : 100 :: 3{\cdot}65 : x. \qquad x = 31{\cdot}8 \text{ per cent.}$$

Commercial hydrochloric acid is liable to many impurities; *iron*, recognized by the colour, and by giving, when diluted, blue precipitates with ferro- and ferri-cyanide of potassium; *arsenic*, by giving, after dilution, a yellow precipitate with H_2S, also by tarnishing copper-foil boiled in it; *alkaline salts* ($NaCl$, Na_2SO_4, etc.), by leaving a residue on evaporation to dryness; *sulphuric acid*, by giving, with chloride of barium, a white precipitate; *sulphurous acid*, by the last test in the B. P., which is identical with that explained under Acidum Aceticum; *chlorine* or *nitric acid* would tarnish copper-foil, and would also dissolve gold-leaf. To ascertain if any gold has been taken up by the sample tested, add a few drops of a mixture of tin chlorides; purple of Cassius makes its appearance.

Acidum Hydrocyanicum Dilutum.—The official preparation is a solution of real acid, containing 2 per cent. It is prepared by distilling yellow prussiate of potash with sulphuric acid and water, and collecting the distillate in a receiver containing distilled water.

$$\underset{\text{Ferrocyanide of potassium.}}{2\,K_4(Fe''C_6N_6)} + 6\,H_2SO_4$$

$$= \underset{\text{Everitt's salt, or ferrocyanide of potassium and iron.}}{K_2Fe''(Fe''C_6N_6)} + \underset{\text{Hydrocyanic acid.}}{6\,HCN} + \underset{\text{Acid sulphate of potassium.}}{6\,KHSO_4}.$$

At the end of the operation the retort contains a solution of bisulphate of potash, mixed with a precipitate of the double ferrocyanide, which is generally green, from the action upon it of the air in the apparatus. The distillate is diluted with water, till 100 grains of it give, when mixed with excess of nitrate of silver, a precipitate of cyanide of silver, which, when washed and dried, weighs 10 grains.

$$\underset{27.}{HCN} + AgNO_3 = \underset{134.}{AgCN} + HNO_3.$$

From this equation 27 grains of HCN give 134 grains of AgCN; so that if the 100 grains of distilled liquid contain 2 grains, as they should, 10 (or more accurately, 9·926) grains of precipitate are obtained.

Hydrocyanic acid may be detected with certainty, even when present in minute quantity, by one of the following processes:—

a. [§ Treated with a minute quantity of a mixed solution of sulphate and persulphate of iron, afterwards with potash, and, finally, acidulated with hydrochloric acid, it forms Prussian blue.]

$$\text{I. } \underset{\text{Hydrocyanic acid.}}{6HCN} + \underset{\text{Ferrous sulphate.}}{FeSO_4} + \overbrace{2KHO + \underset{\text{Potash.}}{4KHO}} + xKHO$$

$$= \underset{\text{Ferrocyanide.}}{K_4(Fe''C_6N_6)} + \underset{\text{Sulphate.}}{K_2SO_4} + \underset{\text{Water.}}{6H_2O} + xKHO.$$

$$\text{II. } \underset{\text{Ferrocyanide of potassium.}}{3K_4Fe''C_6N_6} + \underset{\text{Ferric chloride.}}{2Fe'''_2Cl_6} + xKHO + xHCl$$

$$= \underset{\text{Ferric ferrocyanide, or Prussian blue.}}{Fe'''_4\,3(Fe''C_6N_6)} + 12KCl + x\overbrace{(KCl+H_2O)}.$$

b. Mixed with a few drops of solution of sulphur in sulphide of ammonium, evaporated to dryness, and then moistened with weak solution of ferric chloride, a red stain of ferric sulphocyanide is produced.

$$\text{I. } \underset{\text{Sulphide of ammonium.}}{(NH_4)_2S} + \underset{\text{Hydrocyanic acid.}}{HCN} + S$$

$$= \underset{\text{Sulphydrate of ammonium.}}{(NH_4)HS} + \underset{\text{Sulphocyanide of ammonium.}}{(NH_4)CNS.}$$

$$\text{II. } \underset{\text{Ferric chloride.}}{Fe_2Cl_6} + \underset{\text{Sulphocyanide.}}{6(NH_4)CNS}$$

$$= \underset{\text{Chloride of ammonium.}}{6NH_4Cl} + \underset{\text{Ferric sulphocyanide.}}{Fe_2(CNS)_6.}$$

Alkaline cyanides give no precipitate with a small quantity of nitrate of silver. So long as the proportion of nitrate of silver to cyanide is not more than one molecule to two, a double salt is formed, which remains in solution.

$$\overbrace{KCN+KCN}+AgNO_3 = \overbrace{KCN,AgCN}+KNO_3.$$

When even the minutest quantity of nitrate is superadded, a white precipitate of cyanide of silver begins to form.

$$KCN, AgCN + AgNO_3 = 2AgCN + KNO_3.$$

Upon this fact is based the official quantitative test. 10,000 c.c. of the vol. sol. of nitrate of silver contain 170 grams (= 1 molecule) of the silver salt, and if this quantity were added to 2 molecules or 54 grams of HCN, rendered alkaline by the addition of soda, the liquid would remain clear, but the next drop would produce a precipitate of cyanide of silver.

Now, if 10,000 c.c. indicate the presence of 54 grams of HCN in the liquid tested, the employment of 100 c.c. in the same manner, will indicate $\frac{1}{100}$ of 54, or ·54 gram of HCN.

The quantity of dilute acid which, according to the B.P., contains this amount is 27 grams, which corresponds to two per cent. of real acid; for if 27 contain ·54 what will 100 contain?

$$27 : 100 :: \cdot 54 : x.$$
$$x = 2.$$

Hydrocyanic acid is very liable to decomposition, but is more stable when mixed with a little mineral acid; much of the commercial preparation therefore contains a minute proportion of HCl. The chief products of its spontaneous change are formiate of ammonia—

$$HCN + 2H_2O = NH_4CHO_2,$$

and a brown substance, the nature of which is not understood.

Hydrocyanic acid is also found among the products of the action of water upon bitter almonds. These seeds contain a crystalline principle, *amygdaline*, and another substance of ill-defined albuminoid character, the composition of which is not known, called emulsin or *synaptase.* When both are dissolved in water, the latter, by some unexplained influence, causes the amygdaline to decompose.

$$\underset{\text{Amygdaline.}}{C_{20}H_{27}NO_{11}} + 2H_2O$$

$$= \underset{\text{Essential oil of almonds.}}{C_7H_6O} + \underset{\text{Glucose.}}{2C_6H_{12}O_6} + \underset{\text{Hydrocyanic acid.}}{HCN.}$$

On distilling the mixture, the essential oil and most of the hydrocyanic acid pass over. The aqua laurocerasi, B.P., contains HCN, produced by a reaction probably similar.

Review.

CHARACTERISTICS OF THE PRINCIPAL WINES WE DRINK. By A. DUPRÉ. London: Robert Hardwicke, 192, Piccadilly.

In a short pamphlet, reprinted from the 'Popular Science Review,' Dr. Dupré has given some interesting particulars relating to the common wines to be met with in the wine trade in this country. Towards the end of the pamphlet we notice a very complete table of analyses of Hock, Claret, Hungarian wine, Greek wine, Sherry, Port, and Marsala. The analyses are of recent date, and by himself; and, even if there were nothing else in the paper, they would render it a valuable contribution towards the chemistry of wine.

ESSAY ON THE CULTIVATION OF CINCHONA. By CH. BELANGER, Director of the Botanical Garden of Martinique. Reprinted from the 'Revue Maritime et Coloniale,' April, 1870. Paris: Paul Dupont, 41, Rue Jean-Jacques Rousseau.

DIE PFLANZENSTOFFE IN CHEMISCHER, PHYSIOLOGISCHER, PHARMAKOLOGISCHER UND TOXIKOLOGISCHER HINSICHT. By Drs. AUG. and THEOD. HUSEMANN. Second Part. Berlin: Julius Springer. 1870.

Metrical System.—Of all irregular weights and measures, those in use by pharmacists in different parts of the world were perhaps the very worst. It is with especial satisfaction, therefore, we learn from Buchner's 'Repertorium für Pharmacie,' that in the new Austrian Pharmacopœia, which was issued a few months ago, the metrical weights and measures are adopted. The practice in Austria will of course determine that of the whole of South Germany.

[*** It is high time that a similar step were taken in this country, and in America, where even worse confusion reigns than here in regard to weights and measures.—Ed. Ph. J.]

British Association for the Advancement of Science.—This year's meeting of the Association will be held in Liverpool, on the 14th of September, under the presidency of Professor Huxley, and it is expected to be very well attended. We desire to call the attention of our readers to the fact that, in connection with the British Pharmaceutical Conference held during the same week, there will be an exhibition of objects, illustrating pharmaceutical processes and products. Intending exhibitors are requested to forward, as soon as possible, a description of the articles to be shown, with the space required, to the Honorary Secretary, Mr. Edward Davies, Royal Institution, Colquitt Street, Liverpool.

Preparation of Chloral Hydrate.—D. Müller and R. Paul point out that the chief point to be observed is the passage of chlorine into absolute alcohol until this is converted into a crystalline mass. The chlorine must of course be dry, the current must be copious, and it should be kept up for sixty or seventy hours.

The product thus obtained abundantly and almost pure, should be sublimed into two funnels set one above the other. The spout of one funnel is inserted into a small flask containing the hydrate, and the spout of the other serves as a discharging-tube.—*Report of the German Chemical Society.*

Obituary.

Peter Francis William Boullay, the well-known French pharmaceutist, died in November last year. He was born at Caen in 1777, of a Protestant family, and early devoted himself to the practice of pharmacy. He worked in Vauquelin's laboratory. In the year 1798 he opened a druggist's shop in one of the wealthiest and most frequented quarters of Paris. In 1803 he became a member of the Société de Pharmacie. In 1809, associated with four other pharmaceutists, MM. Boudet, Planche, Cadet, and Destouches, he commenced the 'Bulletin de Pharmacie,' the oldest and most esteemed organ of pharmacy in France, which under another name, viz. 'Journal de Pharmacie et de Chimie,' has survived to the present day.

Boullay was connected with, and took an active part in that Journal for sixty years. Among his contributions to science, should be mentioned his researches on different ethers, viz., on hydrochloric, arsenic, and phosphoric ethers, which he was the first to prepare. He discovered picrotoxin. Conjointly with Boutron, he investigated the Tonka-bean.

On the foundation of the French Academy of Medicine, he was named a member, and for the space of fifty years contributed to the memoirs of that learned body.

June 21; Mr. Benjamin J. B. Crampton, chemist and druggist, New Wortley, Leeds. Mr. Crampton and his wife were passengers by the Great Northern excursion train which met with the terrible accident near Newark, and both were killed on the spot.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the Editor, 17, *Bloomsbury Square.*

Chemists' English: An Echo of "A Voice from the Preliminary."

Sir,—In a recent issue of the 'Pharmaceutical Journal' attention was directed to the numbers who failed to pass the late Preliminary Examinations; and suggestions were offered for preventing these failures in future. Many besides candidates for examination might pay attention to these suggestions with advantage. With the exception, perhaps, of "historic houses," most chemists have occasionally to frame some kind of prospectus or trade circular; but whatever may be the commercial value of such a means of advertising when respectably carried out, it cannot be otherwise than derogatory to issue, as is frequently the case, productions positively ungrammatical, or disfigured by bombastic phraseology. Chemists in general appear unable to describe their qualifications and goods without mutilating the Queen's English or defying Lindley Murray. But for the efforts of the Pharmaceutical Society, our trade would probably have continued to exhibit that low type of intelligence which has for years past placed it, as a whole, considerably below other trades of corresponding social position.* Thanks, however, to the success which has attended these efforts, the once fashionable outcry that education, if not positively harmful to our interests, was of little practical utility, is no longer heard; and the results of this alteration in sentiment, and of our improved legal position, are becoming gradually manifest.

If, however, any difference of opinion might exist as to the relative practical value of the examinations of the Society, the Preliminary (especially as remodelled of late) may certainly, as regards the career of the future chemist, worthily take its place side by side with the higher examinations, although it stands only at the threshold of his professional curriculum. In any undertaking almost everything depends on a good beginning; nothing, therefore, can be more important than satisfactorily "to determine that a youth has been fairly educated for the business upon which he is about to enter." Years ago, as many now in business can testify, the Preliminary Examination was, in many cases, little more than a form; and we cannot, therefore, but admire the decision of the Board of Examiners to remodel it by introducing *written papers*, the results of which can be, in all cases, fairly and accurately determined at head-quarters. This change will undoubtedly in time have the very desirable effect of introducing into the trade a superior class of apprentices, and of deterring those from entering it who are educationally unfitted for its duties, to the manifest advantage of masters, pupils, and the public. Let intending candidates and apprentices, then, give good heed to this timely "Voice from the Preliminary" (nor let employers disregard it),—remembering that, besides enabling them to pass with credit, it will prove of great practical service to them betimes to rub up "their forgotten schoolboy's knowledge," and, as far as possible, to keep it always bright.†

---

* What tradesman, for example, would think of carrying on his business without books? Yet the writer was informed not long since by the widow of a chemist lately deceased, that her husband *never* kept any books; and, on mentioning the fact to a wholesale druggist, he observed that it was by no means unusual amongst chemists. What was still more remarkable, however, was that the chemist in question left no receipt-books or memoranda of any kind, but, as his widow observed, "kept all his receipts *in his head*;" she added, and certainly not unjustly, "he was such a *clever* man."

† With reference to the stringency of the Preliminary Examination, so much objected to at the late Annual Meeting, it may be observed here, that while it is certainly right to show some leniency, for a time at least, to those who have

finished their apprenticeship, or even to apprentices who have been two or three years in the trade, it is clear that some period must be put to this sort of concession, or the object of increased stringency will not be attained. There will always be the same inducements for masters in country places to take lads of imperfect education, and keep them at "porter's work" from morning to night. True, there is, in such cases, neither time nor inclination for study; but whose fault is this? Is it not partly the masters'? And is it not a legitimate effect of the more stringent Preliminary Examination to *compel* employers to take no apprentices who have not had the requisite schooling, and to allow them *some* time at least for study? This is quite as incumbent on employers in the country as in London, for, though there may be more rough work in the provinces, country chemists have duties to perform quite as responsible as those falling to the lot of their London brethren. As a practical suggestion, it might be worth consideration whether, in time, it could not be made compulsory for every intending apprentice to a chemist to pass the Preliminary before his indentures were signed. Given a suitable education, this is no doubt the period when it would be most easily passed; and, where necessary, it would be better to wait a few months before entering on the apprenticeship, than to do so without having passed it.

On the principle that "one fact is worth a hundred arguments," and that "example is better than precept," a few samples of chemists' English, copied *verbatim* from a couple of circulars which have casually fallen into the writer's hands, are appended, in illustration of the above remarks.* They may serve to show the practical value of some acquaintance with English composition in compiling an ordinary trade circular.

Circular No. 1 (issued by A. B.) is remarkable rather for the peculiarity of its diction than for anything positively ungrammatical. Under the heading "Family Medicines," the first article named is described as follows:—

"A. B.'s Family or Antibilious Pills.

"For obviating habitual costiveness, removing giddiness, sick headache, loss of appetite, indigestion, flatulency, heartburn, nausea, nervousness, etc., arising from biliary derangement, visceral obstructions, etc.

"They are compounded entirely from the vegetable materia medica, *therefore require no keeping in the house.* . . . By taking *two or three doses* of these pills, *all* the above symptoms are speedily removed; an unusual degree of serenity pervades the mind . . . ."

And well it may after such a wholesale exorcism of almost "all the ills that flesh is heir to" as is here suggested. The ludicrous inequality of cause and effect clearly shows that the laws regulating the action of *physic* have (in this case at least) no relation to those of *physics.* Another marvellous remedy is—

"A. B.'s Pectoral Cough Mixture.

"This invaluable Medicine has the extraordinary (?) property of immediately relieving Coughs, Colds, Hoarseness, Difficulty of Breathing, etc. It immediately allays the tickling which *provokes* coughing, and removes the unpleasant sensation of *wheezing,* by dissolving the congealed phlegm, and freeing the vessels of the lungs from *acrimonious humours.*"

Towards the close of the circular the public are informed that "Leeches and Medicines, or any *article of necessity,* may be had on Sundays," etc.; and this curious production ends thus: "Every advice given respecting the uses and proper doses of Medicines. Although many of the most useful remedies have not received notice in the above List, it is not for the want of appreciation of their value or usefulness, but simply *from their number being impossible to enumerate all,* but *all* Medicines in general use, and the more recently introduced Scientific Remedies are kept in stock, or will be procured upon the shortest notice."

Circular No. 1 is, however, perspicuity itself compared with Circular No. 2, issued by C. D. The preamble strongly reminds one of the incoherent evidence of an old woman in a police court; it reads thus:—

"C. D. respectfully presents this List of Articles, soliciting *your* favours, and assuring *you* that no exertion shall be omitted to merit *your* patronage and recommendation.

"Personal attention is paid to the Compounding of Physicians' Prescriptions and Family Recipes, *and forwarded* with the least possible delay, *combined with* the greatest care in dispensing and economy in charges."

The following extracts speak for themselves:—

"Digestive Dinner Pills.

"Composed of Rhubarb, Ginger, Camomile, etc.

"They not only aid the Digestive Organs in performing their duty, but will also, *if persevered with,* restore them to their *original* strength."

"Succus Taraxaci.

"The expressed Juice of the Dandelion.

"Recommended for morbid conditions of the Liver and *Organs, subservient to Digestion,* and promoting a healthy secretion of bile."

[C. D. does not inform his customers *what* organs dandelion is good for, whether barrel or chamber; but as they are spoken of in close connection with a *liver,* probably the latter.]

The circular appears to reach its climax, however, in the annexed unambiguous description of the symptoms indicating the use of a familiar pill:—

"Compound Rhubarb Pills.

"Prepared *in accordance* with the British Pharmacopœia, *from the choicest Drugs.* A mild and cordial Aperient, particularly adapted to persons of sedentary habits, whose *confinement* produces Dyspepsia and *confined bowels.*"

We are then informed that "broken Chilblains, Chapped Hands and Lips, or any Irritation of the Face and Skin, are cured" by "Camphorated Cream,"—as the blackbeetles are said to be destroyed by the phosphorous paste,—"*in one night;*" also that "Arnicated Chilblain Liniment, *if* used *as soon as* the itching sensation is felt, will relieve on the *first* application," and that "Gout and Rheumatic Drops" *always* relieve.

The antithesis in the following is remarkably abrupt and striking:—

"Rosemary and Cantharidine Hair Wash.

"For preserving, cleansing, and *preventing the Hair falling off.*

"Confidently recommended for *producing a new Growth of Hair.*"

Two heads (though only *one* wash) are evidently referred to here, one on which there is merely *decadence* of growth and one *absolutely* bald; otherwise there would be a redundancy of properties in this wonderful wash, since by "preventing the Hair falling off," its power to "produce a new growth" would not be called into requisition;—unless (happy thought!) the meaning is that where there *is* hair it *keeps* it on, and where there *isn't* hair it *puts* it on. C. D. is clearly another Rowland, if he does not out-Rowland Rowland.

Although the above extracts thus irresistibly provoke a somewhat humorous treatment, they are not quoted in any sinister spirit, but as illustrations of the practical value of preliminary studies.

Perhaps the chemists in question did not compile these circulars; in that case, however, their dependence on others is a virtual confession of ignorance, while the fact that the circulars bear their names amounts to an indorsement of their contents. With reference to trade interests, it will probably be admitted that if people *do* read circulars (and it is useless issuing them if they do not), the perusal of such as those here alluded to (especially the latter), by persons of fair education, would so tend to depreciate their opinion of the intelligence and capability of the chemists issuing them, as to render such very unwilling to trust them with the preparation of their medicines. It is true, the inference may be unsound, since many a man mixes medicines correctly who makes a frightful hodge-podge of the composition of words and phrases; yet it is a very natural one, and in the main correct. As a rule, it would not be either safe or reasonable, in cases where knowledge is required, to infer a *special,* apart from a *general* capability. Under these circumstances, therefore, a chemist practically acquainted with his business might possibly suffer quite unjustly; so that, rather than send out an ill-worded circular, it is far better to issue none at all.

Nor are the above remarks by any means intended as a slur upon the trade as a whole. It is most gratifying to know that it includes men of acknowledged scientific standing, and that, both amongst pharmaceutists and chemists and druggists, there is a goodly number possessing a high educational as well as commercial status, and that this number is daily increasing. At the same time, it must be acknowledged that specimens of chemists' English little better, in point of

* Both these circulars emanated from shops within the London postal district, A. B. styling himself (though not on the circular) pharmaceutical chemist.

style and grammar, than those given above might be found—for example, in the 'Pharmaceutical Journal's' advertisement sheet.

How frequently wholesale druggists begin or end thus! "With Messrs. —— compliments, soliciting the favour of *your* orders." This use of different persons in the same clause is a very common error.

To those (if there be any) who think accuracy in style of no moment in trade announcements, it is sufficient to reply that persons who make mistakes do not do so intentionally, and would never think of defending their errors on the ground of expediency. There is a sort of involuntary admission amongst mankind that it is a duty to be correct in language as well as in behaviour or morals. But a practical reply might also be given. In these railroad times men have scant leisure; that which reads easily and tersely *is* read; that which reads enigmatically and clumsily is misunderstood or passed over. Besides, there is the *indirect* effect of correctness or otherwise on reputation, which no one can afford to disregard.

Unfortunately, slipshod composition is not a speciality of the drug trade, but common to all professions, as a copy of the 'Times' will easily prove. It is not at all unusual to find even educational advertisements to which just exception might be taken on this score, while general announcements are frequently unintelligible, and sometimes positively nonsensical. In all such cases, no less than in trade circulars, a little attention to the phraseology and composition would be a great advantage to both advertiser and customer in the opinion of

Echo.

"Sic Vos non Vobis."

Sir,—I have anxiously read the reports of the General and Council Meetings, but, so far as I can learn from them, I have reason to believe that, except in the President's speech, there has been no notice taken of the continued and untiring labours for a quarter of a century of Messrs. Squire and Morson as members of the Council, of the Board of Examiners, and each as three times President of the Society.

I do not pretend to know how regularly these gentlemen have attended the various Committee meetings of late years. but I can testify that they have been most active, and well fitted for the honourable posts they have filled; and I can also most confidently assert that, but for the zeal and perseverance of such as these, the Pharmaceutical Society would have sunk into oblivion.

I should like some of the readers of this Journal to calculate how many hours, at the lowest estimate, these gentlemen have devoted to Council meetings, examinations, etc. etc., at Bloomsbury Square; and without considering the money value of their time (which to men in business is great), I would remind them how large a proportion of their ordinary term of existence has been surrendered freely in our service, by forming, carrying on, and permanently establishing a system of education which otherwise we should not been able to avail ourselves of.

I am, Sir, yours truly,
Charles J. L. Russell.

Windsor, July 9th, 1870.

Anonymous Correspondence.

Sir,—I think Mr. Rimmington has shown a great amount of needless alarm on the subject of anonymous correspondence. I believe that it is the best way of bringing "juvenile talent" out, to let the writers please themselves with regard to the name. A great amount of useful information would be missed, were the edict, "no anonymous correspondence allowed," sent forth by the editor. Many young men have not the courage to write their first articles when compelled to subscribe their real name.

I remain, Sir,
"Juvenis et Imperfectus."

Barnsley, July 6th, 1870.

Dispensing by Medical Men.

Sir,—I have read with much interest the able letter of your correspondent "T. Mills, A.P.S." in a recent number of the Journal.

He forcibly sets forth the pitiable condition of a large number of chemists, who, though fully competent for their proper work, find it extremely difficult to eke out a subsistence, in consequence of the system (most objectionable as I think) of dispensing their own medicines, which is adopted by about 90 per cent. of the faculty.

I shall not here enter into the many arguments which can be urged against this system, but with great respect I would invite my *confrères* to unite together, and make a vigorous effort to bring about a better state of things.

It appears to me, that as a sweeping measure of medical reform will soon be passed by Parliament, chemists should agitate for *their rights*, and form themselves into some kind of "Chemists' Defence Association," the main object of which should be, to procure a legislative enactment by which medical men shall be prohibited (except in special cases) from dispensing their own medicines, and be compelled to write their prescriptions, which shall be compounded by duly qualified chemists. It is really absurd that gentlemen, to be registered by Act of Parliament as chemists and druggists, should go through a course of education in chemistry, pharmacy, etc., be obliged to pass a strict examination by the Pharmaceutical Society, and yet have hardly any opportunities of engaging in their peculiar work, viz. the compounding of medicines. This is an anomaly which should not be allowed to exist much longer. I earnestly hope that the aggrieved chemists will consider this matter, and should any of them wish to communicate with me, I beg to say, that letters addressed to me, care of Mr. Judd, Chemist, Alcester, Redditch, shall receive prompt attention.

Your obedient servant,
D. Carroll, LL.B., etc.
Registered Chemist (Exam.)

June 13th, 1870.

Inquirer (Ipswich).—Under the Pharmacy Act of 1869, it is unlawful for any one, not being a registered chemist and druggist, to sell retail vermin-killers containing any of the substances therein referred to.

Coating Pills.—An article on this subject will be found in Vol. III. s.s. p. 562.

A Minor Associate (London) desires to find a good test for detecting the presence of geranium oil in otto of rose.

R. M. S. (Islington).—Fresenius's work is undoubtedly the best.

W. H. Smith (Brighton).—The preparation of nitrite of amyle is described in the 'Laboratory.' It may be obtained from Robbins (Oxford Street) or Bullock.

A Constant Reader (Slough) desires to be informed as to the probable success of a pharmacist emigrating to Canada with a capital of £500 or £600 and a small family, cost of transit, etc.

I. W. (Sheffield).—1. Sulphur is used in making mercurial plasters, with the object of effecting the subdivision of the metal. 2. Tannic acid is sparingly soluble in *dry* ether, as stated under the head "Characters and Tests;" but with ether containing water it forms a thick solution. See Watts's 'Dictionary of Chemistry,' vol. ii. p. 760. 3. We are unable to answer this.

An Assistant (Leeds) writes to protest against the exclusion of anonymous correspondence, and urges that, in many cases, the writers' only fault may be excessive modesty.

Irwell (Hull).—The iron that will not dissolve may be used again, if necessary.

A. Z. (Liverpool) is desirous of obtaining formulæ for preparing fruit essences, such as plum, raspberry, etc., which are mixtures of ethers and essential oils.

"An Age of Progress."—Letters on this subject have been received from Mr. T. P. Gostling, Diss, Norfolk; J. B., Hull; A Provincial; and Mr. R. Goodwin Mumbray, Richmond.

W. D. Gibb (Winchester).—Received with thanks. Shall have attention.

A Country M. P. S.—We should be glad to hear from the writer, in confidence, on the subject of his excellent letter.

Eugene Rimmel.—Received with thanks. Too late for this week.

F. G. Homer (Birmingham).—Handed to the Secretary.

Voster Fide (Yarmouth post-mark).—We shall be glad to hear further from the writer.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary*, 17, *Bloomsbury Square, W.C.*

ALCOHOLIC FERMENTATION.*

BY BARON VON LIEBIG.

Some years ago Pasteur inferred, from a series of experiments as to the behaviour of yeast in vinous fermentation,† that the explanation given by me of the action of yeast on sugar was destitute of foundation. I assumed that the breaking up of the fermentable substance into simpler compounds was to be referred to a process of internal change obtaining in the ferment, and that the influence of the ferment upon the fermentable substance, would continue or cease just as the metamorphosis of the ferment continued or ceased.

The transposition of the sugar atoms in the sugar molecule would thus be a consequence of the decomposition or dislocation of one or more constituents of the ferment,—it would take place only while the two were in contact.

Pasteur considers that "the chemical change in fermentation is essentially a phenomenon accompanying the vital activity of the yeast, beginning and ending with this: vinous fermentation never takes place without simultaneous organization, development, and reproduction, *i.e.* without continued vitality."‡ He regards fermentation as a chemical process, accompanying and dependent upon a physiological process. This view was entertained more than twenty years ago, and, although the nature of yeast was known to me when I put forward my view as to fermentation,§ the physiological process did not come within my province; my endeavour was to refer the chemical change of the sugar to some simple expression comprising all similar processes.

Pasteur has not gone into that which I sought to explain, viz. the disintegration of the fermentable substance in contact with yeast-cells, and, inasmuch as he refers us to "vital activity" as the cause of fermentation, he substitutes, for an explanation, a fact which requires explanation itself.

From the chemical point of view, which I cannot abandon, "vital activity" is a "state of motion," and, in this sense, Pasteur's view is neither inconsistent with nor contradictory of mine. It is matter of observation, I say, that yeast undergoes alteration when kept under water, and ultimately putrefies like animal substances. The commencement and termination of this process indicate that the parts of the yeast are in a state of transposition or motion, terminating with conversion into other compounds that are more simple and do not change further while air is excluded. In this case equilibrium is established when the motion ceases. The state of motion is quite independent of joint action in other substances. It is also observed that a great number of substances undergo alteration in the arrangement of their atoms when in contact with yeast, new substances being produced. Thus, for instance, sugar behaves as if it were a part or constituent of the yeast-cells; there is a transposition or dislocation of the sugar atoms.

Comparing, as I did, the action of the ferment on fermentable substances, with the action of heat on organic molecules, motion of the atoms is evident in both cases. Acetic acid is separated by heat into carbonic acid and acetone, just as sugar is separated by yeast into carbonic acid and alcohol. In the former case the carbonic acid contains two-thirds of the oxygen, the acetone all the hydrogen of the acetic acid while, in the latter case, the carbonic acid contains two-thirds of the oxygen, and the alcohol all the hydrogen of the sugar.

The development of a plant—the formation and increase of yeast—is dependent on the assimilation of food which is internally converted into parts of the living organism; but in fermentation there is, so to speak, an action outwards upon substances that are resolved into products not serviceable for the living organism. Obviously, vital action and chemical action are phenomena which must be considered separately in seeking to explain fermentation.

The view that the decomposition of sugar in fermentation is due to the development and increase of the yeast-cells, is opposed by the fact that yeast causes fermentation in a pure solution of sugar, for yeast consists chiefly of a substance containing nitrogen and sulphur, besides phosphates, which could not be furnished by the sugar. Moreover, beer-yeast causes a similar decomposition of other substances besides sugar; malate of lime is thus converted into carbonic acid, acetate, carbonate, and succinate of lime.

Hitherto sugar fermentation is the only case in which the formation of yeast, capable of separating sugar into alcohol and carbonic acid, has been observed. Malic, citric, and other acids contain no sugar, but they are decomposed like sugar by beer-yeast, and if its influence were due to the physiological process, it should have been increased and developed in these cases also.

Salicin also is decomposed by yeast into saligenin and salicylic acid, and a similar separation of salicin is caused by emulsin, without any recognizable physiological process being concerned in the change.

Emulsin acts upon salicin and amygdalin in like manner, its effects being recognizable in a few minutes by the new products,—in the case of salicin, by the violet coloration with perchloride of iron; in the case of amygdalin, by the formation of Prussian blue.

In the decomposition of amygdalin by emulsin, it is known that water takes part; only so much amygdalin is decomposed as corresponds to the water necessary for dissolving the bitter almond oil produced; any excess remains intact, but, if more water be added, there is further decomposition. Emulsion of sweet almonds, which may be regarded as a strong solution of emulsin, undergoes active vinous fermentation when mixed with grape-sugar.

If the decomposition of salicin by yeast be ascribed to the physiological process of growth and development of yeast, the action of emulsin upon salicin has still to be explained, and, if it be assumed that in this case the readily alterable sulphuretted and nitrogenous constituent of the sweet almond has caused the change, there is also a similar substance in yeast. Those substances are also alike in losing their power to excite fermentation when boiled with water.

But if substances containing sulphur and nitrogen, like emulsin, are, by reason of alteration in the arrangement of their atoms, capable of inducing change in other organic molecules, so that they separate into new products,—there is reason for suspecting that in the action which yeast exercises upon sugar, its sulphuretted and nitrogenous constituent plays a similar

* Read at a meeting of the Bavarian Academy of Sciences.

‡ *Ibid.* p. 359.
§ See Liebig's 'Letters on Chemistry.'

part. That being the case, it remains to explain what the relation of the physiological process in the formation of yeast may have to this substance, which obviously acquires its peculiar power of exciting fermentation only when it becomes a constituent of yeast.

It might be that the physiological process had no other relation to fermentation than that of determining the production of the material which induces the alteration of sugar and other organic molecules, by an action peculiar to itself,—like that of emulsin upon salicin or amygdalin. In that case the physiological process would be necessary for the production of that material, but it would have no further connection with the phenomena of fermentation.

Some experiments I have made in this direction will, perhaps, contribute towards the elucidation of the subject.

There is no doubt as to the nature of beer and wine yeast. It is a form of development of various fungi, and, when washed, consists of cell-membrane enveloped in primordial vesicle, a granular mucous substance, protoplasm, and a watery cell-liquid lying in the protoplasm as drops of various size. "By digesting in distilled water the globules increase in size, sometimes until their outer surfaces nearly touch the cell walls. This result is connected with the swelling up of the yeast-cells, and, like it, is due to membranous diffusion, by which water gains access to the cells, while the cell contents escape into the water."*

"Solution of iodine colours the cells faintly yellow; sugar and sulphuric acid produce a scarcely more distinguishable rose colour, indicating probably that the amount of albuminous substance has been considerably reduced by the action of water.†

I am in doubt whether the substance extracted from yeast by water is really albuminous. When one litre of fresh pasty yeast is washed by decantation four times in succession with six or eight times its volume of water, and the residue digested with four litres of water for three or four hours, only a small quantity of organic substance is extracted, less than 350 milligrams per litre of water, and the power of the yeast to excite fermentation is scarcely at all reduced. When the washed yeast is left for a long time with its own volume of water, the amount of organic substance in the water is increased tenfold, and what is thus extracted appears to be produced by decomposition of a constituent of the yeast. This substance communicates very remarkable properties to the water. Crystalline cane-sugar dissolved in it is rapidly converted into grape-sugar. Even within a few minutes Fehling's test gives a copious precipitate of suboxide of copper. The liquid has a very slight acid reaction, is without taste or colour; with basic acetate of lead and tannin it becomes slightly milky; after standing for some days exposed to the air it loses its transparency, and a white flocculent precipitate is formed.

To form some idea of the action of this organic substance on cane-sugar, I dissolved various quantities in the yeast-water, and estimated the grape-sugar formed after twenty-four hours. It appeared that 25 grm. dissolved in 100 c.c. was fully converted within twelve hours. This 100 c.c. of solution contained ·39 grm. of the organic substance, and I believe that a much larger quantity of sugar was converted in the same liquid. By heating this liquid to boiling it entirely lost its power of affecting sugar.

There can scarcely be any doubt as to the cause of this action, for yeast-water contains material in a state of change, and the conversion of cane-sugar into grape-sugar must be determined by that state of motion. The particles of cane-sugar behaved as if they were parts or constituents of the nitrogenous material, and they underwent transposition. Contact with a very small quantity of this changing material produced the same effect as contact with mineral acids,—the same effect as powerful chemical affinity.

A similar phenomenon is the action exercised by ethyl aldehyd upon cyanogen in aqueous solution; a very small quantity of aldehyd added to this solution determines the formation of oxamide by the union of the cyanogen with two atoms of water. Evidently the aldehyd (part of which is converted into a substance resembling acrolein during this change) produces an effect which consists in a rearrangement of the elements of cyanogen with those of water. Schmit and Glutz have recently observed that contact with strong hydrochloric acid causes the conversion of cyanogen into oxamide in the same way that it converts cane-sugar into grape-sugar. So likewise salicin is broken up by dilute sulphuric acid in the same way as by emulsin.

The nitrogenous substance produced in the germination of many cereal grains, and capable of converting starch into grape-sugar and dextrin, also loses this property when heated to the boiling-point of water. Emulsin acts upon salicin and amygdalin; helicoidin is converted by it into salicylic acid, saligenin, and sugar; arbutin into hydrochinon and sugar; but emulsin does not act on starch or cane-sugar. Diastase acts on starch, not on amygdalin; the substance in yeast-water acts upon cane-sugar, not on starch. A number of other substances act in a similar manner. Saliva acts on starch the same as diastase from barley; it decomposes salicin like emulsin into sugar and saligenin. The pancreatic juice contains a substance which converts starch into sugar, and fats into glycerin and fatty acids. Pepsin belongs to the same class. All these substances are nitrogenous; they all possess the character of becoming inert when heated to the boiling-point of water, and of disappearing after a short time. These substances differ considerably in composition, though they act in like manner; but each has its own peculiar mode of action, proving that this takes place in different directions.

The action of the substance contained in yeast-water is evidently different from that of yeast itself.

None of the chemists who have investigated the composition of yeast have obtained concordant results by analysis. Mitscherlich found 47 per cent. carbon, Schlossberger 50 per cent.; the former found 10 per cent. nitrogen, the latter 12·5 per cent. Reichenbach found 34·57 per cent. carbon and 7·41 nitrogen in four determinations with yeast dried at 100° C. This yeast was very active in the moist state. The composition of yeast may be said to vary from day to day, and this is probably a sure sign of the change that it undergoes incessantly.

Yeast contains sulphur as a constant constituent, and it evolves sulphuretted hydrogen during putrefaction. Mitscherlich found ·6 per cent. sulphur. Determinations in my laboratory with dry

* Lermer.

† According to Dr. Lermer's microscopic examination.

yeast gave ·685, in another case ·568,* and a third ·387 per cent.† The amount of ash also varies in yeast; it averages from 7 to 8 per cent., and contains much phosphate of lime, which is evidently in a state of combination similar to that in cereal grain, for it cannot be extracted by washing.

Two samples of yeast-ash gave the following results:—

	I.	II.	Mitscherlich.
Phosphoric Acid	44·76	48·53	59·3
Potash	29·07	30·58	28·3
Soda	2·46		
Lime	2·39	2·10	12·5
Magnesia	4·09	4·16	
Silica	14·36		
Chlorine, Carbonic Acid, Peroxide of Iron	2·12		

These are the same constituents, and nearly the same proportions, as in the ash of wheat and rye; after deducting silica, they are the same as in the ash of barley. Other fungi, such as truffles and the morel, contain a larger amount of potash.‡

	Tuber cibarium.	*Morchella esculenta.*
Phosphoric Acid	32·96	39·03
Potash	54·51	49·51
Lime and Magnesia	22·83	18·48
Sulphuric Acid	1·17	2·98

The deficiency of sulphuric acid in yeast-ash is remarkable; probably it is explained by the preponderance of phosphoric acid. The ash of ordinary champignons (*Agaricus campestris*) contains 24·29 per cent. of sulphuric acid, and only 15·43 per cent. of phosphoric acid.§

Fungi live as parasites on organic substances produced in the organism of other plants. Their spores have the same relation to the dead plants or animal remains, and to solutions containing their chief constituents, as the blossoms of annual plants (cereals, for instance), which have collected in the growing seeds, the substances contained in the leaves, stem, and roots. Just in like manner the protein substances, phosphates, etc., still remaining in the dead plant-remains, are transferred into the developing fungi, and acquire the form of albumin, legumin, sugar, mannite, cellulose, etc., by the influence of the organic action of the fungi. In decayed oak-wood, Schlossberger|| found scarcely a trace of phosphates, while the parasitic fungus (*Dædalea quercina*) growing on it contained a considerable amount. The instability of yeast when kept is well known: when left in a moist, pasty state, in a cool place, evolution of gas sets in. This gas is carbonic acid free from nitrogen. In the pasty yeast funnel-shaped hollows are formed, from which the gas escapes as from a crater; most of it, however, dissolves in the water, and evaporates with this. When the temperature of the moist yeast is raised, the evolution of gas is more marked; a froth is formed on the surface of the liquid, and the transformation of the yeast is accelerated. Even at 30° or 35° C. a true and almost violent fermentation takes place, just as in a solution of sugar that is mixed with sufficient yeast, and this evolution of gas goes on till the fermentation is ended.

Besides carbonic acid, this yeast fermentation yields another volatile product, viz. alcohol. This has been observed by both Pasteur and Béchamp. Pasteur has also found that when very little sugar is fermented with a great deal of yeast, more alcohol is obtained than corresponds to the sugar, and hence he inferred that alcohol must be produced from the yeast. Pasteur explains this phenomenon as follows:—"The beer-yeast consisting almost entirely of cells that have attained their normal development, or are, so to speak, full grown, is brought in contact with sugar, its life is renewed,—it sprouts. This is a well-known fact. If the liquor contains sugar enough, the buds develope; they assimilate sugar, and the albuminous material of the mother cells. In this way they gradually attain a certain bulk. This is a true picture of ordinary fermentation. If, on the contrary, we suppose the sugar to be insufficient for converting the first shoots into perfect cells, or even into fully-formed visible cells, this has to be done in some way with mother-cells; and, since external food fails, the young buds live at the cost of the mother-cells."

He explained the fermentation of yeast itself thus: The life of yeast manifests itself as soon as its conditions, moisture and warmth, are suitable. Like a seed always ready to germinate, yeast lives when it has the requisite temperature and water, at the cost of its own substance, and its vitality manifests itself by the physiological act peculiar to it,—the formation of carbonic acid, alcohol, succinic acid, and glycerine. If this yeast be brought in contact with sugar, its vitality, which is never interrupted, continues; but in this case it completes its formation with a very much greater apparent energy, because in the same time life and organization have much increased."

I must confess that I am not able to form a clear conception of Pasteur's view as to the cause of the fermentation of sugar and yeast as represented in the foregoing passage. He has enriched the history of fermentation with a number of interesting facts, but in regard to the cause of the breaking up of sugar, our insight into the matter has not been thereby increased.

It can scarcely be doubted that the yeast developed in fermenting beer-wort consumes a certain quantity of sugar for the formation of its cell-membrane; but it remains wholly unintelligible how the conversion of sugar into cellulose—of one carbon hydrate into another with less water—can induce the breaking up of another part of the dissolved sugar.

In one of his experiments, Pasteur mixed a solution of 9·899 grm. sugar with 20 c.c. of a clear watery solution of yeast and a trace of yeast. The liquid fermented, and the yeast added to it as a seed increased considerably. After the sugar was completely decomposed, the yeast was weighed, and it amounted to 152 milligrams. According to Pasteur, yeast contains on the average 18·5 per cent. cellulose. Substituting for this 20 per cent. of sugar, there would have been 9869 milligrams of sugar decomposed in this case, and 30 milligrams of sugar consumed for the production of yeast. But it is scarcely possible to think that the physiological act of transformation of 30 milligrams of sugar into the substance of the cell-membrane of the yeast can have been the cause of converting 329 times as much sugar into carbonic acid and alcohol, or succinic acid, glycerin, and carbonic acid products, which take no further part in the vitality of the cell.

* Reichenbach.
† Dempwolff.
‡ O. Kohlrausch.
§ *Ibid.*
|| Ann. Ch. et Ph. lii. 115.

Pasteur's explanation of the fermentation of yeast alone, with production of alcohol and carbonic acid from its own substance, is still more obscure. If the yeast-cell sprouts like a seed, and bears shoots at a suitable temperature and moisture, the substance of the old cell may be used for the production of new cells; this is intelligible, but it still remains unexplained whence come the alcohol and carbonic acid. The action of the new cells can only be the action of the substance constituting the old ones which they have consumed in their formation.

(*To be continued.*)

BAOBAB.

Adansonia digitata, L.

BY M. C. COOKE.

The introduction of the baobab as a secondary article of materia medica into the Pharmacopœia of India, will be sufficient excuse for directing attention to this somewhat new remedial agent. The baobab-tree is a native of Senegal and Sierra Leone, and has been introduced into India, where it has become well established in several districts. Humboldt states that "the oldest description of the baobab is that of the Venetian Aloysius Cadamosto in 1454. He found at the mouth of the Senegal trunks whose circumference he estimated at 17 fathoms, or 112 feet. Perottet says that he had seen monkey-breadfruit-trees (baobabs) which had a diameter of about 32 feet, with a height of only from 70 to 85 feet. The same dimensions had been given by Adanson in his voyage (1748). The largest trunks of the monkey-bread-fruit-trees which he himself saw in 1749, some on one of the small Magdalena Islands, near Cape de Verd, and others at the mouth of the Senegal, were from 26 to near 29 feet in diameter, with a height of little more than 70 feet, and a top measuring upwards of 180 feet across. Adanson, however, makes the remark, that other travellers had found trunks having a diameter of about 32 feet. French and Dutch sailors had carved their names on the trunks in characters six inches in length. One of these inscriptions was of the fifteenth century, while all others were of the sixteenth. From the depth of the cuts, which are covered with new layers of wood, and from a comparison of the thickness of trunks whose various ages were known, Adanson computed the age of trees having a diameter of 32 feet at 5150 years. In the village of Grand Galarques, also in Senegambia, the negroes have adorned the entrance of a hollow baobab with carvings cut out of wood still green. The inner cavity serves as a place of general meeting, in which the community debate their interests." While, however, the bold calculations of Adanson and Perottet assign to the Adansonias measured by them an age of 5150 or even 6000 years, which would make them coeval with the builders of the Pyramids, or even with Menes, these calculations must be accepted with doubt.

"In appearance *Adansonia* is unlike any other known tree; the enormous dimensions of its trunks bear a striking disproportion to the other parts. It is not unusual to find a trunk not more than 12 or 15 feet from the root to the branches, with a circumference of 75 or 78 feet. The lower branches are very long, and at first horizontal, extending perhaps 60 feet; the consequence of which is that they bend down to the ground, entirely hiding the trunk, and giving the tree the appearance of a huge mass of verdure. The wood is very soft, even when in perfection, and is subject to a disease which may be compared to the very malady of which its celebrated discoverer died,—a sort of softening of all the hard parts, so that the least storm is sufficient to overthrow and dismember its enormous bulk. A curious practice prevails among the negroes, of hollowing its trunk out into chambers, and therein depositing the bodies of malefactors, or of persons to whom the usual rites of sepulture are denied. In this situation the bodies become dried up, and soon acquire the state of perfect mummies."

The fruit of the baobab is a large, oblong, downy pericarp, from 6 or 8 to 10 or 12 inches in length, and in shape somewhat resembling that of the cacao-tree, but even, and without the longitudinal furrows of that species. It is from 8- to 10-celled, but in a dry state the partitions seem to be only formed by tough stringy fibres. Each cell is filled with a pulpy substance, which, when old and dry, becomes pithy, and in this the seeds are immersed. They are kidney-shaped, brown, shining, hard, with a few pale dots.

Baobab has obtained some repute as a remedy in dysentery, for which Dr. Louis Frank has affirmed its efficiency. The part employed is the acid farinaceous *pulp* surrounding the seeds. The *rind* of the fruit, beaten up into a paste with water, is also recommended. Dr. R. F. Hutchinson considers that the action of the farinaceous pulp is due, not to its astringency, but to its virtues as a refrigerant and diuretic. The *bark* has been proposed as a substitute for quinine in intermittent fevers by Dr. Duchassaing, in decoction, one ounce of the bruised bark to a pint of water boiled to a third. Although not mentioned in the Indian Pharmacopœia, the dried *leaves* are said to have been found serviceable in diarrhœa, fevers, and other diseases. Amongst the African negroes the fruit is a common article of consumption.

It must be confessed that confirmation is required of the value of all the forms of this drug, but there seems to be no doubt of its possessing some virtue, and being worthy of more systematic and extensive experiment. A good figure is given in the 'Botanical Magazine,' plates 2791 and 2792.

PURE CAUSTIC SODA.

For some time past pure caustic soda, prepared from metallic sodium, has been an article of manufacture. The method by which the metal is made to yield caustic soda is as follows:—A deep silver vessel, of a hemispherical form, and capable of holding about four gallons of water, is employed. Into this vessel, which is cooled externally with a current of cold water, is placed a very little water, and upon the water is placed a cube of metallic sodium of about half an inch in diameter. The vessel is made to revolve so as continually to bring fresh portions of liquid into contact with the metal, and by this means explosion is avoided. When the first cube of metal has dissolved, and yielded a thick syrupy liquid, a little more water and a second cube of metal are added, and the reaction allowed to take place as before, the vessel being kept in motion all the time. In this manner several pounds of sodium may be worked up into soda. The thick syrup so resulting is next evaporated down, heated to redness, fused, and poured into a mould.

Inasmuch as the price of sodium is five shillings a pound, the yield of soda from a pound of the metal being about one pound and three-quarters, it is plain that the alkali so prepared must be cheap. The danger of explosions (which, however, do not occur when proper care is taken) necessitates the employment of skilled labour in this manufacture, and constitutes a very serious drawback to the commercial success of the process.

NOTE ON THE DIVISION OF POWDERS BY THE EYE.

The practice of dividing powders by the eye (instead of by the balance), so often resorted to in dispensing, is illustrated by the following examples, which we quote from the 'Medical Times and Gazette.'

A number of packets of patent medicines having been purchased, each separate powder in the packets was weighed with the following results:—

Patent Medicine A.

Packet I.	Grains.	Packet II.	Grains.
1	2·25	1	1·49
2	2·23	2	1·87
3	2·22	3	2·07
4	1·99	4	1·84
5	2·09	5	1·57
6	1·42	6	1·60
7	1·83	7	1·60
8	1·73	8	2·78
9	2·74	9	1·93
	18·50		16·75
Mean	2·06	Mean	1·86

From which it appears, that with a mean weight of 2·06 grains for the single powder in a packet of this patent medicine, the weight of one powder taken at random may fall as low as 1·42 grains, or rise as high as 2·74 grains. It also appears that, with a mean weight of 1·86 grains, the weight of a powder taken out at random may be from 1·49 to 2·78 grains.

Patent Medicine B.

Part of a Packet.

1	4·27 grains.

FACTS AND REASONINGS CONCERNING THE HETEROGENEOUS EVOLUTION OF LIVING THINGS.

Under this title, in a paper recently published in 'Nature,' Dr. H. C. Bastian discusses the theory of spontaneous generation. He remarks that in all ages there have always been believers in the possibility that "living things of various kinds could come into being *de novo*, and without ordinary parentage," but that during the last hundred years this doctrine has lost ground. This he attributes partly to the effect produced by opening the field of microscopic research, and partly to the philosophical doctrines which have prevailed.

In order to combat the theory of the possibility of spontaneous generation, the Abbé Spallanzani propounded the hypothesis that "multitudinous, minute, and almost metaphysical *germs* existed everywhere, ready to burst out into active life and development whenever they came under the influence of suitable conditions." This was reinforced by the doctrine of "l'emboîtement des germes," contributed by Bonnet. Armed with these two hypotheses, one set of physiologists have maintained that the low forms of animal and vegetable life which make their appearance during the decay of vegetable and animal matter owe their origin to the development of germs previously diffused through the organic matter, or else reaching it by the atmosphere, which was supposed to be a kind of general reservoir of germs of all sorts. Another set of physiologists maintained that, under certain conditions, complex mixtures of organic matter have the property of evolving lowly organized living beings without requiring the pre-existence of their germs. The details of the controversy between these two sets of physiologists are to be found in the works of Pouchet, Pennetier, and Pasteur.

What is the degree of maltreatment which destroys germs? This question must of necessity occupy a front place in the controversy, and to this question Dr. Bastian first addresses himself.

Those who deny the possibility of spontaneous generation are naturally predisposed to attribute to germs a high power of resistance, for the harder it is to destroy germs, the easier will it be to show that in a given experiment the possibility of germs has not been eliminated. Little fear, therefore, that the *limit of vital resistance* has been set too low. Placed in a liquid, living things will succumb to treatment which does not destroy them when they exist in dry air or *in vacuo*. Comparatively few living beings, either animal or vegetable, are capable of sustaining a temperature of 75° C., if they are immersed in a liquid; and no instance of survival of a temperature of 100° C., applied for one minute, is on record. With regard to the spores of fungi and to bacteria and vibrios,—the living things whose history is in dispute,—there is direct and explicit evidence that they are instantly destroyed by boiling water. Vibrios and bacteria, indeed, appear to die at 55° C., according to M. Pouchet, and below 60° C., according to M. Victor Meunier. Dr. Bastian himself found them not only dead but disintegrated after exposure to boiling water for one minute.

With regard to the resistance in the dry state, a temperature of 130° C. is believed to be necessarily fatal to all organisms; certainly, however, a red heat must be fatal.

Many experiments on the possibility of spontaneous generation have been made as follows (the method being that used by Schwann in the year 1837):—

The solution of organic matter is boiled in a flask, and is by this treatment rendered germless. The neck of the flask opens into a tube containing red-hot pumice-stone, packed closely together. As the liquid cools, air will re-enter the flask, to occupy the vacant space above the liquid. But all air that re-enters has to pass through the tube armed with red-hot pumice-stone, and must, therefore, be in a germless state as it enters the flask.

Now, after the lapse of several months, sometimes living things have been found in the flask and sometimes not. Under these conditions, living things have been repeatedly observed by Schwann, Ingenhousz, Mantegazza, Pouchet, Joly, Musset, Jeffries Wymann, Dr. Child, and even by Pasteur himself, who, however, offers a kind of explanation in order to account for such a result. Under still severer treatment, Jeffries Wymann, of Cambridge, United States, has produced living organisms, viz. in a liquid which had been heated to 120° C., and excluded from *uncalcined* air. Professor Mantegazza heated to 120° C., Professor Cantoni, of Pavia, to 142° C., for four hours, and still obtained organisms.

The author's work is in confirmation of that of Pouchet, Wymann, Mantegazza, Cantoni, and others. He operated thus:—Into a small flask, of about two ounces capacity, was placed the liquid to be experimented upon, and which generally occupied about three-quarters of the flask. The neck of the flask was next drawn out by means of the blow-pipe flame. The liquid was next boiled, and whilst the steam was freely issuing through the narrow neck, the latter was made red-hot. The boiling of the liquid was then stopped, and the red-hot narrow neck sealed up by means of the blow-pipe. After being thus charged, the experimental flasks were maintained at temperatures of 23° C. and 29° C., until the experiment was complete.

By operating in this manner, he got distinct and abundant development of bacteria, vibrios, and leptothrix filaments in solutions of beef-juice and decoctions of turnip, carrot, and hay. The duration of the experiment varied from five days to about one month. The superiority of operations *in vacuo* over those in *calcined* air is insisted on; the influence of pressure being apparently to retard the vital process.

Another set of experiments embraced saline solutions made with distilled water.

Acetate of ammonia, and phosphate of soda gave nothing living after ten days.

Tartrate of ammonia and phosphate of soda, the solution having been boiled for twenty minutes, gave, in eleven days, abundant signs of confervæ.

In other experiments the sealed flask was exposed to a temperature of 140° to 150° in a Papin's digester, and, after this treatment, there was development of organisms, sometimes very abundantly.

NEW MATERIAL FOR BLISTERS.

The following formula for the preparation of a blistering material is given by MM. Delpech and Guichard:—

Take of Gelatine, 30 grains.
Water, 150 grains.
Alcohol, 150 grains.
Cantharidate of Potash, 6 grains.
Glycerine, a sufficient quantity.

The liquid is to be painted on thin sheets of gutta percha, in such quantity than 4 inches square (*i.e.* 16 square inches) shall receive about $\frac{1}{7}$ grain of cantharidate of potash.

The advantage of cantharidate of potash over cantharidine is, that it is not volatile, and does not lose in strength on exposure. It is prepared by the action of potash on cantharidine, and crystallizes in the form of fine scales.

ASHY CROWN CINCHONA IN VENEZUELA.

Dr. Ernst, the President of the Society of Natural and Physical Sciences of Caracas, has rediscovered the *Cinchona cordifolia*, Mutis, var. *rotundifolia*, Weddell (*C. rotundifolia*, Pavon), in the neighbourhood of Caracas, a specimen having been collected in 1829 by Dr. Vargas in the same place.

In an excursion made by Dr. Ernst, the trees were found in groups on the slopes of Papelon, Anauco, Galipan, etc., at an elevation of 4500 feet above the sea-level. The trees were covered with lichens (the *Graphis sulcata*, DC., being particularly noticed), and the largest of them had a circumference of 83 centimetres. The same tree is said probably to occur in Mariches, from whence small quantities of bark were collected for exportation sometime ago. The bark of this tree is known in commerce as Ashy Crown Bark, one of the Loxa or Crown Barks, and occurs in quills. From an analysis made by Señor Vicente Marcano, a member of the same society, 60 grammes of this bark yielded 3 decigrammes of quinine, and 4 decigrammes of cinchonine. The bark, however, was collected at the wrong season.

From Port Cabello another bark, known as Quina Maracaibo, is exported. This is the produce of the *Cinchona Tucujensis*, a tree growing only to the height of 12 to 15 feet, which is found in the forests surrounding the colony of Tovar. In the same forests are found *Cinchona* (now *Buena*) *Henleana* and *Moritziana* of Klotzsch. —*Vargasia: Boletin de la Sociedad de Ciencias Fisicas y Naturales de Caracas*, No. 7, 1870.

Accidental Poisoning by Arsenic.—A shocking case of poisoning through the ignorance of a servant-girl, has occurred at Cradley Heath, in Staffordshire. A little boy in the family where the girl was employed being ill, she resolved, in his mother's absence, to give him a dose of magnesia. Instead of it she gave arsenic, being unable to read the label on the packet. The little boy died. The girl, who took a dose of the poison herself, recovered.

Fatal Case of Accidental Poisoning.—Early on Saturday morning last, great excitement was created in the town of Ashbourn and its immediate neighbourhood, by a report that a whole family, consisting of a man and his wife, his son, a lodger, and female servant, had been accidentally poisoned in Compton. Mr. Abel Harrison (the deceased) and his family occupied a public-house in Compton. The house was undergoing repair, and advantage was taken of this to cleanse the bedrooms. For this purpose Harrison sent for some arsenic (according to the accounts that we can gather, amounting to about a pound), which a man named Welsh mixed with naphtha and turpentine, for the purpose of cleansing the walls of the bedrooms, using a syringe for the crevices which could not be got at with an ordinary brush. This took place nine days previous to the accident. On Friday night the family slept for the first time in the room, and on Saturday morning they all found themselves seriously ill. Surgeons were called in, and gave it as their opinion that they were all suffering from arsenic, which they had inhaled during the night. On Sunday night the deceased had a turn for the worse, and on Monday morning death took place about eleven o'clock. An inquest was held on Tuesday before the Coroner, Mr. Whiston, and a verdict of "Accidental Death" was recorded.

The Pharmaceutical Journal.

SATURDAY, JULY 23, 1870.

THE RULE OF THUMB.

In another part of this week's Journal will be found a set of specimens illustrative of the working of the *Rule of Thumb*. Each powder in six packets of patent medicines was weighed, and the weights showed a variation in quantity of from one to about two; the practical effect of this irregularity being, that the patient, when he takes a powder from a packet of such a medicine, will take half a grain or one grain of calomel, or something intermediate between these quantities, just as chance may favour him. It is a lesson to use the balance, and not to guess at quantities. Nothing is more delusive than the eye as a measure of the weight of powders. A practised eye will one day be strangely successful in making such valuations, and another day as strangely unsuccessful.

THE SEWAGE QUESTION.

The public interest is at present so deeply involved in the determination of an efficient remedy for the sewage nuisance, to which so large an amount of river pollution is due, and the "A. B. C." method has been so confidently advocated for the purpose, that the Royal Commissioners on River Pollution have considered it their duty again to submit this method to careful investigation. Though the results of their previous observations were objected to by the patentees, they did not admit the validity of the objections, and the results of further inquiry given in the Report, just presented to Parliament, fully confirms the unfavourable opinion previously expressed as to the efficiency of the A. B. C. method.

The following are the general conclusions arrived at by the Commissioners:—

"1. The process removes a large proportion of the *suspended* impurities from sewage, but on no occasion, when we have seen it in operation, has this removal been so complete as to render the effluent sewage admissible into running water.

"2. The 'A. B. C.' process removes a very small proportion of the soluble polluting matters from sewage. After treatment by this process, the effluent sewage is very little better than that which is obtained by allowing raw sewage to settle in subsidence tanks.

"3. The manure obtained by this process has a very low market value, and cannot repay the cost of manufacture.

"The manipulations required for the extraction and drying of this manure are attended with a nauseous odour, especially in warm weather, and would occasion a serious nuisance if the works were situated in or near a town.

"It would obviously be rash to set any bounds to the possibilities of chemistry. Substances may, perhaps, be hereafter discovered capable of combining with and rendering insoluble the filthy constituents of our town drainage; but we are compelled to admit that the present resources of this science hold out no hope that the foul matters dissolved in sewage will be precipitated and got rid of by the application of chemicals to the offensive liquid. The chemical affinities of these foul matters are so feeble, and the matters themselves are dissolved in such enormous volumes of water, that their precipitation is a problem of extreme difficulty."

The Commissioners add that the inevitable conclusion from their inquiry is unfavourable to the A. B. C. method in respect of its alleged power to hinder the pollution of rivers by town sewage, and that it is equally unfavourable as to the value of the manure manufactured by this method. The one statement is indeed in some sense the complement of the other; for just in proportion as the impurities of sewage escape separation, so must the value of the manure obtained from it be reduced.

It is interesting to note in reference to the important question as to the value of the A. B. C. manure, that "artificial fortification" is occasionally practised. It appears that during a recent visit to the works at Leamington by Dr. Miller and Dr. Odling, crystals of sulphate of ammonia were discovered in the manure that was being made.

There are also other points in Dr. Odling's evidence before the Royal Commissioners, which throw a very dubious light on this matter.

Dr. Letheby's paper on the subject, which is completed in this number, is in reality little more than an admission that sewage can be defecated by irrigation, and its contents utilized to some extent at least, while his argument against this mode of dealing with sewage simply amounts to the very obvious assertion that it must be properly conducted. This is a truism that few would dispute. It is remarkable that most of those who took part in the discussion declared the subject to be outside their province. Even among the opponents of irrigation there was little accord, for while Mr. Hawksley believed there was nothing to be learned, and Dr. Letheby asserted that medical men were alone competent to decide the matter, Dr. Cobbold regarded it as chiefly one for chemists to deal with. Moreover, in reference to the pollution of rivers by effluent water, Dr. Letheby's advocacy of precipitation methods, which remove so little of the impurity from sewage, is glaringly inconsistent with his assertion that they were preferable to irrigation, which has been proved to purify sewage to much greater extent, and for that reason offers a better prospect of utilization when properly conducted.

A propos of sewage, we learn from the 'Medical Times and Gazette,' that some members of the unfortunate British Association Committee have laid their troubles before the Council of the Association, stating in reference to the protest entered against their proceedings with the money subscribed by towns, that they felt it would be unbecoming in them and derogatory to the dignity of the Association to continue their labours; but we understand the Council resolved that there was no necessity for it to interfere.

LIEBIG ON FERMENTATION.

What is Fermentation?—almost like the question, what is combustion?—is a fundamental problem in chemistry. Many years ago, Liebig was the first to give a chemical interpretation of this subject. He has now returned to it, and recently presented to the Bavarian Academy an important memoir on Fermentation; a translation of the first part of which is to be found at the opening of this week's Journal.

The Secretaries of the British Pharmaceutical Conference are busy issuing a circular to announce particulars of the meeting in Liverpool, and to invite Pharmacists to become members. In future, an annual report is to be published, under the title of 'The Year-Book of Pharmacy,' and a specimen-page is sent with the circular. We hope this undertaking will succeed, and that it may prepare the way for similar reports on other branches of science, which have long been needed and talked of.

We have it on reliable authority that several leading surgeons have determined to visit the seat of the war, in order to make observations on wounds, and advance the science of military surgery.

A Pharmacist, writing to the 'Lancet,' draws attention to the difficulty caused by the continuation of the uncertain term, spt. æther. chloric. by medical men. The strength of such a preparation never having been given authoritatively, dispensers are quite at a loss what to use, and the preparation known under this name varies from 1 part chloroform in 6 of spirit to 1 in 14, 16, or 20 parts,—the result being alike unsatisfactory to prescriber, dispenser, and patient. He therefore urges medical men to adopt the recognized Pharmacopœia preparation and name *spiritus chloroformi*, containing 1 part chloroform in 20.

The 'Pharmaceutische Zeitung' states that the chloral-hydrate made by Roussin, of Paris, is alcoholate, and not hydrate of chloral. It yielded 61·7 per cent. of chloroform, and contained 23·7 per cent. of alcohol.

We learn from the 'Chicago Pharmacist,' that a small lot of quinine, stated to have been manufactured in London, and bearing the label "Light Sulphate of Quinine," was found to be devoid of quinine. The alkaloid appeared to be cinchonine in the state of hydrochlorate. In appearance it resembled sulphate of quinine, but on closer examination the crystals were found not to be so much interlaced.

We have received from M. Soubeiran the proof-sheets of an article about to be published by him in the 'Journal de Pharmacie et de Chimie,' giving an account of the history and organization of the Pharmaceutical Society.

We learn from the 'Times' that milk is an article of export from the States. The total value of condensed milk exported from the port of New York in the year 1869 was $79,652. Milk of the value of $21,870 came to England.

We have received from Dr. Chandler a copy of his report to the Metropolitan Board of Health of New York on poisonous cosmetics sold in New York under the names Circassian Rejuvenator, Bloom of Youth, Eugénie's Favourite, etc. He finds that most of them contain lead in considerable amount. This report has given rise to a complaint by the proprietor of one of these nostrums, that it has "inflicted a great wrong upon him, and almost ruined his business."

We are glad to hear that Dr. Weddell has a paper on the *Cinchonæ* in press, which will, we trust, settle, in some degree at least, the synonymy of the genus. It will be published in the 'Bulletin de la Société Botanique de France.'

The case of Hatun Huamang, the labourer employed by Tschudi "in very laborious digging" (mentioned in the article on Coca which we published last week), reminds us forcibly of the Welsh fasting girl. What would have been the result of a Guy's Hospital investigation into the powers of endurance of Hatun Huamang? By the bye, we learn from the daily papers that the father of the Welsh girl has been sentenced to twelve months', and the mother to six months' imprisonment.

Transactions of the Pharmaceutical Society.

EXAMINATION IN LONDON.

July 20th, 1870.

Present—Messrs. Allchin, Bird, Carteighe, Cracknell, Davenport, Edwards, Gale, Garle, Hanbury, Haselden, and Southall.

Thirty-two candidates presented themselves for examination,—ten Major and twenty-two Minor; the following passed, and were duly registered:—

MAJOR (As PHARMACEUTICAL CHEMISTS).

*Clarke, Richard Feaver ...... Torquay.
Gibbs, James .... Bedford.
Romano, Frederick William Richard .... Rio Grande do Sul.
Hartt, Charles Henry .... Torquay.
Cotterill, Samuel .... Southampton.
Griffiths, Waldron .... Harrow.
Jackson, John Pim .... Leeds.
Pilley, Henry Thomas .... Lincoln.
Robson, James Crosby .... Darlington.

MINOR (As CHEMISTS AND DRUGGISTS).

*Haydon, William Frederic.... Blandford.
*Bowen, John William........ Handsworth.
*Hogg, Joseph Fawcett ...... North Shields.
Cooper, James .... Wycombe.

Braddock, Henry .... Oldham.
Butterworth, Albert .... Sowerby.
Reinhardt, William Tynedale. . Leeds.
Habgood, Henry .... Wells.
Ball, George .... Ormskirk.
Williams, John Havard ...... London.
Broad, John Morris .... Hornsey Rise.
Butterfield, Edward .... London.
Keightley, Joseph .... Tunstall.

The above names are arranged in order of merit.

EXAMINATION IN EDINBURGH.

July 11th, 1870.

Present—Messrs. Buchanan,

The following passed their respective Examinations :—

MAJOR (registered as a Pharmaceutical Chemist).

Howie, William Lamond .... Edinburgh.

MINOR (registered as Chemists and Druggists).

The names are arranged in order of merit.

Robinson, James .... Darlington.
Hay, James Henry .... Macduff.
Todrick, William .... Edinburgh.

MODIFIED (registered as Chemists and Druggists).

Bates, John Freer .... Manchester.
Clark, Simon Prince .... Glasgow.

PRELIMINARY (registered as Apprentices or Students).

Clark, Adam Douglas .... Kelso.
Gardner, Robert .... Kelso.
Graham, John .... Dumfries.

Three candidates were unsuccessful in the Minor Examination, and one candidate failed to pass the Preliminary Examination.

Errata in List of Local Secretaries.—P. 30, col. 1, for "Dorchester . . . Evans, Alfred," read "Dorchester . . . Evans, Alfred John;" p. 31, col. 1, for "Neath . . . Hibbert, William," read "Neath . . . Hibbert, Walter."

Meetings of Scientific Societies.

PARIS.—SOCIÉTÉ DE PHARMACIE.

1*st June*, 1870.

M. Mialhe, President.

The death of M. Leroux, the discoverer of Salicine, and one of the oldest correspondents of the Society, was announced. He was seventy-five.

M. Poggiale presented a note on the preparation of bromhydrate of quinine and cinchonine by M. Latour.

M. L. Soubeiran gave expression to his sense of the sympathy manifested by the Pharmaceutical Society of Great Britain, and of the cordial manner in which he had been received by the Society on the occasion of his recent visit to London.

MM. Boudet and Poggiale referred to the recent discussion in the Académie de Médecine respecting the "fortification" of wines.

The proposition made by M. Cap to form a French Pharmaceutical Association by affiliating the provincial societies to the Société de Pharmacie de Paris, was reported upon and discussed. It was not, however, adopted.

THE PRESENT PROSPECTS OF THE SEWAGE QUESTION IN RELATION TO THE PUBLIC HEALTH.

BY HENRY LETHEBY, ESQ., M.B.

(*Read before the Metropolitan Association of Medical Officers of Health, May* 21, 1870.)

(*Concluded from p.* 50.)

4. There is another very important objection to sewage irrigation — the danger of propagating parasitic diseases. Sewage contains myriads of ova of intestinal entozoa—every segment of a tape-worm discharged from the human body is crowded with them; and if distributed with sewage upon the land will become attached to the grass and other green fodder which is produced thereon. This is eaten by cattle, whose bodies quickly become infected with the parasite in its larval condition, and thus the measly meat becomes the agent of disease in our own bodies. At present, the distribution of these ova, and their access to the bodies of herbivorous animals, is entirely a matter of accident; but make it a matter of certainty, as most assuredly you will by distributing sewage upon the fodder-producing land, and the consequences must be serious. Dr. Cobbold, who is our highest authority on this subject, has published an essay to warn the public against the danger of this method of disposing of town sewage; and he has hinted at the probable introduction into this country of a terrible helminthic malady (*Bilharzia*), which is now common in Egypt, in Africa, and the Mauritius, and would assuredly be propagated throughout the land by this dangerous scheme of irrigation. "Have the kindness," he says, "to observe that every colonist returning from the Cape is liable to bring this parasitic treasure with him as a 'guest' indeed, dwelling in his blood, and feeding on his life stream. In the advanced stages of the malady, the afflicted individual must frequently evacuate the eggs and their contained embryonic larvæ, which are thus conveyed into the ordinary receptacles of such voidings. There let them remain, or convey them into a cesspool, and no harm follows. If deemed preferable, you may transport them, along with myriads of other human parasite eggs and larvæ, into a common sewer, and thence into the sea; still, entozoologically speaking, no harm follows. Here, however, let me invite you to pause; for if, without due consideration, you adopt any one of the gigantic schemes now in vogue, you will scatter these eggs far and wide; you will spread them over thousands of acres of ground; you will place the larvæ in those conditions which are known to be eminently favourable for the development of their next stage of growth; you will bring the latter in contact with land and water snails, into whose bodies they will speedily penetrate; and, in short, you will place them in situations where their yet higher gradations of non-sexual growth and propagation will be arrived at. After all these changes, there is every reason to believe that they will experience no greater difficulty in gaining access to our bodies here in England than obtains in the case of those same parasites attacking our fellow-creatures, whose residence is found in Egypt, in Natal, in the Mauritius, or at the Cape. In a natural history point of view, it would not be an altogether singular result, if, twenty years hence, this parasitic malady should be as prevalent in this country as it is now known to be in particular sections of the African continent. Foreseeing the possibility, not to say probability, of this contingency, am I not right," he says, "after years of long study, to raise my voice in the hope of preventing such a disaster?"

Nor is it unlikely that the Trichina may be distributed in the same manner, for it swarms in the intestines of those who have just become infected with it, and may be discharged into sewage, and scattered upon the land, and eaten by creatures whose flesh will give it back to us again. No one, indeed, but the helminthologist can say what particular parasite may not be distributed and propagated by this dangerous agricultural process. "May we not, indeed," as Dr. Cobbold observes, "but too reasonably conjecture that the wholesale distribution of tape-worm eggs by the utilization of sewage on a stupendous scale, will tend to spread abroad a class of diseases, some of which are severely formidable? So convinced am I," he says, "of the truth embodied in an affirmative reply to this latter query—so certain am I that parasites are propagated in this particular way—so surely do I foresee unpleasant results, if no steps be taken to counteract the evil, that I feel myself bound to speak out boldly, and to produce no uncertain sound in the matter which most closely concerns humanity." The whole question, in fact, is of vast hygienic importance.

But, fifthly, let us see if the system, in a sanitary point of view, is so successful as to render the sewage innocuous, before its admission into a running stream. Go to a sewage farm after you have given due notice of your intended visit, and you will be taken to places where the subsoil water is running from the land apparently pure and drinkable; and no doubt with proper management, under proper conditions of thorough and effective filtration, such a result may be achieved; but the real question is how far this is really and practically accomplished, for it involves such a nice adjustment of all the appliances, such a continuous distribution of the sewage over successive areas of land, and such constant supervision, that it is rarely effected. To judge of the results, therefore, you must visit these places, as I have done, without previous notice, and you must examine the whole district, for it is not uncommon to find byways for the disposal of the sewage which the land will not take. Not long ago, as I have said, I visited Aldershot, with Mr. Hawksley, Mr. Eggar, and Professor Ansted. This you know is a pet place with the advocates of the system, but at the time of our visit we found that nearly all the sewage was passing along the carriers to the outfalls, and going bodily into the river. I took samples of the sewage as it entered the farm from the two camps, and as it flowed from the farm to the river. The original sewage contained 54 grs. of soluble matter per gallon, and 44 grs. of insoluble, each of which contained about 30 grs. of organic matter. As it left the filter-tank it contained the same amount of soluble matter, and 35 grs. of suspended, of which about 26 grs. were organic. As it ran along the carriers to the lower part of the farm, it retained its black offensive character, and this was very marked upon that portion of the land where a little of it was distributed. At one of the outfalls into the Blackwater river it contained 52 grs. of soluble matter per gallon, of which 28 grs. were organic; and 3·84 grs. of suspended matter. At three other outfalls from the farm the soluble matters amounted respectively to 52 grs., 58 grs., and 54 grs. per gallon, of which 24 grs., 20 grs., and 22 grs. were organic; the suspended matters being 26 grs., 6 grs., and 5 grs. per gallon respectively, of which 12 grs., 2 grs., and 3 grs. were organic. At the several points of discharge into the river the sewage was black and fetid, and there were large accumulations of sewage mud in a high state of decomposition. I took a sample of the river water before it received the outfall sewage, and after; the former contained 19 grs. of soluble matter per gallon, and the latter 24 grs., of which the organic amounted to $3\frac{1}{2}$ grs. and 5 grs., the ammonia in the two cases being 0·264 of a grain, and 1·545 gr., showing an enormous pollution of the river by the so-called defecated sewage. Everywhere upon the land where the sewage had been distributed there were masses of fecal matter, waiting for the first heavy shower of rain to wash them away into the nearest outfall; the neighbouring ditches were in a most offensive condition, and we were told by the occupants of the houses adjoining the farm, that in times of flood the whole roadway was covered with sewage matters. Considering the praise which has been bestowed on the alleged success of this farm, I was not prepared to witness such a frightful condition of things.

At the Craigintinny meadows, near Edinburgh, it is notorious that the outfall water from the farm is shockingly offensive, but as it runs into the sea it is not complained of as a nuisance. A like condition of things, but not to such an extent, I have seen at Norwood, at Rugby, at Warwick, and at Banbury; in fact, at the last-named place the ditches around the farm were full of sewage, and the water was running from the outfall in a very offensive state, showing that the system, although susceptible of good results, is rarely so in practice, unless it receives an amount of attention that makes it a serious business. Besides which, there are times when no attention will prevent the discharge of foul sewage from the land, as when the soil is heavy, and a flood of rain sweeps over it, and when vegetation is dormant. In winter time it will freeze upon the land and kill the grass, and, as it thaws, run off to the nearest stream. At Warwick we saw acres of ground thus despoiled, where the defecation of sewage was entirely a matter of surface filtration. All authorities, indeed, agree that the success of this system is dependent upon a combination of circumstances which are not always attainable, and upon the strictest care and supervision. Even then, according to Dr. Frankland, although it may purify sewage to a great extent, it does not sufficiently purify it to render it admissible into potable water without danger; "the risk arising not only from the considerable amount of animal organic matters which the effluent water still retains in solution, but also from the absence of any guarantee for the removal of the germs or other noxious suspended matters which are frequently present in sewage."

The other means of dealing with sewage, so as to separate the suspended matters, and to remove a certain portion of those which are dissolved, is to submit it to chemical treatment. Already there are sufficient facts to enable us to review this part of the subject.

At Leicester, at Hertford, and formerly at Tottenham, the sewage was defecated with lime, the lime being used to the extent of from 5 to 20 grs. per gallon of sewage. The treatment is effected by adding the lime to the sewage, and then briskly agitating it; after which it flows into subsiding-tanks, where the sedimentary matters deposit, and the clear supernatant water runs off by a weir placed a little below the surface. At Hertford the supernatant water is filtered before it is discharged into the outfall, and in summer time a little chloride of lime, amounting to about half a grain per gallon of sewage, is also employed, as it is found to deodorize the sewage, to check secondary putrefaction, and to prevent the growth of the sewer fungus in the outfall channel. In the year 1858, when I first examined this process at Leicester and Tottenham, for Messrs. Bidder, Hawksley, and Bazalgette, the referees appointed by the Metropolitan Board of Works to consider the question of the main drainage of the metropolis, I found that with 12 grs. of lime per gallon of sewage the whole, or nearly the whole, of the suspended matters were removed, and that the soluble organic matter fell from $13\frac{1}{2}$ grs. per gallon to $10\frac{1}{2}$ grs. When 20 grs. of lime were used, the soluble organic matter fell to about 9 grs. On the occasion of a more recent visit to Leicester, with Dr. Frankland and Dr. Odling, at the instance of the Thames Conservancy Board, we found that the soluble matters of the sewage were reduced from 63 grs. per gallon to 48 grs.—the organic matter falling from 15 grs. to 5 grs. At Hertford, where the original sewage is remarkably weak on account of subsoil water, I have ascertained from many experiments that the organic matter in solution is reduced from about 3 grs. per gallon to 1·6 gr. All these results accord well with laboratory experiments, and they show, as I stated in my original report to the referees alluded to, that, "judging from the experiments which I have made, and the observations of practice on a large scale, it is ascertained that about 12 grs. of lime to a gallon of sewage will effect the speedy separation of all the suspended matters, and also about one-fourth of the dissolved organic matter, leaving a clear liquor which has lost a great part of its offensive odour; and when the clear liquor is mixed with from five to seven times its bulk of water, and is exposed to the air, it is no longer offensive."

At Leicester, where the lime method has been adopted, the river Soar, into which the sewage flows, has undergone a remarkable improvement. Before the works were established the river was most offensive, the fish were killed, the vegetation of the river was destroyed, and those who inhaled the effluvia from it were constantly ill. At the Belgrave Mill, which is just below the point where the sewage enters the river, the foulness of the stream was such that in summer-time the water of the mill-dam appeared to boil with putrefaction; the stench from it was intolerable, and so large was the quantity of sulphuretted hydrogen evolved, that the silver in the men's pockets turned black in a few hours. At that time the men were constantly afflicted with diarrhœa, they lost their strength, and their appetites always failed them; one man only out of thirty men in eighteen years had been able to stand it, and he it was who gave me an account of the matter. Now, however, and for the last three years since the lime process has been adopted, the river presents an entirely different appearance—aquatic plants have begun to flourish, the fish have ventured to return, the black mud has ceased to accumulate, and the mill-dam is no longer offensive. All along the stream the people speak of the change with satisfaction, and it would appear that the process fulfils the requirement of the local Act, which demands that the water discharged from the works shall not occasion a nuisance, or be injurious to the health of those who live or are employed on the banks of the stream.

Crude sulphate of alumina is another precipitating agent. It is employed at Stroud, in Gloucestershire, in what is known as Bird's method. The crude sulphate is made by adding about 20 lbs. of sulphuric acid to 1 cwt. of powdered clay, and allowing it to stand for some time. This material is mixed with sewage in the proportion of 1 cwt. to from 20,000 to 30,000 gallons of sewage, and the sedimentary matters are collected in a properly-constructed tank. Sulphate of alumina is decomposed by the ammonia of the sewage, and the alumina flocculates and precipitates the suspended matters, leaving a clear supernatant liquid, from which a good deal of dissolved organic matter has been removed.

To ensure the precipitation of the alumina, Dr. Anderson, of Coventry, recommends the addition of lime. He uses about one pound of crude sulphate to every 100 gallons of sewage. This mixture is well agitated, and then a quarter of a pound of lime in a creamy condition is added. Again it is agitated, and the flocculent alumina, together with the suspended matters, rapidly falls. The sediment is collected in subsiding-tanks, which are worked alternately, and the clear liquor is run off from it. As in the last case, the suspended matters are entirely removed, with a considerable amount of the dissolved organic matter.

Chloride of iron, with lime, is also a powerful defecator. It was formerly used at Northampton, and is still, to some extent with lime,—the lime being first added to the sewage in the proportion of about a bushel to 8500 gallons of sewage, and the chloride of lime to the extent of about half a gallon! The chloride is made at the works, and contains about 9500 grs. of the mixed chlorides of iron per gallon. In this case also the precipitation of the sewage is very complete. At present, however, the local authorities are using sulphate of iron and alumina instead of the chloride. The compound is made by mixing 3 cwts. of crude sulphuric acid with 2 tons of a ferruginous earth obtained in the neighbourhood. After standing for a few days the mixture is ready for use, and it is added to the sewage in the above proportion to a million gallons of sewage.

At Leamington, where there is an injunction against the discharge of unpurified sewage into the river Leam, the authorities have resorted to the use of the "A. B. C." process of Mr. Sillar, which is worked by the Native Guano Company at its own cost. The sewage flows to the works by gravitation, and there it is mixed with the A. B. C. material (consisting of alum, clay, sulphate of magnesia, bone ashes, wood charcoal, and a little blood diffused through water). The material is added to the sewage in the proportion of 1 gallon to 200 gallons of sewage, and the whole of it well agitated. It then flows through subsiding-tanks, where the precipitated matters subside, and the clear water flows off from a weir into an outfall channel with a filter. The tanks are worked continuously for about a week, when the precipitated matter is removed to a centrifugal machine, and drained to the consistence of putty. This is further dried by exposure to the air, and its ammonia is fixed by means of a little sulphuric acid, which also breaks up the organic matter. In this state it is riddled, and sold freely at a good profit for manure.

Samples of the Leamington sewage were taken for examination by the Royal Pollution Commissioners on the 11th of December last, and duplicates of them were furnished to me on the following day for analysis. I ascertained that the original sewage contained 66 grs. of solid matter in solution per gallon, of which 14·43 grs. were organic, while the effluent water before filtration contained 67 grs. of soluble matter per gallon, of which 11·27 grs. were organic, and the filtered water contained 61 grs. per gallon, of which 7·58 grs. were organic. Again, the suspended matters in the original sewage amounted to 113·6 grs. per gallon, while in the effluent sewage before filtration it was 7·64 grs., and in the filtered sewage 3·12 grs. The Royal Commissioners, in describing their results, do not mention the filtered water, but in other respects their results accord pretty closely with mine.

Lastly, there is a method of the late Mr. Blyth, which is very deserving of attention. Mr. Blyth was the chemist of the old Board of Health, and he had great opportunities of studying this matter. His plan is first to add a soluble phosphate of lime and sulphate of magnesia to the sewage. After agitation, the mixture is neutralized by means of a little slaked lime, and the precipitated magnesian phosphate carries down with it the whole of the sedimentary matter, and a portion of the soluble ammonia. A million tons of sewage require about 1 ton 3 cwts. of Blyth's compound, and 4 cwts. of lime for neutralizing. The resulting dry precipitate weighs about 3 tons 8 cwts., and contains about 58 per cent. of organic matter (yielding 4·5 ammonia) and 8·66 of phosphate of lime.

All these methods are manifestly capable of separating from sewage all the sedimentary matter, and also of removing considerable portions of dissolved organic matter; but to be effective there should not only be good agitation of the sewage after the addition of the precipitating agent, but there should also be sufficient tank-room for the deposition of the sewage for not less than four hours; and there should also be a means of filtering the defecated sewage before it is discharged into the river or other watercourse.

After witnessing the action of lime as a defecator at Leicester and Hertford, Dr. Odling, Dr. Frankland, and myself reported to the Thames Conservancy that the following were the conditions necessary to its success:—

1. The proportion of lime should not be less than one ton to a million gallons of sewage, and there should also be used 56 lbs. of chloride of lime.

2. That the mixture of the sewage with the lime and chloride of lime should be very complete, and that the mixture should be agitated, so as to aggregate the suspended matters, and thus assist in the subsequent precipitation of suspended matter.

3. That the sewage when thus treated with lime

should flow along two subsiding-tanks in series; the first should be capable of holding at least one hour's flow, and the second of holding not less than four hours' flow. The tanks should be four deep in depth, and the overflow of the defecated sewage should be by a weir only half an inch below the surface.

4. That there should be a double set of tanks for alternate working.

5. That the defecated water should flow through a shallow open conduit of not less than a quarter of a mile in length before being received into a stream of freely running water, of not less than eight or ten times the volume of the defecated sewage.

In this way, or by any similar method of defecation, the sewage of towns may be easily and safely dealt with, so as, on the one hand, to ensure its purification before it is discharged into a running stream, and, on the other, to avoid the many dangers of irrigation.

I refrain from entering on the subject of the pecuniary aspects of this question, for they are nowhere encouraging, notwithstanding that the most sanguine opinions have been expressed of the commercial and agricultural value of sewage. Irrigation, like precipitation, except in the case of the Leamington method, is everywhere unprofitable, when it is conducted in such a manner as to prevent the pollution of the neighbouring streams; and I warn you against the glowing accounts which are given of the profitable returns of certain sewage farms, for, if the cost of outlay is considered and balanced with the average returns, it will always be found to be a losing affair. The most sanguine enthusiasts have generally abandoned the system after a trial of its merits. Little or nothing, in fact, can be profitably grown upon the sodden land but Italian rye-grass, and when this is abundant it must be cut, or it will rot upon the ground, and it must be sold for what it will fetch. In the summer of 1866, when I was in Edinburgh, I saw acres upon acres of rye-grass rotting upon the far-famed Craigintinny meadows; and when I asked the cause of it I was told by the manager that the cattle plague had ruined his customers, and there was nobody to buy it and nothing to eat, and there it must rot. Besides which, there are considerable doubts as to the value of it as fodder. Mr. Campbell, of Rugby, who ought to be a high authority on the subject,—for it was a pet of his,—honestly declares that his experience does not show a profit in the use of such fodder, and he gives a good example of it. Twelve Ayrshire cows, which calved about the same time, in May, 1869, yielded, at the end of twelve weeks, an average quantity of 9½ quarts of milk per day per cow. Their daily consumption of rye-grass was 1½ cwt. per cow. If they had been milked for nine months, the average daily yield of milk would have been only from 5 to 6 quarts per cow. The cost of the grass, at 10*s.* a ton, was 9*d.* per cow per day, and the other expenses of the dairy raised it to 1*s.* 3½*d.* per cow. The milk, at 8*d.* per gallon, was worth only 1*s.* 7*d.*, and when the cost of sending it to market was taken into account, together with the wear and tear of utensils, he vainly asked for profit.

But all this is, as I have said, no part of my present inquiry, for my business is solely with the sanitary part of the question; and I would ask you whether, having regard for the public health, there are not serious dangers in the rash recommendations of the Royal Pollution Commissioners to scatter the sewage of every city and town in the kingdom broadcast upon the land? Medical authorities of some sanitary experience are alone able to engage in such important pathological considerations, and it must strike every one who is interested in the subject, that a Royal Commission, without any pretence of medical knowledge, is singularly incompetent to deal with such a matter. What importance the public or Parliament may attach to their recommendations I am unable to learn, except from former experience, but it is clearly our duty, as public health officers, to examine the subject from a medical point of view, and I doubt not what will be the conclusion.

Dr. Cobbold said that individually he regarded the sewage question as one which was three parts out of four a chemical question. On this account he thought the chemists should have the advantage of speaking first upon it. Dr. Letheby had referred specially to the remarks made by him in his *brochure.* Now, though the observations he made there were written in a warm, perhaps too warm a strain, he believed there was no statement which he was not still prepared to substantiate. And he thought since he had gained more experience in experimental researches, that he could now write a pamphlet much more cogent than that to which Dr. Letheby had alluded. With reference to parasitic diseases, he would only say that he knew of two patients in this country who were suffering from that frightful malady which was so destructive in Egypt. These patients at every urinary discharge must pass a number of the eggs of this parasite, and if the number of persons so afflicted was increased fivefold, the chances of the extension of this disease must likewise increase. But happily there were so many contingencies which the parasites had to encounter before they arrived at the human body that the community were yet spared; still he held by the statements contained in his pamphlet. Then take the case of ordinary tape-worm disorders, respecting which he had had much experience. There were about 3000 persons in London suffering from this cause, who each passed from four to twelve joints a day, each joint containing 30,000 mature eggs, which would give at least a daily return of 450 millions, but he believed 1000 million eggs was nearer the mark. A certain number of grains of organic matter per gallon were found by chemists in sewage, of which organic matter these eggs must be part and parcel. A handful of large entozoa parasites had been taken from the Craigintinny meadows. If this sewage was distributed far and wide, it was certain that a considerable portion of these millions of eggs must gain access to the herbivora. It was known, from experimental researches, that measles were developed productively in beef. It was a popular notion that pork only developed measles, but he would assert that in underdone beef persons ran a greater risk. The proportion of tape-worm disease derived from measly beef was as seven or eight to one in the case of pork. It was, therefore, to incur an enormous risk to distribute sewage which contained these germs over the land. It was possible to decimate the population of any town within a certain number of months by the distribution of tape-worm germs, there being one tape-worm in particular which produced a disease of the human body at present causing the death of 400 persons annually in this country. If that parasitic disease should increase in the same proportion as other parasitic diseases, such as the ordinary tape-worm, a result would follow such as still obtained in Iceland, where one-sixth of the population died annually from this cause. Having these facts to deal with, and knowing the developmental process through which these parasites passed, he thought they were called upon to ask people to pause before adopting a scheme so gigantic as that now proposed, fraught as it was with consequences so serious as those which he believed were involved in it.

Mr. Holland said he did not believe any portion of Dr. Letheby's paper, and he thought the writer was inconsistent with himself. In the first place he alleged that twenty times its volume of water would purify the sewage poured into it, and afterwards he asserted that even a small quantity of water from irrigation meadows was poison. Was Dr. Letheby prepared to recommend that the soil should be burnt; if not, what did he propose to do with it? Unless he was prepared to recommend that all human manure should be burnt to avoid the supposed risk, his argument went for nothing. He (Mr. Holland) believed that the danger of spreading dis-case by the irrigation system was purely imaginary. Where was the evidence of disease having been produced where the system was adopted? He had made inquiries on the subject and could find none. At Carlisle he asked whether the sheep had the rot, and was answered that they had not. At Edinburgh cows had been fed with grass from the irrigated meadows for sixty or seventy years, but there was no evidence of the prevalence of disease among them. It was true that they were not very healthy, but this arose from their mode of life. Everything was done to stimulate the production of milk from them, and they suffered from want of exercise and fresh air. Sewage was nothing but manure suspended in water, and the error was not in putting it on the land at all, but in putting it on in excess. At Carlisle he had been told that the residents in the neighbourhood of the irrigated fields were unhealthy, but on inquiry it turned out that there were no inhabitants in close proximity, and of those who were anywhere near, there were abundant causes of unhealthiness in the condition of their houses.

Dr. CARPENTER considered that the arguments of Dr. Letheby were based upon a false foundation, and that either he had little practical acquaintance with the facts from which he had drawn his inferences, or had taken only such portions of them as were calculated to sustain his view of the case. Dr. Letheby had alluded to some statements made by him, and had specially referred to the sanitary state of the fields at Beddington. The people of Croydon were among the earliest to adopt any sanitary arrangements at all. They were compelled to adopt some plan, because of the terrors of the law—no less than five or six injunctions having been obtained against them, and the Local Board were threatened with committal to prison unless they ceased to do certain acts. That was in 1858, and in 1859 and 1860 they obtained powers to do what they had since continued to do. In 1860 the irrigation meadows were laid down, and they had been in active operation to the present time. Until this year no complaint, either officially or otherwise, had been made of injury arising from these meadows. Previous to 1860, the town had been put to thousands of pounds expense for damage occasioned by the sewage, but from that year till within the last nine months they had been free from such liability. In 1860 they laid down 276 acres of land for the purpose of irrigation, and to remove the mischief which 19,000 people produced by their sewage. Since then the population of the town had increased to 50,000, and he was free to confess that the quantity of sewage was too much for the land. The result had been that occasionally of late the water was not so effectually purified as it should have been. Until 1867 no cases of fever occurred there. The water of the effluent stream passed through the grounds of a gentleman residing in the neighbourhood, and even at the present time trout might be seen swimming about in it. That being the case, was it not evident the plan adopted for dealing with the sewage was the correct plan? Indeed, Dr. Letheby said so himself, and it had been shown in that room that, if sewage were made to pass through five feet of earth, it would be rendered perfectly innocuous, and would be perfectly oxidized. Surely, then, the passage of sewage over land where it was exposed to the air, and came in contact with growing vegetable matter, would remove from it all those elements which were injurious to health, and the water would go off perfectly pure. Dr. Letheby was in the position of an engineer, who, some years ago, wrote a pamphlet to prove that it was totally impossible for a steamboat to cross the Atlantic, because she could not carry sufficient coals, the pamphlet being issued at the very moment that a steamer was actually accomplishing the feat. The town of Croydon was a standing proof that sewage could be successfully disposed of in the way Dr. Letheby asserted to be impossible. With regard to the question of health, he might state that, since the beginning of the year, there had not been a single case of fever reported to the Board of Guardians from Beddington, and he might add, as the medical attendant of most of the wealthy families there, that he had not had a single case of fever, either typhus or typhoid, among them since the irrigation meadows commenced. With reference to the effect upon the inhabitants of Croydon proper, surely, if the emanations from the farms were so dangerous as represented, the inhabitants of the densely populated low-lying parts, which were within 500 yards of the outfall of those farms, would have suffered from typhoid. But for a long period there had not been a single case in that low district, and with the exception of a few cases of scarlet fever there had been no fever there at all. The irrigation system went on during the winter as well as the summer, and in the former period of the year the water had gone off pretty nearly free from those elements which were injurious. This was the result of experience of the system forced upon the parish of Croydon, and which they had not taken up of their own will. Having observed the system, and seen its effects, he was positively convinced that the air which passed over the fields, instead of being injurious, was a benefit to the people living around. It was a positive fact, with regard to Norwood, that the moment the irrigation fields were established the mortality fell from 18 to 15, and had remained so. Dr. Letheby said he had evidence of water coming off the fields in an impure state. He (Dr. Carpenter) knew that there had been such instances, arising from the fact that persons had gone to the fields, broken down the carriers, and pulled at the sluices, letting the water out. Dr. Letheby knew very well that the argument to be drawn from the chemical analysis of the water was valueless, unless he was aware of all the circumstances of the case.

Professor ANSTED, being referred to by the chairman, as having had experience of these matters in connection with the city of Milan, said he hardly felt qualified to take part in the discussion, although, perhaps, so far as a certain amount of familiarity with works of this kind went, he might be able to afford some little information. The general subject appeared to him as far more belonging to the medical man than the geological engineer, if he might so denominate himself. Having had the opportunity, now and then, of noticing the results obtained during the irrigation of considerable tracts of land on a large scale, with material more or less mixed up with sewage, he thought he was justified in saying that in most cases, if not in all, those results had been certainly unfavourable to the general health of the neighbourhood. The chairman alluded to his experience at Milan. He knew the town well, and the way in which the sewage was conducted over the fields in the lower part of the town, and he believed, on the evidence of medical men—some of whom had been examined by parliamentary committees in this country, and whose evidence might be found in blue-books—that the result of the system pursued there was eminently unsatisfactory with regard to the health of the people living near where the works were carried on; and it was not astonishing, for no one could go into the lower parts of the town near the stream and the works without being conscious of their being eminently disagreeable, and probably unhealthy. The Italians were not particular on the subject of smells, but it was confessed that these were very objectionable. The sewage was carried over the fields, and took its course. Sometimes it was used, and in all probability, when that was the case, it passed off the ground without doing any damage to the water of the stream; but during a great part of the year such was not the fact, and the consequence was that the stream in its course was much polluted. And this was a result which he had also observed in other parts of the world. A few days previous he had the opportunity of visiting the irrigation works at Aldershot, and there it was perfectly clear to him that the farm which took the camp sewage and was working it, was utterly inadequate for the quantity put upon it, and that, from the nature of the irrigation, the sewage water carried over the fields could only be used upon a very small scale, while the greater part of it necessarily ran away into the river. He could not help thinking that in most cases this must be the result. It was not for him to say what was the right method of getting over the extraordinary difficulty which the public were called upon to face, but that some method must be adopted was evident. The question before the meeting was whether that particular method of carrying on the work suggested by the Royal Commission on the Pollution of Rivers was likely to be practically useful. As far as his own experience and knowledge were concerned, it seemed to him that the method of carrying away the sewage and utilizing it by irrigation might be successful upon a small scale, where the population was limited and the acreage was large; but he could not see much probability of its being successful upon a large scale, for what upon a small scale would practically do no harm—say in the case of 200 or 300 acres—would be attended with very serious results in the case of a large city or town. It might be very well in the case of Croydon, where the population was small, but the limits of the adaptability of the system were soon reached, and could not be advantageously extended.

Mr. Liddle remarked that in dealing with the subject they had two enthusiasts to encounter—Dr. Letheby and Dr. Frankland—whose papers were always read with attention, and probably between the two some useful information might be gathered. He was disappointed in the paper just read, because it contained very little which was of practical benefit to the meeting as a body of sanitary officers. It raised objections to the existing modes of operation, but it gave them no hint as to what could be done with the sewage, how to utilize it without creating a nuisance, and exposing the community to those fatal consequences which Dr. Cobbold had described.

Mr. Creasy thought it was necessary to explain in some degree the sort of conflict of evidence which had taken place. When Beddington was mentioned, it should be known that it was a large district, and that a portion of it had little to do with the sewage question. The sewage fields of Croydon had been well chosen with reference to population, but certainly in every cottage on the estate there had been typhoid fever through the whole course of the time—not a cottage had escaped. And as to the outfall at Beddington Corner, every well was contaminated, and not a house was free from fever. At Carshalton he had had cases of enteric attack. At Beddington Corner, near the outfall, four children had been taken out of one house in a day stricken down with scarlet fever.

Dr. Carpenter interposed the remark that the local nuisances in connection with those cottages were quite sufficient to produce all the fever complained of, without seeking a cause in the outfall sewer a quarter of a mile off.

Mr. Creasy said that might be, but the watershed went in that direction. In every one of those houses an examination of the tongues of the inhabitants would show that there was enteric irritation. The same indications which were caused by the Croydon sewage on one spot arose from the existence of cesspools on another.

Mr. Hawksley said he could fully justify the statements made by Mr. Creasy, for few persons were better acquainted than himself with the results of the irrigation works at Beddington Corner. He had been professionally called down to look at those works at intervals for many years, and also in consequence of complaints having arisen, although Dr. Carpenter stated there had been no such complaints since 1860. When on other occasions he had been in the neighbourhood on totally different business, he had taken samples of the water as it fell into the Wandle, and had them analysed. He had also been up the stream, and looked at the confluence of the two waters, which ran over the meadows in different directions. On one recent occasion he found one of those waters exceedingly clear, and the other about as foul as it could be. These two waters met, and passed down by the side of the cottages just mentioned, and thence to the Wandle. In the month of February last he was down there; the sewage was then frozen over the whole surface of the land for acres and acres, and was not in the state which Dr. Carpenter had described. But, besides that, he had been there in the summer, and in the summer it depended very much upon the state of the water whether the sewage, when passed upon the land, stank or not. In warm weather it often stank frightfully, especially on "muggy" evenings. The sewage then gave off a very sickening, though not necessarily a very powerful odour. The same sort of thing occurred everywhere when sewage was applied to land—at the Barking farm, at Edinburgh, at Aldershot, and every place he had visited. It had been stated, to his great surprise, in the course of this discussion, that at Carlisle the sewage did not stink. Most assuredly it did in hot weather, although the entire quantity of sewage put upon the enormous acreage of land there was only from 200,000 gallons a day as a minimum, to something under 400,000 gallons as a maximum, which was only one-sixth of the sewage of Carlisle. And it was there of so little value that the other five-sixths were allowed to run away into the river, though the acreage of land for its reception was sufficient to utilize the whole. As to the commercial economy of the system, he had made a great many inquiries, and he had been told very frequently of crops being sold at £18, £20, and even £25 an acre, and that every one was delighted with the effects. But when he came to ask what was the net result of the year's working, he was answered, "Ah, that is another thing." "Well, but what is it?" "Well, we lost so many hundred pounds last year," and in some cases so many thousands. There was not one single place he had heard of where the application of sewage for the purpose of sanitary disinfection was proved to be a commercial success. It was a commercial success at Edinburgh. Why? Because it was not applied for sanitary purposes. They used as much as they required for irrigation purposes, and the remainder ran into the sea or river nearly as foul as when it entered upon the land. But this was not the question now before the meeting. The question before them was one which almost every one could answer for himself. Take the case of plain irrigation by water only—pure water—water issuing, as in the majority of irrigation schemes in this country, from chalk springs. They all knew that when water was put upon land in certain seasons of the year in that state it did fertilize the land, and good grass crops ensued. But what was the result in a sanitary point of view? Fever and ague were produced. Go to Italy. He had been over all the irrigation works there, extending for 200 miles in one way, by 60 or 70 in the other, and what was the result? The people were in a state of actual decrepitude, not simply affected with fever, but with rheumatic complaints, and there was a great deal of cretinism. The same thing existed in the south of France, where irrigation by water only was adopted. Superadd to this foul organic matter, and what must be the result? He believed there was really nothing to be learned upon the subject. His own opinion was that of all unsanitary applications the most unsanitary was that of the application of sewage to land by way of irrigation.

Mr. Creasy said the Beddington grass was irrigated as long as it could stand up, and then it was sent away to market with the sewage some inches up the stem. So that if Dr. Cobbold was right, there was an opportunity for the development of entozoa there.

Dr. Letheby, in bringing the discussion to a close, said he thought Mr. Holland had not quite apprehended the statements he had made. He had said all along that sewage going into a running stream where there was abundance of vegetation, fish, and a large quantity of oxygenated water, even in the condition of sedimentary sewage, was by a natural process quickly disposed of. But what he also said was that the main cause of all those nuisances, which arose from the discharge of sewage into running streams was the sedimentary matter it contained, and that the distribution of sewage upon the land at the present time did not provide a remedy, and was accompanied by a large number of disadvantages. He said, further, that there was another means whereby these sedimentary matters could be separated; that by a process of chemical precipitation, as by lime, sulphate of alumina, or the agents employed by the A. B. C. Company, or that recommended by Mr. Blyth, they had the power to do certainly, and without danger, what they were not doing certainly when the sewage was put on the land, and with a great deal of danger. By this system of precipitation they could separate those solid elements, and could superadd agents which were not particularly injurious to the highest forms of animal life, but were deadly to those creatures referred to. There was, indeed, a mode within their reach, of dealing with those sedimentary matters which were the real cause of nuisance by accumulating in the rivers, and of rendering the water in such a condition that it might safely be admitted into a stream of eight or ten times its volume. It was a fact that in every one of the places visited, where the irrigation system was adopted, they found—whether by accident or design—abundant evidence of those evil results which it was most desirable they should seek to avoid. The system of precipitation, by chemical processes, could, however, be carried on without the slightest danger to the public, but this could not be said of any system of irrigation; for it was indisputable, from the investigations of Dr. Murchison, that sewer gases would produce sewer fever; and as these gases are abundantly evolved from irrigated land, no doubt it was a question open to a great deal of discussion how far they must be diluted before they would cease to produce dangerous consequences. He had told them what he found in his own experience at a model place—the Hebble Brook—where the inhabitants were so decimated by fever that the system was obliged to be stopped. He was asked whether the sewage then was to be wholly lost, and not utilized upon the land? He hoped he had sufficiently answered those questions by showing that the proposed mode of dealing with it was open to the objections that it was dangerous and uncertain, and that there were other and better means of dealing with it. He did not mean to say that by irrigation sewage could not be defecated, but he contended that the system required great attention, and that the result could not be realized in practice; whereas, by the adoption of chemical processes, there was a safe and certain mode of accomplishing the object, and, so far as he knew, these processes were more economical, for there was not a single instance in the country in which the utilization of sewage by irrigation had proved profitable.

On the motion of Mr. Liddle, a vote of thanks was given to Dr. Letheby for his paper, and the proceedings terminated.

Morphia Collodion. — A preparation under this name is recommended in 'L'Union Médicale,' as an application for neuralgic pain. It is made in the proportion of 1 part of hydrochlorate of morphia to 30 parts of flexible collodion, and is applied by means of a camel's-hair brush.

Reviews.

A System of Botanical Analysis applied to the Diagnosis of British Natural Orders; for the use of Beginners. By W. Handsel Griffiths, Ph.D.E. London: Wyman and Sons. 1870. Pp. 26.

This artificial key, published at the request of the author's pupils, is compiled from various botanical works, but differs from most analytical keys in being arranged *along* the pages, and having the less important characters indented from the more important. This renders it much easier to consult, and it may prove a useful aid to beginners.

Vollständige Anleitung zur Fabrikation kunstlicher Mineralwässer und der Brause-getränke, etc. etc. By Dr. Hermann Hager. Second Edition. Breslau: E. Günther. 1870.

In Germany the manufacture of aerated water and artificial mineral water is now almost entirely in the hands of pharmacists, and there is scarcely a town where they are not made. It is to provide for the wants of those engaged with such work that this book has been prepared, and the information it affords in regard to machinery, materials, and formulæ is such as to be very useful. It would probably repay the trouble of translation.

Science for the People: a Memorandum on Various Means for Promoting Scientific and Practical Knowledge among the Working Classes, addressed to Lord Henry Gordon Lennox, M.P., Chairman of the Council of the Society of Arts. By Thomas Twining, one of the Vice-Presidents of the Society. London: C. Goodman, 407, Strand. 1870. Pp. 136.

The object of this book is to consider the best means of disseminating a knowledge of domestic economy amongst the lower classes, so that they may "know how their dwellings should be constructed in accordance with sanitary principles; what household improvements they may derive from the discoveries of science, or borrow from the customs and appliances of other nations; what fabrics they should wear; what food they should eat, and how it ought to be cooked; how they may distinguish things which are genuine, wholesome, substantial, durable, and really cheap, from those which are cheap only in appearance; and, in short, how they may live with judgment, and get the best money's worth for their money." But to enable the working classes to attain to this happy state, Mr. Twining has found they must have a certain modicum of scientific instruction, some knowledge of the elements of physics, chemistry, human physiology, and natural history. This want he has endeavoured to meet by instituting at the Twickenham Economic Museum and elsewhere, short courses of lectures of the most elementary character. In this attempt he has felt the want of a sufficient staff of lecturers who could restrict themselves to giving merely outlines, and yet make them interesting and instructive. The plan he has generally adopted has been to provide written lectures, which could be read while an assistant acted as demonstrator.

Mr. Twining also urges the necessity of establishing popular museums in furtherance of his object. These museums are to contain typical collections of natural history specimens, the examples being so chosen as to illustrate as completely as possible the principles of structure and classification. Also illustrative examples of domestic economy, such as building designs, household furniture, utensils, clothing, food, etc.

This groundwork of science, especially if it becomes a part of primary education, may prove of great use in enabling the workman to master his trade, and to work from principle rather than from rule of thumb.

Although these suggestions are not intended for those whose profession renders real scientific training indispensable, yet the book will be read with interest by many, as containing the views of one of the prime movers for technical education, and the spread of a knowledge of the principles of domestic economy.

THE CULTIVATION OF THE CHINCHONAS OR PERUVIAN BARK-TREES IN JAVA. By K. W. VAN GORKOM, Superintendent of the Plantations (with Notes by C. HASSKARL). Translated from the German. London: Her Majesty's Stationery Office. 1870. Pp. 62.

The high value always placed on the curative properties of the quinine barks, has made the medical world anxious to secure continuous supplies, and the fears excited by the testimony of Weddell, Delondre, and other travellers of the reckless destruction of these trees by the Cascarilleros, or bark-gatherers, have directed attention to the desirability of cultivating them, so as not to be dependent on native sources, which may one day fail. The Dutch Government, through the representations of Reinwardt, De Vriese, Blume, Mulder, and others, gave their attention very early to this subject. Dr. De Vriese, who took a warm interest in Economic Botany, fortunately obtained, in 1851, a plant of *Cinchona Calisaya*, in Paris, which he dispatched to Java. This plant had been raised from seed collected in South America by Dr. Weddell, and became, in Java, the stock of a numerous offspring.

In the same year, also, Mr. Pahud, the Minister of State for Holland, dispatched Dr. Hasskarl to South America, to collect live plants and seeds of valuable species. Dr. Hasskarl landed at Callao, in Peru, in December, 1852, and, after an arduous journey and much opposition, obtained plants and seeds of some *Cinchonæ*, chiefly of *C. Pahudiana*, Howard, at first mistaken for *C. ovata*, Weddell.

He arrived in Java with his collection in December, 1854, and together with Dr. Teijsmann, the Director of the Buitenzorg Gardens, began the cultivation. Unfortunately, the site chosen for this operation was one having only about 6 inches of soil, and when, in 1856, a scientific staff was appointed, the plantation was not in a very successful state. The new director, Dr. Junghuhn, had associated with him Dr. J. E. de Vrij, a chemist well known for his abilities, and eight overseers. Only seventy plants were found of any value, and the plantation was removed to a more favourable situation, and while under Dr. Junghuhn's management, much better results were obtained.

Mr. Van Gorkom, the present Superintendent, reports that there are now under cultivation in Java, 840,653 plants of *Cinchona Calisaya*, 39,512 of *C. succirubra*, 159,149 of *C. Condaminea*, 812 of *C. lancifolia*, and 409 *C. micrantha*. Of *C. Pahudiana* no number is given; the last estimated number was 900,000, but its cultivation is not now particularly attended to, as it is generally agreed to be of little value.

Though the past history and present position of Cinchona cultivation in Java is not all that one could desire, yet it must be remembered that the cultivation of the *Cinchonæ* is fraught with manifold and various difficulties, and requires an almost delicate adjustment of light and shade, heat and elevation. Mr. Van Gorkom is very sanguine of the future success of the undertaking. He says that courage should be derived "from the certainty that we are on the right path, and indulge in the well-founded hope that the persevering efforts of successive Governments—efforts which have aroused a sympathetic feeling in the educated world in general, and amongst scientific men in particular—will end in glorious success." And in this hope we most heartily join in with them.

ESSAIS DE CULTURE DU QUINQUINA A LA MARTINIQUE. Par M. CH. BELANGER, Directeur du Jardin Botanique de la Martinique. Paris: 1870. Pp. 7.

In 1862, M. Belanger, having obtained some cinchona plants, began their cultivation, in order to test whether they could be successfully acclimatized in that colony. He finds that, though he has not been able to command all the elements of success desirable, yet he has experimented sufficiently to convince himself of the success of the scheme, if the French Government would undertake it. At present there are growing in Martinique plants of *C. Calisaya*, *C. lancifolia*, *C. officinalis*, *C. succirubra*, and *C. Pahudiana*,—altogether 90 in number, and ranging from half a metre to 3½ metres in height. Bark of three years' growth has been submitted to analysis, and said to yield very fair results.

THE MANUAL OF COLOURS AND DYE WARES. By J. W. SLATER. London: Lockwood and Co., 7, Stationers' Hall Court. 1870.

This book is the work of an accomplished chemist, for many years practically engaged in the special branch of industry to which it relates. It is calculated to supply a gap, the existence of which forces itself upon the attention of all men who take a rational interest in the manufactures of this country. A passage in the preface to the book before us places, in a clear light, the state of affairs in this department of literature.

"If their authors be mere *littérateurs*, or even men of abstract science, they cannot furnish all the required particulars. If they are practical men, they will not."

The book before us contains much information that is not easily accessible. The arrangement followed is *alphabetical*, and the descriptions are admirably clear. Under "Hydrometer" will be found some valuable information concerning the irregular scales in vogue.

Obituary.

On the 17th July, at his residence, 33, St. John's Wood Park, Benjamin Brogden Orridge, Esq., F.G.S., in the 57th year of his age.

JAMES COPLAND, M.D., F.R.S.

Force of character, with geniality of temperament, unusual powers of generalization and research, with literary accomplishments of a high order, were the moral and intellectual features of Dr. James Copland, who died on the 12th inst., after a brief but painful illness, at Kilburn. The doctor was by birth an Orkney man, and first saw the light in November, 1791. His education was commenced and carried to the University stage at the town of Lerwick, in Shetland, from which, at the age of fifteen, he came to Edinburgh; and with a view to qualifying for the Church, passed through the curriculum of arts. After profiting to the full by the deep and varied culture of the Edinburgh curriculum, he abandoned the clerical for the medical career, and threw himself with characteristic energy into his chosen pursuit. Four years' assiduous attendance at the classes under the (then) efficient professoriate, qualified him to graduate as doctor in medicine in 1815, when with the instincts of so many of his countrymen, he migrated southward, and attempted to establish himself in London. He failed, however, to win immediate success, and after profiting as far as he could by the professional opportunities afforded at the metropolitan schools, he visited Paris, where he availed himself of all the advantages of her clinique. Thence he proceeded to Germany, in whose hospitals, filled to overflowing with the sick and hurt from the newly-terminated war, he was an industrious and vigilant observer. The febrile and dysenteric disorders of which he saw so much were now his chief study, and with a view to extending his knowledge of them, he took service under the African Company, and sailed for the Gold Coast. On his way thither, he touched at various settlements, such as Senegal, Gambia, and Sierra Leone, at which latter place three-fourths of the crew were stricken down with yellow fever, from which, however, his skilful and energetic treatment rescued them all but two. He was the last to be seized, but the measures which had issued so happily for his patients, were applied with equal success to himself. Powerful tonics and stimulants were the remedies he chiefly relied on, as we learn from his 'Dictionary of Practical Medicine,' in which he gives a most interesting account of the epidemic, and the mode in which he combated it. After a few months' residence at Cape Coast Castle, he returned to Europe by way of Accra and Benin, and after a brief visit to his native Orkney, he again passed through Edinburgh and London for the Continent, where he sojourned chiefly at Paris, and attended her hospitals for some months. He returned to London, and established himself at the "Terrace," at Walworth, having previously became a licentiate of the Royal College of Physicians, and physician to the Royal Infirmary for Diseases of Children.

In 1821 began his medico-literary career. He contributed to the 'Quarterly Journal of Foreign Medicine' a number of papers on fever and the medical topography of the West Coast of Africa. After applying without success in the same year for the post of Government commissioner on the origin and nature of the yellow fever then prevailing in the Spanish peninsula, he concentrated his energies on home-practice, established the South London Dispensary, and before the end of 1821, he published his celebrated memoir on turpentine as a therapeutic agent, the value of which he had been so impressed with on the Gold Coast. In the January of the following year he took the editorship of the 'London Medical Repository,' and enriched its pages with a vast number of contributions on the most various topics, from public hygiene to private or consulting practice. Most of these articles found their way, in substance at least, into his great 'Dictionary of Practical Medicine.' In 1824 he translated and edited Richerand's 'Physiology,' and threw out, in the notes, anticipations of those views on the nervous system which afterwards brought so much distinction to Dr. Marshall Hall. In 1825 he projected his 'Dictionary,' but he did not commence it till 1830, when the announcement of a rival work, supported by sixty contributors, supplied the doctor with the needed stimulus. Night and day for twenty-eight years he continued to labour at his work; and in spite of the incessant inroads made on his time by an increasing practice, he did not fail to subject every article to the most exhaustive consideration, and to embody his ripest judgment on its details in a style singularly forcible and effective. As a single-handed effort it has been compared to the Dictionaries of Bayle and Johnson; while its value, though diminished by the progress of science, will always be great enough to secure it an honoured place in the library of the physician. In its abridged form, under the able editorship of his nephew, Mr. J. C. Copland, it has renewed its popularity with the rising generation of practitioners; while many of its suggestions have been silently adopted by the sanitary reformer or incorporated with special treatises on medicine.

The doctor was unusually fortunate in the honours he received, among which we may single out his being made a Fellow of the Royal Society in 1833; a Fellow of the Royal College of Physicians in 1837; Gulstonian Lecturer in 1838; Censor of the College in 1841, 1842, and 1861; Croonian Lecturer in 1844, 1845, and 1846; seven times Councillor between 1844 and 1863; Lumleian Lecturer in 1854 and 1855, and Harveian Orator in 1857. He delivered his discourse on this latter occasion in Latin remarkable for its freshness and force,—not a cento of phrases, like the majority of such orations, but the work of a man to whom the language was almost native. For the last few years he had ceased to engage so extensively in consulting practice; and, though a constant frequenter of the societies, he fixed his residence out of town. To the last, however, he was always willing to give the poor artist or the struggling man of letters the benefit of his gratuitous advice; while to all appearance his hale and vigorous physique gave promise of a lengthened continuance of his genial and philanthropic labours. But within the first week of July his old enemy, the gout, renewed the attack; and, in spite of every medical aid, he gradually sank till the 12th, when he died, in his seventy-ninth year.

Climate of the Azores.—The Hon. E. Monson, in his consular report on the trade and commerce of the Azores, expresses regret that so few tourists visit those islands. He says they are chiefly Americans who prefer taking a southern route to Europe, and like to break the voyage by halting for a short time in Fayal; while the very few Europeans who find their way there are such as the casualties and exigencies of business compel to undertake a voyage from which they anticipate no pleasure. Thus these islands, replete though they are with objects of interest, no less to the man of science than to those who travel for mere amusement, will remain neglected until, in the process of time, the so much needed harbour improvements are completed sufficiently to encourage the visits of ocean steamers. The island of St. Michael's, he says, should be peculiarly attractive to the invalid. It is blessed with a climate equable and mild, although somewhat humid. According to careful observations, the mean temperature of the winter months is 2° colder than Madeira, 5° warmer than Lisbon, 13° warmer than Nice, 12° warmer than Rome, and 12° warmer than Naples. According to the estimate of Sir James Clark, the mean annual temperature of St. Michael's is 62° 40′, that is about 2° less than Madeira during the whole year. The mean monthly range of the thermometer during the winter is stated to be 7° 6′ at St. Michael's, against 12° at Madeira,—showing that, while the St. Michael's winter is only 2° colder than that at Madeira, it is more equable, or, at any rate, not less so. The south and westerly winds are soft, relaxing, and warm; the north-easterly are colder and more bracing, but never keen and thin. The extent of the surrounding ocean, and the mildness of the temperature, naturally cause the climate to be extremely humid; in fact, the state of the atmosphere has been frequently compared to that on board a ship at sea; but this condition of the air is not productive of disease, nor is it even a source of inconvenience to those who are in tolerable health. The native poor, who are exposed to it all their lives, and whose cottages (rarely possessing glass windows and invariably having earthen floors) are not at all calculated to resist its influence, are a healthy, robust, and handsome race. Neither cholera nor yellow fever has ever visited the islands, and epidemics of any kind are almost unknown. Owing to the same causes which produce the humidity, a cloudless sky is very rare; and this adds considerably to the advantages of the Azores as a place of residence for an invalid, as the direct heat of the sun does not prevent a person in delicate health from spending the greater part of the day in the open air. Added to these advantages there are wonderful mineral springs with which Madeira has nothing to compete. The striking volcanic conformation of the islands is worthy of the study of geologists, and the magnificent scenery would afford endless opportunities to the artist; yet, Consul Monson adds, even to the inhabitants of the mainland of Portugal they remain almost a *terra incognita*, while to the world at large they are as remote and mysterious as were the Hesperides to the civilized world in the classic days of Greece and Rome.—*Pall Mall Gazette.*

Hay-Asthma.—A correspondent in the 'Lancet' reports the case of a patient who has for several years suffered from this malady, but found no permanent relief from any of the usual remedies. The following treatment, however, proved efficacious:—A small barrel of sea-weed, taken fresh from the shore, was given to the patient to sniff whenever an attack came on. Five minutes' inhalation of the sea-weed sufficed to stop the symptoms, after which the barrel was securely closed, and placed in a cellar for future use. It is suggested, that the active principle of the sea-weed should (to obviate the cumbrous device of the barrel) be concentrated, like salts, in a smelling-bottle; and this idea has been carried out with success. Such a pocket-companion might prove serviceable to those whose liability to hay-asthma is not proof against the odour of the flowers which decorate dinner-tables and drawing-rooms. Sea-weed should be brought up fresh from the shore by rail, and kept for use in hospitals where strumous affections are treated,—an application of the *inutilis alga* which might be of benefit to other patients, who would fain, if they could afford it, "suffer a sea-change."

Granular Citrate of Magnesia (effervescent).—H. C. Archibald gives the following formula:—

Take of Acid. Citric.	. .	4 lbs.
Magnesiæ Calc.	.	1½ „
Sodæ Bicarb.	. .	3 „
Acid. Tart.	. . .	3 „
Pulv. Sacch. Alb.	.	6 „
Ol. Limon.	. . .	1½ fl. oz.
Alcohol Fort.	. .	q. s.

Powder the citric acid and add the sugar: mix thoroughly, then add the soda, magnesia, and tartaric acid. Pass the whole through a No. 40 sieve three times; moisten with strong alcohol and pass through a No. 8 sieve; place it on a wooden tray to dry, then add oil of lemons and bottle instantly. It usually takes twenty-four hours and a temperature of 120° F. to dry the salt perfectly.—*American Journal of Pharmacy.*

Brown Hair Dye.—The hyposulphite of lead, dissolved in excess of hyposulphite of soda, forms a hair-dye which gradually becomes brown from absorption of oxygen and deposit of sulphuret of lead on the hair. The following formula for the preparation of this dye, is given in the 'American Journal of Parmacy:'—

℞ Acetate of Lead	. . . .	ʒij
Hyposulphite of Soda	. .	℥j
Rose (or other Perfumed) Water	. . . . . .	℥xiv
Glycerine	. . . . . .	f℥ij:

Dissolve the acetate of lead and hyposulphite of soda in separate portions of water, filter separately, mix the solutions, and add the glycerine.

Death from Escape of Gas.—An inquest was held last week, at Haverstock Hill on the body of Charles Lawley, aged sixteen, son of a reporter on the 'Field,' who was found on Wednesday suffocated in bed. The gas-burner in deceased's bedroom was found broken off from the joint, and the room was full of gas. How the joint got broken off is unknown. The jury returned a verdict of "Accidentally suffocated with gas."—*Standard.*

[*⁎* Probably the cause of death was poisoning by carbonic oxide, which exists abundantly in gas; ethylene, which likewise occurs, is very poisonous.—Ed. Ph. J.]

Eucalyptus Oil.—The essential oil of eucalyptus now being introduced into use in perfumery by Mr. Rimmel, has lately been examined by Cloetz. He took the product of *Eucalyptus globulus*, originally a native of Tasmania, where it was discovered by Labillardière, in the year 1792. It has since been acclimatized on the shores of the Mediterranean. From 10 kilogrammes of fresh leaves of the plant, 275 grammes of the essential oil were obtained by distillation with water. In another experiment about double the quantity of oil was obtained. The oil is very fluid, almost devoid of colour, and having a smell analogous to that of camphor. It begins to boil at 170° C., and rises in boiling-point as the distillation proceeds, until above 200°. The more volatile liquid, after purification with caustic potash and with fused chloride of calcium, boils regularly at 175° C.,—this is eucalyptol. Its specific gravity at 8° C. is 0·905; it deflects the ray of polarized light to the right; it does not freeze; its vapour, mixed with air, is fresh, agreeable when inhaled, and has been employed as a therapeutic agent; it is hardly soluble in water, but very soluble in alcohol; its alcoholic solution, when highly diluted, is said to afford a perfume equal to the rose. The composition of eucalyptol is represented by the formula $C_{12}H_{20}O$ (vapour density 6·22). By the action of anhydrous phosphoric acid upon it, a liquid hydrocarbon of the formula $C_{12}H_{18}$, and named eucalyptene, has been obtained. This liquid boils regularly at 165° C., and has a sp. gr. of 0·835 at 12° C. Its vapour density is 5·3. It is derived from eucalyptol by the loss of the elements of water. At the same time a polymer of eucalyptene is produced. This liquid boils at temperatures above 300° C. Decomposition of the substance at the high temperature required for the determination of its vapour density, prevented a determination of that important datum. The name eucalyptolene is proposed for it. The behaviour of eucalyptol towards hydrochloric acid gas is very interesting. Cooled to zero and then treated with a current of dry hydrochloric acid gas, it absorbs the gas abundantly and solidifies to form a mass of crystals. Very soon, however, these crystals undergo spontaneous decomposition, and are resolved into an aqueous solution of hydrochloric acid and a hydrocarbon, boiling about 168° C., and apparently identical with eucalyptene. In chemical history, therefore, eucalyptol resembles camphor, of which it appears to be a homologue—two steps higher in the series.—*Répertoire de Pharmacie.*

BETTS' SUITS.

Sir,—The report of "Betts' Suits," contained in your last number, is very complete and accurate; still, for those who are not acquainted with the commencement of these prosecutions, the part I played in this affair remains somewhat obscure, and I hope you will allow me to give the following explanations to your readers, without any reference or prejudice to the action still pending between Mr. Betts and myself in the Court of Chancery:—

Since I commenced using capsules at my London manufactory, I procured them from three different makers,—Dupré, of Paris, the original inventor of metallic capsules; Courdouzy, of Bordeaux, and Espinasse, of Paris. These capsules were sold me as being made of tin, or alloys of tin, and never having had any warning from Mr. Betts as to an alleged infringement of his patent, I never dreamt they could be made of his metal. I was, therefore, much astonished at being served with a Bill in Chancery by Mr. Betts in April, 1865, without the slightest previous intimation. I naturally turned to those who had supplied me, and inquired what was the material of the capsules they had sold me. Dupré and Courdouzy made affidavits that they were not composed of the metal patented by Mr. Betts, and these affidavits were confirmed by chemical analysis made by Dr. Odling and Dr. Redwood. Mr. Betts himself tacitly acknowledged the truth of Dupré's declaration, by withdrawing, at his own expense, a Bill he had filed against Mr. Fisher, of Leadenhall Street, for selling a bottle of my toilet vinegar with a capsule bearing that maker's name.

Espinasse alone admitted that the capsules he had supplied me with were made of the metal patented by Mr. Betts, although his billheads bearing the words, "Fabrique de Capsules en Etain" (Tin Capsule Manufactory), had led me to suppose that he sold nothing but *tin capsules*. He added, that he worked under a licence of Mr. Betts, but when I asked him to produce it, and thus take the blame on his own shoulders, as he had never informed me of that circumstance whilst supplying me, he refused to interfere, saying he would do nothing against Mr. Betts's interest.

Now it turns out, on cross-examination of Mr. Betts, in the suits just tried, that the house trading in Paris under the name of *Espinasse*, was, in reality, the property of Mr. Betts, Espinasse being only his foreman,—so that Mr. Betts actually supplied me *himself* with the capsules which he called afterwards an infringement of his patent; and not only did he supply me, but he forwarded capsules from the same house direct to my London manufactory, so that even the poor plea of *Betts the Frenchman* and *Betts the Englishman* falls to the ground.

As I said before, Mr. Betts filed his Bill against me in April 1865, and, three months after, whilst negotiations for an amicable settlement were going on, he issued his batch of Bills against my customers without any previous warning to them or to me. You may judge how surprised I was at seeing him thus seek his remedy on both sides. The first three persons who came to complain to me of having been served (all in one day), I consoled with the assurance that I should see them through, but when I heard that twenty-five bills had been filed all at once, and that there were many more in the course of preparation, I offered Mr. Betts One Thousand Pounds to put a stop to this system of prosecution which was calculated to ruin my trade. This sum he at first accepted, and afterwards declined. It was then that meetings were convened, and a Defence Fund was subscribed.

I hope that the foregoing statements will suffice to establish the two chief points which I wish to impress on your readers; firstly, that I used proper caution in the purchase of my capsules, and was the victim of a deception which could not be foreseen; secondly, that I spared neither trouble nor expense to protect my customers, unconscious as I was of having done any wrong.

I remain, Sir, yours respectfully,
E. RIMMEL.

London, July 12, 1870.

NAVY DISPENSERS.

Sir,—The members of the Pharmaceutical Society, and the readers of your Journal generally, must have been at least pleased with the congratulation offered to them in your article upon the action of the Government in respect to dispensers and assistant-dispensers in naval hospitals at home and abroad.

That medicines in naval hospitals should be compounded and dispensed by hands as skilful, and directed with the same education as those required by civil communities, there can be no question; but, I think we may fairly ask in how far the naval service is likely to become popular, or an object of ambition? and also what class of candidates the Admiralty will be likely to obtain for the remuneration they offer?

The claims of Pharmacists to recognition as members of a profession have long been admitted, and by the determination of the Government as regards the navy dispensers another step is gained; but this advance becomes undesirable in proportion as the recognized position is made the excuse for inadequate remuneration.

It is to be feared that the very imperfect knowledge, founded upon a baseless tradition as to the value of drugs, entertained by the public, and the ignorance that exists as to the disproportion of the remuneration to the responsibility incurred by the retail druggist in every prescription he dispenses, may have, in some measure, guided the Lords of the Admiralty; and it would have been very desirable if the remarks of Mr. R. W. Giles and Mr. Walter Powell, on the subject of the relation of remuneration to Pharmaceutical responsibility, published in the 'PHARMACEUTICAL JOURNAL,' s. s., vol. x., could have been laid before the Lords Commissioners at the time they considered their scale of salaries. It is not, however, too late for the professional Pharmacist to press his claims with the Admiralty still further, but he ought to be supported by the body of his profession.

In order to establish the professional position of the Pharmacist, the myth of the value of the materials employed must be swept away, and an adequate remuneration demanded by the retail druggist for skill and labour bestowed.

Mr. Walter Powell, in reiterating* the sentiments expressed by Mr. R. W. Giles† in the highly important letter he addressed to the Norwich Conference, gives it as his opinion that "the hope of better days, when the Pharmaceutist shall be regarded as a member of an honourable profession, rests upon the excision and abandonment of all illegitimate departments of his business, and a more exclusive devotion of time and talent to his true profession." He remarks further, "that, to do this, considerable augmentation must be made in charges, which cannot longer be based upon the intrinsic value of medicines, nor upon the time occupied in their dispensing, but on the knowledge which enables the dispenser faithfully to further and interpret the wishes of the physician, thus rendering the former responsible trustee of the public weal."

Again, Mr. Giles clearly exemplifies the sacrifice of social status resulting from the association of a general trade with the special business of dispensing, and he shows that vending of perfumery, hair washes, and the like, must remain a more profitable, as it is a less responsible employment for the qualified assistant, whose services it is necessary to engage, so long as the claim for skill, on the part of the professional dispenser, is unrecognized and inadequately remunerated.

It is something to have established a claim to Government recognition, but it must not be forgotten that responsibility is engrafted on to, and inseparable from a recognized position; and that, therefore, a claim for remuneration commensurate with the responsibility must be established too. A qualified assistant can earn five shillings a day, and more, without the responsibility attaching to the navy appointment. Why then should he gratuitously undertake the responsibility? The very education the qualified dispenser has obtained is an investment, the bare interest of which, at least, is reasonably due to him in addition to salary, while the latter ought to be very considerably in advance of that of an ordinary artisan.

* Pharm. Journ. s.s. vol. x. p. 313. † *Ibid.* p. 160.

By now making a stand and demand for their just due, Pharmacists, on entering Government employ, may materially strengthen their position, and further their claims to consideration as a professional body. Now is their opportunity, it seems a golden one, and the embracing of it cannot too strongly be encouraged. It will indeed be a pity if the new field for service now opened is allowed to become a refuge for the destitute, and I sincerely trust that the subject will at once be taken up by those who have it in their power to further the end in view.

I am, Sir, your obedient servant,

J. T. D.

London, 18th July, 1870.

Citrate of Magnesia.

Sir,—I perfectly agree with Mr. Rimmington, that this salt is often badly manufactured; but I differ from him in considering the use of sugar as promoting deficiency of carbonic acid in the carbonate of soda. The sugar exercises no chemical action whatever on the salt. It is simply used for two objects: one, to give adhesion to the granules, and the other, to impart a zest to the draughts made from the citro-tartrate of soda, *alias* citrate of magnesia. It is owing to the chemical action which takes place on the addition of the acids to the alkali, with a small quantity of water, used for damping, that the bicarbonate loses part of its carbonic acid. This is absolutely unavoidable, so long as the crude and destructive method of damping the acids and alkali together is adopted. The carbonate of soda also parts with some of its carbonic acid during the process of drying. This additional loss might be prevented, if a proper degree of heat were applied during the granulation. The manufacture of citrate is generally intrusted to mere laboratory porters, who have no knowledge whatever of the influence of heat upon chemical compounds, or the degree requisite in particular cases. To expedite their work, they apply an excessive amount of steam to the drying-pan. As this salt is fast displacing the ordinary seidlitz powders, it is to be regretted that its manufacturers still pursue their ordinary and destructive method. A better product might be obtained by damping the acids and alkali separately, and applying a proper degree of heat in granulating. Another point worthy of remark is the fact, that nine-tenths of the people who use the citro-tartrate, generally put the water into the glass first, and the salt upon the surface. The salt ought first to be placed at the bottom of the glass, and the water poured upon it. No directions of this nature are given on the manufacturer's labels.

J. Hughes.

High Street, Cheltenham, July 15th, 1870.

Anonymous Writing.

Sir,—I mean to append my name to this letter, and therefore may, even by those who object to anonymous writing, the subject having "cropped up," be allowed to say a few words in favour of it.

First, however, I agree that—

Nothing personal, or at all affecting injuriously the moral character of private individuals, should be admitted in print without the name of the writer;

Nor any *general* attack be permitted to be so made upon the motives or capabilities of any person or society, public or private.

There may also be this further objection taken by editors of periodicals to anonymous letters, that, being without a name, they may be necessitated to do what they have hardly time for, *i. e.* read them *through* carefully.

But this one great advantage—of an essay relying solely upon its own merits, unaided and unobscured alike by the addition of a well-known or of an unknown name—can be secured *in no other way* than by anonymous publication.

I do not know, nor care to know, how often a novel idea, an unpopular sentiment, or individual partiality or dislike, may have consigned a well-written and telling article to the waste-basket, because unintroduced and unrecommended by a name, but it needs small knowledge of human nature to feel assured that this must often be the case. And who knows not the power of a name to give currency and weight to the dullest mediocrity?

Let me suppose—I am sure these gentlemen will pardon the supposition—that it were possible for a Redwood, an Ince, or a Squire to write nonsense; would a communication signed by one of them be either refused insertion on this account, or operate as fairly upon the mass of readers as it would if unweighted by the influence of an eminent name? On the other hand, it is next to impossible impartially to criticize and examine in print the demerits of such a production otherwise than anonymously. Men usually, if not always, require the stimulus of a sense of personal affront or injury—of private or public animosity—to stir them up to array themselves in open antagonism to a high reputation or deserved eminence. Yet those who have attained both may err, and if they do, their very superiority only makes it the more needful that errors upheld by commanding influence should be impartially exposed, without fear and without favour. Import, however, the element of personal feeling, and farewell to anything like fair criticism, or cool and impartial judgment.

This one consideration alone (there are others) should, I think, arrest in some degree the tide of this present, almost universal, crusade against anonymous correspondence in public prints, and moderate the zeal of those who engage in it, and, at the same time, desire not merely to give, but to listen to, unbiassed opinion.

Politically, I am not afraid of the ballot, but I conceive that question to rest on an entirely different basis. I am not here advocating the moral cowardice of hiding one's name from fear of personal consequences, but the advantage which would accrue to the cause of truth from the absence of suspicion of personal interest or motive on the one hand, and on the other of a fair and free investigation of facts and arguments.

Of two kinds of anonymousness (I must coin the word), —that in which the correspondent's name is unknown even to the editor he addresses, and that which conceals it from the public only,—I am here treating chiefly of the former. And I will go the length of saying, that if a writer of note wishes to ascertain his own true weight in the scale of public estimation, or whether he has gained or lost ground in an opinion which he values, he should occasionally, not only only omit his name, but likewise employ an amanuensis.

I am, Sir, yours respectfully,

Thomas Lowe.

Liverpool, July 18th, 1870.

George B. Clarke (Woburn).—

1. Entry is not necessary in the cases mentioned, neither is the signature of the purchaser required by the Act.

2. The articles referred to are not included in both Parts of the Schedule, but only in Part I. Part II. refers to Tinctures, and all vesicating liquid preparations of Cantharides, or preparations of Corrosive Sublimate. It is only necessary to label these.

3. No.

R. Jones Owen.—The book referred to has not been received.

R. R. (Leighton Buzzard) wishes "Echo" to favour him with the correct rendering of the sentence criticized at page 60 of the last number.

C. Brook, jun. (Southville) inquires if a 'Flora of Hampshire' is to be procured; if so, where and at what cost?

Label (Maidenhead) shall be answered by post.

A. Z. (Liverpool) will find some information in chapter 8 of 'The Practice of Perfumery.'

E. B. S. (Norwich) wishes to learn who is the maker of "Symond's Ale Preserver."

J. R. M. (Witham) should write to the Secretary of the Royal College of Surgeons, Lincoln's Inn Fields.

R. J. (Southport).—1. Next week. 2. The *o* is short in the word podŏphyllin.

A Country M.P.S.—If the writer will favour us with his name and address, we will write to him.

M. P. S. (Liverpool).—The dose is large, but, failing to see the prescriber, we think it might be dispensed with safety. The case was probably that of hæmorrhage.

ALCOHOLIC FERMENTATION.

BY BARON VON LIEBIG.

(*Continued from p.* 64.)

Pasteur thinks that in the fermentation of yeast the cellulose of the old mother-cells is converted into sugar, part of which is consumed in the formation of the cell-membrane of the young sprouts, while another part must be converted into alcohol, carbonic acid, succinic acid, etc. This view might be readily tested by determining the cellulose and the alcohols. In the same proportion as alcohol was formed cellulose should disappear.

I have endeavoured to prepare cellulose from yeast by Schlossberger's method,* but I have not succeeded in obtaining it quite free from nitrogen. I did not obtain more than 17 per cent. from the yeast, generally less. Pasteur found in three experiments 17·77, 19·29, and 19·21; mean, 18·76 per cent.

The determination of the alcohol is not difficult.

The yeast used for this purpose was bottom yeast; it was washed with water, and separated by means of a fine sieve from the remains of hops and beer. What passed through the sieve was allowed to settle; the deposit, mixed with ten times its bulk of water and repeatedly washed with fresh water by decantation, until the supernatant water was no longer coloured. After this treatment the yeast presented no foreign cells when examined by the microscope.

As already mentioned, the fermentation of yeast takes place most freely at 30° or 35° C., and after thirty-six hours there is no further evolution of gas. A temperature of 60° C. kills the yeast-cells; after exposure to this temperature in water, they no longer undergo fermentation, and do not cause fermentation in sugar solution.

I. 1500 c.c. moist yeast, = 147 grm. dry yeast, gave, after eighteen hours, 14·792 weak alcohol, 0·8472 sp. gr. = 11·981 alcohol.

II. 1200 c.c., = 48·81 grm. dry yeast, gave, after thirty-six hours, 6·188 alcohol.

III. 1200 c.c., = 91·5 grm. dry yeast, gave, after twenty-four hours, 8·23 alcohol.

IV. 1000 c.c., = 79·22 grm. dry yeast, gave, after eighteen hours, 6·66 alcohol.

V. 1000 c.c., = 100·58 grm. dry yeast, gave, after thirty-six hours, 13·9 alcohol.

Reducing the alcohol obtained in these five experiments to cellulose, for comparison with the cellulose contained in the yeast taken, the following results are obtained:—

	Yeast.	Cellulose.	Equivalent alcohol.	Alcohol obtained.	Percentage of the cellulose.
I.	147·0	27·57	15·7	11·98	76 per cent.
II.	48·8	9·16	5·2	6·18	118 „
III.	91·5	17·16	9·7	8·23	87 „
IV.	79·22	13·85	7·8	6·66	85 „
V.	100·58	18·86	11·26	13·90	120 „

In these calculations, Pasteur's determination of the amount of cellulose has been adopted.

It will be seen that the amount of alcohol obtained was greater in proportion to the duration of the fermentation.

If this alcohol were formed from the cellulose of the yeast cell-walls, all the cells should have disappeared in the experiments II. and V.; but it was evident that the cells were not reduced in quantity, and that they do not disappear.

* Ann. Ch. Ph. vol. li. p. 205.

The cellulose was determined in the deposit from experiment V., and it amounted to 11·75 grm., independent of loss in the operation.

According to the microscopic examination by Prof. Nägeli, "the cells of yeast that has been fermented without sugar exactly resemble in form and size the cells of ordinary yeast; they differ from them in so far that they do not sprout any more, in having coarser and thicker cell-membrane, in their granular and reduced plasma contents,"—they are, in fact, dead cells, and the process of yeast fermentation consists in the destruction of the cell contents. During this fermentation there is no perceptible smell of putrefaction.

The liquid obtained by washing the fermented yeast, gives, on boiling, a coagulum similar to albumen: baryta water produces a precipitate of phosphate: mixed with alcohol as long as it is rendered turbid, a syrupy mass separates, and after the alcohol is removed, the clear, yellow, supernatant liquid deposits crystals which consist of ordinary leucin.

The substance precipitated by alcohol is highly nitrogenous and contains sulphur. The residue (consisting of dead cells) washed and dried, is a brown, tough mass, containing on the average 5·64 per cent. nitrogen and ·493 sulphur. The first yeast contained 7·4 per cent. nitrogen or 1·76 per cent. more than the fermented yeast. It is evident, therefore, that in the fermentation of yeast, its nitrogenous constituent undergoes decomposition; the greater part of it becomes soluble and part remains in the yeast cells. Weak potash solution dissolves out of them a substance similar to casein, but containing only 11·39 per cent. nitrogen.

It is clear that if it is not the cellulose of the yeast which yields material for production of alcohol and carbonic acid, these must originate from a substance analogous to sugar and constituting part of the cell contents. Moreover, since this substance cannot be extracted by washing the yeast, it must be in the state of a fixed compound with some other substance in the cell which contains nitrogen and sulphur.

Reducing to sugar the alcohol obtained in experiment V., it represents 27 grm. ($C_{12}H_{12}O_{12}$), and adding this to the cellulose in 100 parts of yeast the sum of the non-nitrogenous constituents would be 45·6 according to Pasteur, or 43·5 per cent. according to my determination of cellulose. Hence there would remain 54·4 or 56·5 per cent. nitrogenous substance, containing 7·41 nitrogen, corresponding to 13 or 13·5 per cent. nitrogen in this substance, about 1·5 or 2 per cent. less than in the albuminates. Considering that yeast must contain less than 16·5 per cent. of pure cellulose, with some solid and liquid fat, and a bitter, resinous substance, probably derived from hops,* there would be no great error in assuming that in yeast the substance containing nitrogen and sulphur is either an albuminate or one closely related: there can be no doubt that it originates from an albuminate.

There is, I believe, no difference of opinion as to the behaviour of yeast in beer wort; so soon as perfect yeast-cells have been formed, the decomposition of sugar commences, and at the same time the formation of yeast goes on incessantly until all the sugar is decomposed.

As already mentioned, the breaking up of sugar is

* Schlossberger, *op. cit.* p. 198.

accompanied by a decomposition of the cell contents, from which a nitrogenous substance is dissolved by the fermenting liquid. This liquid loses nitrogenous constituents if these become part of the cells, and it again receives some by the decomposition of the cell contents.

So far back as 1853, Graham, Hofmann, and Redwood ascertained that a hopped wort of pale malt, containing ·217 per cent. of nitrogen before fermentation, contained only ·134 per cent. after fermentation, so that only ·083 per cent. of the nitrogen remained in the yeast, the rest remaining in the fermented liquid. The numerous nitrogen determinations in beer by Feichtinger,* etc., showed a constant, and on the average, larger amount of nitrogen in Bavarian beer.

According to experience in brewing, the yeast added for setting up fermentation is increased eighteen or twenty-fold, or there is obtained from 1800 to 2000 parts for each 100 parts of pasty yeast.

In the fermentation of sugar with yeast there cannot be any increase of yeast, for there is no substance containing nitrogen and sulphur to serve as food for the yeast-cells. Pasteur has formed a peculiar opinion respecting this process. He says, "If this matter be examined more closely, it will be evident that in the fermentation of sugar in the presence of albuminates there is *not more, but rather less yeast formed* than in the fermentation of pure sugar solution." If increase of yeast means addition and multiplication of the yeast-cells, this assertion of Pasteur's is perfectly unintelligible and inconsistent with the facts ascertained by himself. In one of his experiments he added 20 c. c. of an aqueous decoction of yeast, containing ·334 nitrogenous substance, to a solution of 9·899 grm. sugar, and then added a trace of yeast. After the fermentation had ceased, this yeast had increased to ·152 grm. of dry yeast. If this trace of yeast weighed 2 milligrams this increase would be about seventy-sixfold, or 100 parts of yeast would have given 7600 parts.

In his experiments with sugar-water and yeast† 100 grm. of sugar was fermented with 4·625 grm. yeast, and the yeast weighed, after fermentation, 3·230 grm., having lost 30 per cent. In another experiment 100 parts of yeast were reduced to 91 parts.

Comparing the increase of weight in the first mentioned experiment with the other, in which it was only 42 per cent., the large difference appears remarkable, and the cause of it is easily intelligible, for in the former case there was a substance present that served for the increase and propagation of the yeast-cells, while in the other case the fermentation took place in pure sugar solution.

By increase of yeast nothing else can be understood but multiplication of yeast-cells, and this presupposes the presence of a nitrogenous substance for the production of their nitrogenous contents. It is, therefore, impossible to suppose, that in the fermentation of sugar with yeast there can be any multiplication of active yeast-cells, and any increase of weight must be due to some other cause.

However, Pasteur adopted entirely different assumptions for establishing his statement. When a fermented sugar solution is evaporated to dryness, and the residue treated with alcohol and ether, there remains a nitrogenous substance whose constituents Pasteur regards as originating from the yeast. He describes it as the "soluble part of the yeast that passes into solution during the fermentation," and he considers that it must be added to the yeast remaining after fermentation, in order to ascertain the actual increase of weight.

It is in this way that he makes the dissolved contents of the fermented liquid in the experiment to amount to 2·320 grm., and adding this to the yeast residue = 3·230 grm., obtains 5·550 grm. as the total quantity of yeast, or ·934 grm. more than the quantity taken at first. In this way he makes the deficiency of 33 per cent. appear as a surplus of 20 per cent. It is quite true that the liquid, after fermentation, contains in solution a nitrogenous substance that must have originated from the yeast; but the whole of the residue obtained by evaporating this solution cannot be regarded as originating from yeast, and Pasteur has himself given the most convincing proof of this.

In the fifth section of his Memoir, headed "*Succinic Acid, Glycerine, Alcohol, and Carbonic Acid are not the only Products of Vinous Fermentation*," he describes an experiment in which he fermented 100 grm. of sugar with yeast, and then determined the succinic acid, glycerine, and extractive material. The yeast taken weighed 1·198 grm.; the extract (free from succinic acid and glycerine) 1·130 grm., and the remaining yeast 1·700, so that the extract weighed only 68 milligrams less than the yeast taken. Therefore, it is self-evident the greater part of this extract could not have been derived from the yeast, otherwise there would not have been any yeast left after the fermentation, while, in fact, there was more than the quantity taken at first.

The experiments of Graham, Hofmann, and Redwood may also be considered in reference to Pasteur's observations, as furnishing additional evidence that the greater part of the residual extract does not originate from yeast. They mention that in the fermentation of sugar, however far it is pushed, there is formed, besides alcohol and carbonic acid, a peculiar substance; this is the case with pure sugar solutions as well as with beerwort. A solution of cane sugar mixed with 1½, 3, and 6 per cent. by measure of liquid yeast gave, after fermentation, 4·4, 3·72, and 3·7 per cent. of that substance, the characters of which resembled those of glucic acid or caramel. It was not susceptible of further fermentation, and presented the appearance of a dark brown syrup, with a bitter and rather acid taste. Though a mixture of various substances, it did not contain any dextrin or sugar, but precipitated suboxide when boiled with an alkaline solution of copper. It is true these residues were not washed with alcohol and ether before weighing; but comparing their weight with the quantities of yeast taken in the different experiments, it is evident there is no relation between the two; with two or three times as much yeast, there was no more extract than where the smaller quantity was taken, and it must be remembered that neither succinic acid nor glycerine reduce alkaline solution of copper. Consequently, it is not admissible to regard the extractive material contained in a fermented liquid as being derived from the yeast, and to take it into account as residual yeast as Pasteur does.

In a saccharine solution containing nitrogenous and sulphuretted material suitable for the food of

* Ann. Ch. Ph. vol. cxxx. p. 227.
† Page 491.

yeast fungus, the number of active yeast-cells is sometimes increased a thousandfold and more, while the amount of nitrogenous substance in the solution decreases. During the fermentation of a pure sugar solution mixed with yeast, the liquid extracts some nitrogenous material from the yeast. In this way the efficacy of the yeast is reduced, and when a further quantity of sugar solution is added, less sugar is decomposed. I have found that if the yeast remaining after fermentation of sugar solution be washed with water before adding it to fresh sugar solution, it ceases to produce fermentation after this has been done twice. When it is not washed each time, it causes very slight fermentation in the fifth quantity of sugar, but is then exhausted.

Consequently, in regard to the formation and multiplication of yeast-cells, there is a difference between the fermentation of sugar solution with yeast and the fermentation of saccharine solutions containing nitrogenous material applicable as food for the yeast fungus. Pasteur's statement, that in both cases there is an equal production of yeast, is destitute of any foundation in fact.

Like Pasteur, I have found that when 1000 c. c. of a 10 per cent. sugar solution is mixed with 15 or 20 c. c. of moist yeast, containing 3½ to 5 grm. of dry substance, the weight of the yeast remaining after the fermentation is less than that of the fresh yeast taken. In this case the fermentation is very rapid and violent, the liquid becoming clear within three or four days. So long as the turbidity continues, this may be regarded as a certain indication that fermentation is still going on.

My experiments further confirm Pasteur's observation, that when sugar solution is mixed with less than the above proportion of yeast, the weight of the yeast, after fermentation, is not less but more than at first. This increase is from 5 to 12 per cent. by weight. The cause of it has been discussed by Pasteur, but I believe definite evidence can now be furnished that it is due to the remarkable circumstance, that the nitrogenous material extracted from the yeast during fermentation may itself serve as food for the production of new yeast-cells. In that case, it is easily intelligible that the yeast should increase in weight. At the commencement of the fermentation, and for some time afterwards, nitrogenous material is extracted from the cell-contents of the yeast by the liquid still rich in sugar. The residual living yeast behaves to this liquid like fresh yeast that has been added to beerwort,—it sprouts and forms new cells which consume the dissolved nitrogenous material in reproducing the originally active cell-contents. Then, inasmuch as these new cells act upon sugar, there is again a separation of nitrogenous material, and this may continue to go on for months.

The formation of new cell-membrane goes on parallel with the production of new cells, and, since that consists of cellulose, the weight of the yeast is thus increased, while, at the same time, its relative amount of nitrogen decreases. The process just described may be made apparent if a litre of 10 per cent. sugar solution be completely fermented with 15 c.c. moist yeast paste. If the clear liquid above the remaining yeast be filtered two or three times through a double filter, there will not be any trace of organized substance recognizable in the liquid. By boiling this for some time to remove alcohol, there remains 450 or 500 c.c., containing the nitrogenous substance that has been separated from the yeast in the fermentation. If some 30 or 40 grm. of sugar be dissolved in the liquid, and, after cooling to 20° C., a trace of yeast* added to it, the whole being left in a small closed flask, fitted with a discharge-tube for gas dipping into water, it will be found that, after ten hours, there is distinct evolution of gas and a sensible deposit of yeast. The discharge of gas constantly augments, and after three or four days the yeast produced will amount to 450 to 600 milligrams in the pasty condition. After eight or ten days, the whole of the sugar will have disappeared. By repeating the same series of operations with this liquid the process is again repeated, and in this way I have succeeded in producing yeast of perfect activity four times successively in the same liquid. This yeast behaved towards sugar solution yeast in the same way as fresh yeast.

The only precaution necessary for succeeding in this experiment is that, after the end of each fermentation, the filtered and evaporated liquid must be exactly neutralized with carbonate of potash, to prevent its becoming too acid.

The slow progress of the fermentation when there is only a small quantity of yeast, or what is known as the after fermentation, is due to the circumstance that, while the nitrogenous and sulphuretted material transferred from the yeast-cell to the liquid in consequence of the metamorphosis taking place there, has not in itself the power of converting sugar into alcohol and carbonic acid. It nevertheless acquires that power again; this happening by its serving as material for the production of new yeast-cells, and assuming in the cells that state of combination in which it produces decomposition of sugar.

During fermentation a separation of the nitrogenous cell-contents takes place; one part remaining in the exhausted cell in an insoluble state, and that is the reason why the action of the yeast is limited. If all the nitrogenous constituents were separated from the cell, and they had the capability of serving again for the production of new cells, the process of fermentation would be a true perpetual motion.

The cases of fermentation of sugar solution with washed beer-yeast, described above, constitute a tolerably good representation of all similar kinds of fermentation. With a certain proportion of yeast, the fermentation is rapid, and the yeast decreases in weight; with a very small amount of yeast, the fermentation is slow, and may last for months or years, as in the after fermentation or maturing of wine, and in this case there is an increase in the quantity of yeast.

It is conceivable that in both cases the process is the same, and that the difference is due merely to the quantity of yeast; but if the continued formation of cells were a necessary condition of rapid fermentation, then the number of cell vessels and the weight of cellulose should increase in the same ratio, as in the slow fermentation, while the fact is that the yeast decreases in weight in rapid fermentation.

Disregarding mere opinions our actual knowledge of yeast and of its action is limited to the following:—

1. Yeast consists of plant-cells, that develope and multiply in a liquid containing sugar and an albuminate, or some substance derived from an albuminate. The chief mass of the cell contents consists of a

* For this purpose a piece of pasty yeast, the size of a pin's head, is mixed with 10 c.c. water, and of this 1 c.c. is taken.

compound of some substance containing nitrogen and sulphur with a carbo-hydrate or sugar.

From the moment when the formation of yeast is complete, and when it is left in contact with water, there is a molecular motion which takes place, and manifests itself by the transformation of the cell-contents. The carbo-hydrate (or sugar) contained in the cells is converted into alcohol and carbonic acid, while a small portion of the substance containing nitrogen and sulphur becomes soluble, and communicates to the liquid its own molecular motion, in consequence of which it has the power of converting cane-sugar into grape-sugar. In this process no other substance takes part besides water.

When cane-sugar is added to a mixture of yeast and water, it is first converted into grape-sugar, and the particles of sugar, penetrating the cell-membranes, behave in the same manner as the sugar or carbo-hydrate that is a constituent of the cell-contents; they are converted into alcohol and carbonic acid (or succinic acid, glycerin, and carbonic acid), —or, in other words, the sugar undergoes fermentation.

Up to the present time there is no well-established case in which yeast has been formed without sugar, or in which sugar has been converted into carbonic acid and alcohol without the presence and influence of yeast-cells.*

Schlossberger observed that many juicy fungi (for example, *Agaricus russula*, etc.), when kept in narrow-mouthed, open flasks, underwent vinous fermentation spontaneously, and that alcohol could be obtained from the expressed liquid on distillation; meanwhile true yeast-cells were formed.

According to this, the significance of the plant organism in the phenomenon of fermentation appears to be clear, for it is only through its agency that an albuminate and sugar can be united into a peculiar compound in the liquid where the yeast-plant is developed, or, in other words, associated in that manner in which they can, as a constituent of the fungus, exercise an influence on sugar. When the fungus ceases to grow, the bond uniting the constituents of the cell-contents is dissolved, and it is the molecular motion acquired by the cell contents which enables the yeast-cells to determine a dislocation of the sugar elements, or their separation and rearrangement into other organic molecules.

* It is not here meant that, besides the organized yeast ferment, there is no other which could convert sugar into alcohol and carbonic acid. In regard to this point, it is necessary to direct attention to the highly remarkable characters of the madder ferment discovered by E. Schunck. See Erdmann and Werther's Journal für Prakt. Chemie, vol. lxiii. p. 222.

Schunck showed that in madder, and in its aqueous extract, fermentation took place at a moderate temperature, in consequence of which rubian is converted into a number of new substances, among which alizarin is the most remarkable. Neither yeast nor casein decomposes rubian, and the action of emulsin is only partial. The madder ferment, which Schunck calls erythrozym, is obtained by mixing an aqueous extract of madder with hydrochloric acid, when it separates as a brown flocculent precipitate. In the second stage of its decomposition, it produces a true vinous fermentation in sugar solution, and Schunck found succinic acid among the products (1854), the presence of this substance in all fermented liquids having been ascertained so far back as 1848 by C. Schunck in Dorpat. See Handwörterbuch, vol. iii. p. 224.

(*To be continued.*)

RHATANY FROM PARA.

BY DR. F. A. FLÜCKIGER.

Since the end of last century the roots of *Krameria triandra*, a native of Peru, have been known in medicine under the name of rhatany. At a later period—about 1852 in Germany—it was found to be mixed with the roots of *Krameria Ixina*, a native of the northern parts of South America and of the Antilles. It has been shown by Hanbury (1865) and by Triana* that this plant yields the rhatany† of Savanilla or New Granada. This kind is nowhere properly officinal, but it had, nevertheless, recently and for a time, almost displaced the Peruvian root; until later this has again become abundant.

A third variety of rhatany root was described by Berg,‡ in 1865, as of Brazilian origin, and coming from Para. He obtained it from Gehe and Co., of Dresden. I also obtained this drug from the same source, so that I am able, from my own observation, to confirm Berg's description, adding to it only, that the transverse figures frequently present a jagged course, and sometimes surround the root. They are, on the whole, very regularly distributed; and though at some places they are entirely absent, they become apparent when the root is bent backwards and forwards. The Para rhatany presented in this case a very peculiar elasticity as compared with that of Payta and Savanilla, even when in sticks, $\frac{1}{4}$ inch and more in diameter. Some pieces also presented the very remarkable appearance of numerous corky worts. Like the Savanilla variety, the Para roots become bluish-black when thin slices are immersed in sulphate of iron solution. Very probably this was the root examined by Mettenheimer.§

I have also obtained the same root lately from Étienne Roques and Co., in Paris, and was assured it came direct from Para.|| It is in pieces 16 to 20 inches long, and $\frac{1}{8}$ to $\frac{3}{4}$ of an inch diameter, inclusive of the bark. They are all of a dull, uniform, dark brownish or greyish colour, like the sample obtained from Gehe and Co. This colour in itself is not striking, but if the three varieties of rhatany are compared together, there is a distinctly recognizable difference between them. The Peruvian or Payta rhatany is red, the Savanilla is violet, and the Para root is greyish-brown. The two latter are most alike superficially, and this is probably due to the preponderance of tannin that colours sulphate of iron bluish-black.

The structure of Para rhatany, as described by Berg, corresponds closely with that of the two specimens above-mentioned. But while Berg speaks of its structure as being very different from that of Savanilla rhatany, I should limit that difference to the fact, that in the Para root the middle bark is always

* This word is, as commonly thought, of Spanish origin; but is much more probably derived from the language of the district where the plant grows. Spruce, who is acquainted with this language and with Spanish, directed his attention to the krameria in examining the cinchona region between 1859 and 1861. According to him, *rattani* in the Quichua language, means to hold, fasten, bind together; and the word rhatany appears to be derived from it. In the Spanish Pharmacopœia of 1865 it is called Ratania.

§ Wiggers, 'Jahresbericht,' 1852-53 and 1857.

|| Berg's name, *Radix rhataniæ brasiliensis*, is too comprehensive; *Krameria Ixina* also grows in Brazil.

made up of eight or ten rows of cells, while in the Savanilla kind there are only half as many. Other differences do not appear to be general, when the comparative examination is extended to a large number of sections from roots of various thicknesses. Thus, for instance, in thin pieces only a few cells of the parenchyma are filled with oxalate of lime, while in thicker pieces this is frequently the case, as in the Savanilla roots. Even in regard to the thickness of the bark, the difference is often only one of degree. Moreover, since the parenchyma fibres in the Para variety present a very scattered appearance at the outer circumference of the sections, it is not easy to distinguish precisely between the middle bark and the interior bark.

The identification of Para rhatany is sufficiently ensured by means of the external characteristics above mentioned, except in the case of some few pieces.

After having thus assured myself as to the identity of Berg's Brazilian rhatany with that obtained from Para through the French house, I received a memoir read before the Paris School of Pharmacy by Cotton in 1868. This laborious paper, entitled 'Etude Comparée sur le Genre Krameria et les Racines qu'il fournit à la Médecine,' first specifies the 21 different varieties of Krameria that are known, and then treats of the roots belonging to each. After the Payta root, which is the only officinal kind in France, Cotton describes the Savanilla kind, and explains that there are two very different types of it, viz. the New Granada, or true Savanilla, and that from the Antilles. In reference to the first named type, Cotton gives no information that is new to me, and it corresponds with the Savanilla rhatany described in German works. He states that the roots from the Antilles are now commencing to displace those from New Granada and Peru.

Cotton distinguishes two forms of rhatany from the Antilles, viz. a black kind (*Ratanhia des Antilles à surface noire*) and a brown kind (*R. d. A. à surface brune*). The former is characterized by numerous transverse fissures; the latter is destitute of them, but has longitudinal fissures. Although he is disposed to regard these two forms as being derived from different varieties of Krameria, he, nevertheless, finds all kinds of intermediate specimens. From the description and drawings of the anatomical structure given by Cotton, nothing definite can be inferred. He states, further, that the Antilles kind (probably both the black and the brown) comes from several places on the coast of South America, near Cumanas, and "as far as Guadeloupe." It appears to me, therefore, that it is not especially entitled to the designation of Antilles rhatany.* Cotton adds, that it is generally, and perhaps with reason, ascribed to *Krameria Ixina*, and he believes he has proved this opinion to be correct by his comparison of specimens in the Paris herbarium with those of commerce. But, as will be evident, this applies only to a few fragments of the stem or branches, and not to the roots themselves, so that Cotton's assumption requires further demonstration, as he points out himself, since in regard to the brown kind or variety of Antilles rhatany, he is disposed to regard *Krameria spartioides* (Klotzsch) as the plant it is derived from, and, up to the present time, this is certainly known only in the northern and north-eastern parts of South America.

The question now arises, whether this so-called Antilles rhatany is a new kind, or whether the black form is "identical with that described by Schuchardt* in 1855, under the name Savanilla, while the brown root corresponds to a "false" rhatany, mentioned by Martigny,† as Cotton suspects. I think it very necessary to inquire further into these questions; but, at present, it is my object to clear up the relation between Cotton's rhatany, of the Antilles, and that from Para. Through the kindness of my colleague, Professor Planchon, of the Paris School of Pharmacy, I was enabled to examine the specimens described by Cotton, and to select typical examples of the brown and black kinds of his Antilles rhatany. By comparing these with Para rhatany, I have come to the conclusion that both these forms are identical with it. I may remark also, that this conclusion is based on the examination of twelve pounds of Para rhattany.

The author sums up his remarks as follows;—

1. There are, at present, in commerce, three different kinds of rhatany, which are best named after their principal ports of exportation,—Payta, Savanilla, and Para.
2. The first two kinds are described according to origin and characters in every modern work on pharmacognosy.
3. The Para root was first described by Berg, as "radix ratanhiæ brasiliensis;" by Cotton as rhatany of the Antilles.‡
4. Its colour varies between dark grey and brown; the extremes of this colour were regarded by Cotton as black and brown varieties.
5. This colour is very distinct from that of Payta and Savanilla rhatany.
6. The origin of Para rhatany is unknown.
7. The substitution, in medicine, of Payta rhatany by another is inadmissible. There exist in regard to the tannin, chemical differences which deserve to be investigated. The tannins predominating, or exclusively present perhaps in Savanilla and Para rhatany, produce bluish-black precipitates with iron salts.

---

* Originally this was ascribed to *K. Ixina* in the French Codex, also by Mettenheimer in 1852, by Schuchardt in 1855, and by Berg in 1866. Here the confusion began, inasmuch as Berg (Jahresb. 1856) characterized Savanilla rhatany correctly, but did not refer it to *K. Ixina;* while he declared Schuchardt's *Ratanhia antillica* to be identical with it. Wiggers (1856) likewise regarded it as a peculiar kind; Mettenheimer (Jahresb. 1857) identified the root mentioned by him with Berg's (Savanilla or) Granada rhatany, and disputed their identity with the Antilles root from *K. Ixina.* Perhaps Mettenheimer's description may, nevertheless, as already suggested, be referred to Para rhatany, although it is not sufficiently definite. After Hanbury (Pharm. Journ. 1865, Vol. VI. p. 461) referred Savanilla rhatany to *K. Ixina,* it was again classed with the original Antilles kind. In reporting on Hanbury's memoir, Wiggers (1865) was correctly under the impression that the Antilles kind was peculiar, and hence he assumed that, in the Antilles and in Venezuela, *K. Ixina* yielded this particular kind, as the true Antilles root, while the variety *granatensis* was obtained from the same plant in New Granada, as the Savanilla root. Whoever traces these modifications in the idea of Antilles rhatany, will share with me the wish to follow them out completely. After all, it seems to me very questionable whether the former French Codex was right in referring its Antilles rhatany to *K. Ixina.*

SPOGEL SEEDS.

Plantago ispaghula, Roxb.

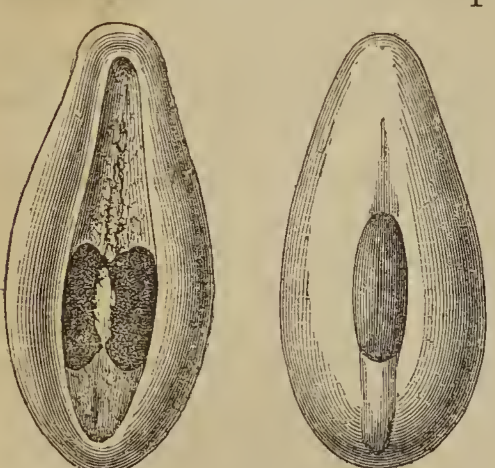
BY M. C. COOKE.

Spogel seeds have long been known and employed in the East. Probably both seeds and the report of their virtues were first derived from Persia. The seeds of several species of Plantain, as *Plantago amplexicaulis*, Cav.; *P. ciliata*, Desf.; *P. decumbens*, Forsk., and *P. major*, var. *asiatica*, are used in North-Western India, as well as those of *P. ispaghula*. Dr. Stewart says that all these, and it may be others of the wild species, at times, are collected and sold as the officinal seeds, known under the two names of "isafghol" and "bartang." They are considered cooling and emollient, and given in diarrhœa and fever. Honigberger states that the seeds of *P. major*, which are brought from Cashmere, are officinal with the Hakims.

The true spogel seeds are those of *P. ispaghula*, Roxb. They are the 'Ispagool' of the Persians, called by the same name in Hindustani, the 'Ispungur' of Sindh, 'Ispoghol' of the Tamuls, 'Isphagula' of the Teloogoos, the 'Buzr-katoona' of the Arabs, and the Yonanee 'Fuslioon.'

The plant itself is thus described:—Stem very short, soon dividing into three or four ascending round villous branches which are a few inches in length. Leaves alternate, linear-lanceolate, 3-nerved, luxuriant in young plants, remotely denticulate, somewhat woolly, towards the base channelled, and stem-clasping, length six to eight inches, by a quarter to half an inch broad. Peduncles axillary, solitary, naked, erect, round, a little villous, the length of the leaves. Spikes solitary, terminal, when in seed 1 to $1\frac{1}{2}$ inches long, and erect. Capsule ovate, 2-celled. Seeds solitary, ovate-elliptic, convex on the outside, concave on the inner. Integument rather thick, tough, and brown.

The seeds are the officinal part, and are about the eighth of an inch in length, of a greyish colour, with a pinkish tinge. Under the microscope they bear some resemblance to a minute cowry shell, the concave side having a deep longitudinal furrow or cleft, which is gaping at the middle and narrowed towards each end. They yield to water an abundance of tasteless mucilage.



Ainslie observes that the seeds are of a very cooling and mucilaginous nature, and are, on that account, much prized by the native practitioners, who prescribe an infusion of them in cases of gonorrhœa, catarrh, and in nephritic complaints. He adds, this is one of the few articles of the Tamool Materia Medica, the virtues of which are so well ascertained by the English inhabitants of India, as to have rendered their use common in the regimental hospitals.

Dr. Waring, in his 'Remarks on Bazaar Medicines' says, "These seeds, which are procurable in most bazaars, are highly useful, by their demulcent and mucilaginous qualities, in diarrhœa and dysentery, and they may be advantageously employed, whether fever be present or not. In the early stages of these diseases they are best given in decoction, prepared by boiling four drachms of the bruised seeds in two pints of water, till the quantity is reduced to one pint, and straining. The whole of this may be taken, in divided doses, in the course of the day. It need not interfere with the use of opium, or any other remedies deemed necessary. In chronic diarrhœa they are best given whole, in doses of two drachms and a half, mixed with half a drachm of sugar-candy or sugar. In their passage through the intestines they absorb as much fluid as make them swell, and by the time they reach the lower part of the canal, they give out a bland mucilage, and in general continue to exercise their mucilaginous property until they are passed by stool. They are chiefly useful when the stools are very watery. A low diet and small doses of opium aid their operation.

In the new India Pharmacopœia, this drug is included amongst the primary articles, an evidence of the esteem in which the authors held it for Indian practice. On one or two occasions only it has appeared in the English market. The only preparation named in the above work is the decoction of the seeds, but, when bruised and moistened with water, they are also recommended as forming a good emollient poultice.

Mr. Twining, in his 'Diseases of Bengal,' quotes the report that a slight degree of astringency, and some tonic property may be imparted to the seeds by exposing them to a moderate degree of heat, so that they shall be dried, and slightly browned. "This remedy," he adds, "sometimes cures the protracted diarrhœa of European and native children, after many other remedies have failed."

In Spain, perhaps also in other parts of Southern Europe, and on the northern coast of Africa, the seeds of another species of Plantain, *P. psyllium*, Linn., are employed for their mucilaginous properties, and are made into demulcent drinks as a substitute for linseed or marsh-mallows. Many other species possess like properties in a more or less eminent degree.

THE CHEMISTRY OF THE ATMOSPHERE.

BY J. ALFRED WANKLYN.

Having treated of the general conclusions to be drawn from chemical examinations of the atmosphere, I will now consider the analytical operations by which the composition of the atmosphere has been investigated.

The amount of oxygen in air is determined by ascertaining the degree of contraction which a mixture of a certain volume of air with an excess of hydrogen gas undergoes on being exploded by the electric spark; one-third of the contraction is equal to the volume of oxygen contained in the original air. Another method, which is very nearly, but not quite so accurate, is to absorb the oxygen directly, by means of pyrogallate of potash. The determination of the proportion of oxygen in air ranks among the most accurate operations of chemical analysis. This has been splendidly exemplified by Regnault and Bunsen.

The carbonic acid in the atmosphere has been determined by several methods in recent times. The plan of absorbing the carbonic acid by means of potash, and then reading the contraction thereby produced, is very unsatisfactory, inasmuch as the normal quantity of carbonic acid in the atmosphere is not more than twice as large as the experimental error involved in the two readings requisite for determining on the amount of contraction sustained by the volume of air experimented on. This will be apparent from the following figures:—In 100 volumes of average air, there is from 0·030 to 0·040 of a volume of carbonic acid. The readings of "original volume of air, before absorption by potash," and "volume after absorption by potash," cannot be depended upon as being accurate within less than the $\frac{1}{10000}$ of the total volume operated upon. In the instance, therefore, of a perfectly pure gas, absolutely devoid of carbonic acid, we should sometimes get 0·02 for the percentage of carbonic acid. In other words, a variation of 0·02 per cent. is devoid of meaning when this method is employed. But 0·02 per cent. is equal to more than one-half of the average percentage of carbonic acid in the atmosphere; consequently this method cannot be depended on for determining the actual variations which occur in the carbonic acid of the atmosphere, and this should be borne in mind in reference to results obtained in this way. Possibly the abnormal results obtained by Dr. Frankland in the examination of air from the summit of Mont Blanc, were due to this cause.

Another method employed for this purpose, is to ascertain the gain in weight, which an apparatus charged with solution of caustic potash undergoes when a known volume of air is transmitted through it. This method is obviously unsatisfactory, for a gas, containing so little carbonic acid as the atmosphere, cannot be deprived of its carbonic acid unless it be passed through solution of an alkali at a rate far slower than is practicable, and it is impossible to ensure that the immense volume of inflowing gas shall be in exactly the same state of dryness as the outflowing gas. The third method, which alone is satisfactory, is rather an old one. It consists in enclosing a known volume of air with a quantity of lime or baryta-water, and subsequently observing the quantity of carbonate formed. De Saussure, who was the first to operate in this manner, weighed the carbonate of lime; Dalton, and later, Pettenkofer accomplish the same end by means of titrations; the strength of the volume of lime or baryta-water being known beforehand, a titration of the lime or baryta-water, after the absorption, furnishes the requisite data. As has been said, we never meet with so much carbonic acid in a badly-ventilated room as to be of any importance in itself; inasmuch, however, as the discharge of carbonic acid into the atmosphere never takes place without being accompanied by other contamination, the amount of carbonic acid in a given specimen of air may be useful as an index to the general purity of the specimén. From this point of view, accurate determinations of the carbonic acid in air acquire a value. They are, moreover, very easily made.

Referring to Dr. Smith's Report for 1869, let us consider the method of research followed in his inquiries. This may be characterized as consisting in washing a known and generally enormous volume of air with a relatively small volume of water, and then examining the water. The results of the water-analysis are subsequently to be referred to the volume of air which has been submitted to the process of washing.

The first question naturally arising is, how far washing with water is capable of removing microscopic quantities of impurity from air? I have no hesitation in asserting that the operation of washing air, or other gas, with water is adequate for the entire transference of all finely divided solids, and all *vapours* from the former to the latter. A few years ago the author had a large quantity of gases, wherein was diffused the vapour of a liquid. That vapour was the product of a new reaction he was studying, and from the circumstances of the case, it could be obtained only as vapour mixed with large volumes of gases. How to extract the vapour was the question? By reducing the temperature as far as possible nothing was to be expected. For, unless at the lowest temperature reached, the tension of the vapour should fall so low that the volume of the gas would become supersaturated with vapour there could be no condensation at all. Even when condensation did occur, a certain quantity of vapour would necessarily remain, sufficient to saturate the gases at that temperature. Washing the gas with water was therefore tried, and it proved successful; the liquid sought for, which had existed in the form of vapour diffused through an immense volume of gas, was found in the wash-water. The ease with which such absorptions are effected, and the obvious completeness of the operation will commend themselves to all who make experiments of this kind.

In order to ensure the complete absorption of every trace of vapour and finely divided solid, the method adopted by Dr. Ransome, in his recent experiments on the organic matter of respired air, will doubtless prove very advantageous. Dr. Ransome cooled the air until the aqueous vapour in it began to condense, and then shook up with water. A little consideration will show how admirably this method of procedure is calculated to promote a thorough washing of every particle of the air under examination.

In the new air-analysis, this extraction of the liquid and solid impurity by means of washing with water is a cardinal method, and it deserves a prominent place among the resources of modern chemical analysis.

The method of water-analysis, used by Dr. Angus Smith for the examination of the wash-water, was that invented by Wanklyn, Chapman, and Smith, viz. the ammonia-process.

CHLORAL.

BY C. A. MARTIUS AND P. MENDELSOHN-BARTHOLDY.*

In the course of our experiments on the preparation of hydrate of chloral, it fell in our way to examine different preparations found in commerce, the purity of which was guaranteed by crystallization from sulphuret of carbon and ether, and subsequent pressing out. Our attention was also directed to the varying statements respecting the points of fusion and ebullition of hydrate of chloral, and to the possibility of admixture of foreign substances, even after the renewal of free chlorine and hydrochloric acid, and notwithstanding its solubility and apparent homogeneity; and that to these foreign substances might be due the discrepancies relative to physical properties, and possibly also the physiological discrepancies found by different observers. We were especially struck by the differences in boiling-point in different preparations, and led to the preparation of a series of

* Buchner's 'Repertorium für Pharmacie,' 1870.

compounds which threw light upon these discrepancies, and which are, moreover, of some scientific interest.

It had been observed by J. Personne* that chloral enters into combination with alcohol just as it does with water. According to our observations, the other alcohols of the fatty series behave similarly to ethylic alcohol. When one equivalent of chloral is mixed with one equivalent of anhydrous ethylic alcohol, there is union accompanied with development of heat, and, on cooling, the resulting compound solidifies into a crystalline mass. The same takes place when methylic, butylic, or amylic alcohol, or mercaptan, is substituted for ethylic alcohol.

We may regard these compounds as intermediate trichloracetals.

Acetal.	Trichloracetal.	Chloral-hydrate.
$CH\begin{cases} CH_3 \\ OC_2H_5 \\ OC_2H_5 \end{cases}$	$CH\begin{cases} CCl_3 \\ OC_2H_5 \\ OC_2H_5 \end{cases}$	$CH\begin{cases} CCl_3 \\ OH \\ OH \end{cases}$
Chloral alcoholate.	Chloral amylate.	Chloral mercaptide.
$CH\begin{cases} CCl_3 \\ OH \\ OC_2H_5 \end{cases}$	$CH\begin{cases} CCl_3 \\ OH \\ OC_5H_{11} \end{cases}$	$CH\begin{cases} CCl_3 \\ SH \\ OC_2H_5 \end{cases}$

Inasmuch as the production of these compounds takes place without formation of any bye-products, analysis of them appeared to be unnecessary. We have, however, taken the vapour-densities of some of them, and found that, like chloral-hydrate itself, they have only half the condensation indicated by their formulæ.

With the *ethers* of the alcohol-radicals chloral does not combine. The compound of chloral and ethylic alcohol boils at 115° to 116° C., and solidifies at 40° C., becoming crystalline. At 40° C. (in the fluid condition) its sp. gr. is 1·143.

In cold water it dissolves only slowly, but on warming, the solution is complete. In ether, alcohol, acetic ether, and petroleum, it is easily soluble; and on cooling the hot concentrated solution, it crystallizes out in long beautiful needles.

The methylic compound resembles the ethylic compound very closely. It boils at 98° C.

The amylic compound boils at 143° C., and at 25° C. has a sp. gr. of 1·2340. At 25° C. it solidifies to a crystalline mass, which is soluble in ether, alcohol, and petroleum. From the last-named solvent it is capable of crystallizing in long tufts of needles. Only on prolonged boiling with water is the decomposition into chloral and amylic alcohol complete.

Chloral-mercaptide, chloral, and mercaptan combine with great evolution of heat, and form a crystalline compound, soluble in ether, alcohol, sulphuret of carbon, and capable of crystallizing easily out of its solutions in these solvents.

We can easily understand that the alcohol-compound has been often taken for the hydrate of chloral, and that the hydrate has been often contaminated with the alcoholate.

It appears to us to be especially interesting to study the physiological characters of the alcohol-compounds; according to O. Liebreich, the physiological effects of the alcoholate differ essentially from those of hydrate. In preparing the hydrate for medicinal use, one of the main points to be attended to is its freedom from alcoholic compounds. Pure hydrate of chloral boils at 95° C., as we have ascertained by numerous experiments.

MUSHROOMS.

Two cases of cryptogamic poisoning have been reported within the last fortnight, and it is certainly very much to be regretted that the difficulty of distinguishing between poisonous and non-poisonous Fungi is so great, since mushrooms are held in such high estimation as a delicacy by all classes, and are gathered and consumed in great quantities with so little discrimination. Looking at the whole class of Fungi, and the purpose served by its members in the economy of nature, we may consider them in the light of highly nitrogenized, and therefore nutritious material, their special office being to convert organized material into organic mould, serviceable for the growth and nourishment of the more highly organized plants, while their own growth is supported by the nitrogenous elements of their nidus.

The phenomenon of their growth may be simply illustrated by observation of the yeast-plant in the fermentation of beer, or of the vinegar-plant in the production of vinegar. Both these Fungi are species of *Mycoderma*, and, speaking generally, they grow in a fluid containing nitro-hydro-carbonaceous material mixed with variable quantities of accidental elements and compounds, and, by appropriating to themselves the nitrogenous element, they leave the hydro-carbonaceous atoms to rearrange themselves. But it happens that in the progress of these changes an alkaloid, or sometimes probably more than one, is often developed, and may be taken up by the fungus. These alkaloids are all more or less aerial, and according to the degree of their acridity they render the fungi containing them more or less poisonous.

The material forming the nidus affects the character of the alkaloid. Specimens of the same species of *Agaricus* grown in different beds will vary in acidity to a degree corresponding with the nature and composition of the bed in which they have been raised. Climate also appears to possess considerable influence in the production and assimilation of the alkaloids in fungi, since many species may be eaten without risk in one country, while in another the same species are markedly poisonous.

The mushroom we use commonly in England, for instance, is held to be poisonous in Italy, and prohibited in the Italian markets; while in Paris the only species allowed in the markets is the *Agaricus campestris*, excepting, of course, the truffle (*Tuber æstivum*) and morel (*Morchella esculenta*). *Boletus edulis* has, however, been cultivated in the south of France. The mushroom most highly esteemed in this country is the *Agaricus campestris*, of which the pileus is fleshy and dry, plano-convex, flesh-coloured, becoming brown; the stem is stuffed and even, with a white ring, somewhat torn, placed about its middle; the gills are free. In some parts of the country the *Agaricus arvensis* is much prized, but it is coarser, and more likely to be acrid. It is white, afterwards becoming a pinkish-brown, and it often attains an enormous size.

A third variety is the *Marasmius oreades*, or champignon, which may usually be eaten with impunity; it, however, is sometimes very acrid, and requires to be gathered with judgment, for *Marasmius urens*, which often grows in the same meadow, is of very much the same appearance, and is particularly acrid. The last-named, however, is darker, and has narrower gills.

In France, the ordinary mushroom, *Agaricus campestris*, is in common use, as already stated; *Boletus edulis* has also been cultivated, and is thought much of. The appearance of this fungus, however, is against it; it is high-coloured, watery-looking, and forbidding. The truffle (*Tuber cibarium*) is considered an exceptional delicacy, and is much sought after.

It is not, however, the epicurean view of the subject we now desire to take, but the practical and interesting question how to distinguish non-poisonous fungi from those which are poisonous. The duty of gathering mushrooms for commercial purposes usually falls to the share of the uneducated. They, with a little experience, and provided they exercise due care, are morely likely to discriminate than educated persons, or even sometimes than the botanist, paradoxical as this may appear; because, from their daily practice, they are familiar with both the good and the bad growing in their neighbourhood. But accidents do occur, and will continue to

* 'Comptes Rendus,' vol. lxix. p. 1363.

occur, notwithstanding all precautions; and it seems impossible to lay down any rule that would entirely provide a safeguard, since even the cultivated *Agaricus campestris* may produce nausea. Still, there is good reason to believe that more casualties arise from carelessness than from ignorance; and attention to a few simple rules may prevent much unpleasantness and alarm.

As a rule, the edible mushrooms may be distinguished from their poisonous brethren by their delicate sweet aroma, as contrasted with the heavy acrid smell of the false mushrooms. Secondly, the delicacy of the true mushroom—which is free, or almost free, from warts—contrasts with the scaly surface of the false. The true are either white or brownish; their flesh is brittle; they grow in the open dry pastures, and usually are solitary, while the false often grow in clusters, in wet ground and in the shade, are tough and watery, and highly coloured.

There can be very little doubt that many species now avoided might be eaten, but are neglected for want of experiment.

Experience has gone to show that, after pickling in vinegar, mushrooms, however indiscriminately they may have been gathered, rarely give rise to discomfort, probably from neutralization of the alkaloid by the acid of the vinegar.

Sufficient cooking also appears to render the alkaloid inert; and it is possible that good dressing would render many fungi, not only harmless, but nutritious articles of diet. Darwin found the inhabitants of Tierra del Fuego living on a bright yellow globular fungus, *Cyttaria Darwinii*, found on the beach; and, in Australia, the *Mylitta australis* is used as a staple article of food, and called native bread.

It must not, however, be forgotten that there are certain persons whose constitutions are obnoxious to fungi, the least possible quantity producing in them nausea and a sense of sinking, with a dread of impending dissolution, which are the characteristic symptoms of fungus poisoning. But, with the exercise of care in selecting only those that are quite perfect and fresh, proper cooking, and by taking a reasonable quantity of some other food, such as bread or meat, at the same time,—above all, not indulging in them too plentifully,—mushrooms may be eaten with impunity; and they constitute at once a nutritious article of consumption, and, to many, a grateful luxury.

REPORT OF EXPERIMENTS ON THE IODIDE OF POTASSIUM USED IN MEDICINE.

With the object of ascertaining the degree of purity which may be looked for in the iodide of potassium as supplied by the druggist to the medical man, we procured six samples of the drug and submitted them to chemical analysis. These samples were obtained from hospitals and from druggists in various parts of London.

The chemical examination was made as follows: 8·305 grains of the iodide, in the undried state and not previously powdered, was dissolved in a little water, and to it a very little alkaline chromate of potash was added, and a standard solution of silver was then dropped into the liquid until the red tinge (the sign that the iodide of potassium was completely saturated with nitrate of silver) made its appearance. The quantity of standard solution of silver being noted, the quantity of silver was of course known. As will be seen from the tabular statement, the quantity of silver used up was that indicated by theory in the first five cases, while in the last only it was a little in excess of the quantity required for absolutely pure iodide of potassium.

After noting ~~the qu~~antity of silver solution, the resulting iodide of silver was washed first with very dilute nitric acid, then with pure water, and finally dried and weighed. The following is a tabular statement of the results thus obtained, viz.:—

No.	Obtained from	Quantity of Iodide of Potassium taken. (grains.)	Quantity of Iodide of Silver. (grains.)	Quantity of Silver employed. (grains.)
1.	Moorfields Eye Hospital	8·305	11·49	5·40
2.	London Hospital	8·305	11·68	5·40
3.	Skin Hospital	8·305	11·66	5·40
4.	Leo Lee and Co., Bishopsgate Street	8·305	11·66	5·40
5.	Hancock, Fleet Street	8·305	11·48	5·40
6.	Warner and Co., Fore Street	8·305	11·68	5·51
	Theoretically pure iodide of potassium	8·305	11·750	5·40

From these results it appears, firstly, that the iodide of potassium is remarkably free from bromide and chloride; and secondly, that, as actually sold, it is very dry. According to these analyses, 100 parts of commercial iodide of potassium contain from 99·3 to 97·7 parts of absolute iodide of potassium, the remainder being the inevitable "hygrometric moisture." It is most satisfactory to find this drug to be commonly supplied in so high a state of purity. We cannot, however, forbear remarking on the high price which is charged for it. A druggist commonly asks two shillings an ounce for iodide of potassium. Now, iodine itself is dear at one shilling an ounce, and iodide of potassium ought not to cost more than iodine; it ought, indeed, to be cheaper than iodine.

There are two varieties of iodide of potassium—the *opaque* crystals and the *transparent*. Fashion has led to the opaque kind being preferred; but there is no other reason in favour of the opaque. The transparent crystals are just as pure.—*The British Medical Journal.*

CHEMICAL EXAMINATION OF SEVERAL SORTS OF CONDENSED MILK.

BY L. KOFLER.

The following samples, examined by the author, were exhibited at the Agricultural Show at Schwarzach:—

I. From the Anglo-Swiss Condensed Milk Company, in Cham, Canton Zug; in air-tight tin boxes containing one pound.

II. From the manufactory at Sassin; in square glasses.

III. From the German-Swiss Milk Extract Company, at Vivis and Kempten; in glass vessels.

IV. The same; in tin boxes.

For the purpose of comparison, a similar preparation was made with milk that had been examined during twelve days previously, with the following results:—

	Specific gravity.	Amount of Cream.
15 October	1·034	13
16 "	1·036	13½
17 "	1·040	14
18 "	1·034	13
19 "	1·034	13¼
20 "	1·034	13
21 "	1·035	12
22 "	1·033	12
23 "	1·034	13½
24 "	1·036	12
25 "	1·035	15
26 "	1·033	15
Mean results	1·035	13·1

This preparation was marked V., and underwent the same examination as the other samples.

Determination of Water.—By drying until the weight remained constant.

Determination of Fat was made by extraction with ether, until the residue examined under the microscope presented no fat globules.

Determination of Casein and Albuminous Material was made by slightly acidifying with acetic acid at a gentle heat, filtering, and drying.

Determination of Salts by incineration. The further examination of the ash showed that it contained, like the ash of pure cow's milk, upwards of 40 per cent. of phosphates, and that one-half consisted of potash, soda, lime, and sulphates.

The amount of sugar in the samples varied between 25 and 30 per cent.; the amount of milk sugar, between 14 and 18 per cent.

The following table gives the general results:—

Constituents.	I. Cham.	II. Sassin.	III. Kempten.	IV. Kempten.	V. Standard.
Water . .	22·180	18·824	22·421	18·810	20·770
Fat . . .	12·260	12·625	12·030	13·650	12·830
Caseine and Albumen .	28·100	24·240	25·960	24·900	29·600
Ash . . .	2·180	2·482	2·673	2·430	2·865

All of these samples, dissolved in four or five times the volume of water, furnished milk which, in appearance and taste perfectly resembled fresh boiled milk, except that it was sweet, owing to the admixture of sugar.—*Vierteljahresschrift für Praktische Pharmacie.*

FACTS AND REASONINGS CONCERNING THE HETEROGENEOUS EVOLUTION OF LIVING THINGS.

(*Continued from page* 66.)

In his essay bearing the above title, Dr. Bastian criticizes Pasteur. We quote the following passage:—

"Before closing this paper, it will be necessary that I should refer more particularly to a certain part of M. Pasteur's researches, seeing that these have so strongly influenced the opinions of very many scientific men on the question of the truth or falsity of the doctrines of the heterogenists. As an experimental chemist M. Pasteur takes a most honourable position in the foremost rank of workers, and all his investigations on this subject appear to have been conducted with the most scrupulous care. His reasonings also may seem, at first sight, to be all-convincing, so that most people might be inclined to admit that he had 'mathématiquement démontré,' as he so frequently claims to have done, all that he set himself to prove. The case may seem at first a poor one indeed for the heterogenists; but as soon as one gets over the first impressions produced by the various experiments, and begins to inquire whether the reasonings concerning them have been in all cases fair and logical, then it may be seen that the evidence against the occurrence of heterogenesis is very far from being so strong as it, at first sight, appeared. On two or three occasions, when it was very important that results should be looked at from different points of view, M. Pasteur has altogether failed to do this, and has wished to interpret them only in accordance with the views of the panspermatists, *quietly ignoring the equally legitimate interpretation of the same results which might have been given by the heterogenists.* At present I shall confine myself to one instance of this kind, because I think that on this particular point the reasonings of M. Pasteur are as mischievous as they are illogical. If others were to follow his example, then certainly we could never hope to get rid of the clouds of controversy which at present obscure the subject.

"The experiments of Schwann were for some time erroneously believed by very many to have upset the doctrines of the heterogenists. No organisms, it was said, were ever developed in hermetically sealed vessels when the solutions containing the organic matter had been boiled, and when all the air which was allowed access to them had been previously calcined. Schwann's experiments did yield uniformly negative results when solutions of meat were employed; though his experiments concerning alcoholic fermentation yielded results which were sometimes positive and sometimes negative. M. Pasteur also, for a time, obtained only negative results in repeating the experiments of Schwann. In these experiments, however, he had generally made use of 'l'eau de levure sucrée,' of urine, or some other fluid which was naturally unfitted to undergo evolutional changes of a high order, or even to produce lower organisms in great abundance. But there came a time when M. Pasteur chanced to repeat his experiments, using precisely the same precautions as before, and yet the results were quite different,—organisms were now found in his solutions. There was one important difference, it is true. In these latter experiments, M. Pasteur had made use of milk. Now the quantity of organic matter contained in milk is, of course, very great; it is a highly nutritive and complex fluid. It might, therefore, and ought perhaps, to have suggested itself to M. Pasteur, that the different results of his later experiments were possibly explicable on the supposition that the restrictive conditions—the boiling of the solution and the closed vessel already containing air—were too potent to be overcome by the organic matter in the one solution, whilst they were not too potent and could not prevent evolutional changes taking place in that of the other."

In fine, M. Pasteur, having made the observation that milk, even after boiling and being sealed up in calcined air, produces bacteria and vibrios, draws the conclusion that therefore the germs of bacteria and vibrios are capable of resisting a temperature of 100° C. Dr. Bastian, on the other hand, maintains that the production of bacteria and vibrios in the milk after this treatment is a proof that these living things have arisen *de novo.*

Pasteur has observed that in alkaline or neutral solutions of sugar, etc., there is frequent development of low forms of living things after boiling and sealing, in contact with calcined air; whilst in acid solutions, other things being the same, there is no development of organisms. Pasteur says that the acid kills the germs. Bastian and the evolutionists, on the contrary, say that the acid is unfavourable to "evolutional" processes.

At the present stage of the controversy, it is admitted by the opponents of the doctrine of spontaneous generation, that organisms do arise in solutions which have received no germs from the air and have been exposed to a temperature sufficient for the destruction of the developed organisms.

In order to avoid having to admit the doctrine of spontaneous generation (which otherwise would be established by such examples), the hypothesis has been started, that the germs of such organisms are endowed with far greater powers of resistance than the organisms themselves. Since there is no microscope powerful enough to render these germs visible, and the only test of their presence being the production of the appropriate organism, it must, in the nature of things, be a difficult task to experiment upon the resisting powers of these germs.

Chinchonæ in Java.—Professor Miquel has given in the last published part of his 'Annales Musei Botanici Lugduno-Batavi' (tom. iv. fasc. 9, 1869), descriptions of all the Chinchona plants at present cultivated in Java. They are as follows:—*Chinchona Calisaya*, Wedd.; *C. amygdalifolia*, Wedd.; *C. scrobiculata*, H. et B.; *C. euneura*, nov. sp. Miq.; *C. Hasskarliana*, nov. sp. Miq. (this appears to be a hybrid between *C. Calisaya* and *C. Pahudiana*); *C. carabayensis*, Wedd.; *C. officinalis*, L.; *C. lancifolia*, Mutis; *C. ovata*, R. et P.; *C. subsessilis*, Miq. (= *C. purpurascens*, Wedd.); *C. caloptera* (= *C. pubescens*, *a. Pelleteriana*, Wedd.); *C. micrantha*, R. et P.; *C. pubescens*, Vahl; *C. Moritziana*, Karst. The Pharmaceutical Journal.

SATURDAY, JULY 30, 1870.

DR. RUMSEY ON THE PHARMACY ACT.

In some recent comments on the Laws relating to Public Health, Dr. Rumsey, the well-known sanitary reformer, remarks—touching the connection, so obvious in theory, between legislative control over the supply of drugs and poisons, and laws affecting the exercise of medical and sanitary functions—that the two departments are so sharply separated in this country, that the late attempt to establish some normal relation between them, in framing the Sale of Poisons Act of 1868, was defeated by the antagonism of its leaders. Yet, in Great Britain alone of all European nations, is the practice of pharmacy legally undertaken by physicians and surgeons acting as apothecaries. The fact that there is no law applying indifferently to all pharmacopolists, and the existence of a controlling power over the examinations of chemists, vested in the Privy Council, are anomalies Dr. Rumsey objects to, as well as the circumstance, that whilst the Medical Council is the sole authority in the compilation of the national Pharmacopœia, it should possess no control over the selection of articles to be included in the Schedule of Poisons. Dr. Rumsey's efforts, as our readers may perceive, are resolutely directed to secure a distinct separation of the duties of dispenser and prescriber. This is a utopian project to many minds, but it is one surely, though slowly, making its way with the medical profession as both desirable and necessary for the true interests of the public as well as the profession. Dr. Rumsey complains, that though there is all the rigidity of caste in the legal separation between the two registers, yet a large number of the men on either register invade at pleasure the occupation of those on the other. He further states, that "Pharmacists have become, in fact, a new race of unqualified practitioners." This is anything but a just way, and it is certainly a one-sided way, of putting the case, considering Dr. Rumsey admits that many of his professional *confrères* systematically usurp the duties of the pharmacist. One more regret is expressed by Dr. Rumsey, that there is no independent supervision of the practice of pharmacy and sale of poisons in the public interests, no inspection of druggists' shops and stores, etc. We believe that Dr. Rumsey is in a distinct minority on this point. Mere inspection, as such, will do little for the public. Their interests are directly secured, (in the only certain way,) in proportion to the excellence of the education of the pharmaceutist and of the examination, by which he becomes qualified for enrolment in the register list. In like manner, mere legislation can do little to promote the desired demarcation between physician and pharmacist. This can alone be brought about successfully by the increased education of the twain.

HYPODERMIC INJECTION.

From the 'Medical Times and Gazette,' we learn that the Committee appointed by the Royal Medical and Chirurgical Society to investigate the hypodermic method of administering medicines, reports as follows:—

1. That, as a general rule, only clear neutral solutions of drugs should be injected.
2. That, whether drugs be injected under the skin or administered by the mouth or rectum, their chief physiological and therapeutical effects are the same in kind, though varying in degree; but
3. That symptoms are observed to follow the subcutaneous injection of some drugs which are absent when they are administered by other methods; and, on the other hand, certain unpleasant symptoms which are apt to follow the introduction of the drugs by the mouth and rectum, are not usually experienced when such drugs are injected under the skin.
4. That, as a general rule, to which, however, there are many exceptions, neutral solutions of drugs, introduced subcutaneously, are more rapidly absorbed and more intense in their effects than when introduced by the rectum or mouth.
5. That no difference has been observed in the effects of a drug subcutaneously injected, whether it be introduced near to, or at a distance from, the part affected.
6. That the advantages to be derived from this method of introducing drugs are:—rapidity of action, intensity of effect, economy of material, certainty of action, facility of introduction in certain cases, and, with some drugs, avoidance of unpleasant symptoms."

In commenting on this report, the 'Medical Times and Gazette' remarks:—

"We may safely take, as a broad guide in practice, the rule that the physiological activity of nearly every substance which can thus be used, is three, if not four times greater when it is given by the skin, than when it is swallowed." The proper commencing dose of strychnine is $\frac{1}{120}$ grain of the sulphate. The dose of atropine is also $\frac{1}{120}$ grain at first. The dose of morphia is $\frac{1}{10}$ grain to $\frac{1}{6}$ grain.

The circumstance, that the action of medicines administered hypodermically is very rapid and often instantaneous, renders the method invaluable in certain cases; as, for instance, in cases of poisoning.

POISON REGULATIONS.

The 'Pall Mall Gazette,' in announcing the fact that this Society is in future to certify the competence of dispensers in naval hospitals, expresses the opinion that this is a very proper proceeding on the part of Dr. Armstrong, the Director-General, and adds that the Society's monopoly is thereby completed. It goes on to say, "All monopolies of the kind are to be regarded with distrust, and watched with anxiety in the public interest. This Association has a twofold position: it has public duties and private interests to consult. The two may not always concur. It is one part of the duties of the Society to lay down regulations for the storing and dispensing of poisons, so as to prevent, as far as possible, the lamentable calamities from accidental poisoning, which so often shock the public mind. We will not say that they have shown any indifference to this duty; but its discussion has been productive of so much difference of opinion, that the matter has been postponed, though we hope not abandoned."

It is evident from these remarks that the action of the Society in regard to poisons is not lost sight of outside its limits and we would suggest that those members who have propositions to offer on this subject should communicate them for publication in the Journal and for criticism by others. It is possible that in this way some good service may be done, while leisurely discussion of the subject and consideration of proposals may lead to a suitable issue more readily than hasty debate would do.

Some few weeks ago an article appeared in a medical contemporary, making use of very strong language in reference to the proceedings of the Nottingham and Notts Chemists' Association. The only assignable foundation for the strictures contained in that article was so obviously misconception, that they might have been passed by in silence had it not happened that two journals connected with Pharmacy have reproduced this objectionable article without any comment and have thus given it an importance it would not otherwise possess. What took place at the Nottingham meeting was reported as follows in the 'Pharmaceutical Journal' of April last:—

"A matter of some considerable importance to the trade was brought forward, namely, the issue of catalogues, not only of surgical instruments, but of many druggists' sundries, by Messrs. Maw, Son, and Thompson, to the medical profession throughout the country, at prices identical with those sent to the trade. Great indignation was felt and expressed by the meeting at the course adopted by this house, which, more than any other, receives the support of the chemist."

From this it will be evident that the vexation expressed by the meeting was not because Messrs. Maw and Co. had sent their catalogue of surgical instruments to the surgeons of the kingdom. Such an objection would have been unreasonable, and the true ground of objection was, that they not only did this in the legitimate exercise of their business, but also issued to medical men catalogues of druggists' sundries. In the article we have referred to, it is assumed that Pharmacists desire to coerce medical men into buying surgical instruments through them. We need not reply to the argument that such a desire would be absurd, further than by stating that it has no existence.

From the 'Journal de Chimie Médicale' we learn that, as a therapeutic agent, bromide of sodium offers several advantages over the corresponding potassium-salt, being much easier of elimination from the animal economy. M. E. Decaisne has administered it to a patient during a whole year without producing that saturation which is observable in the case of bromide of potassium.

We have much pleasure in making known that Dr. F. A. Flückiger, whose paper on Rhatany appears in this number, has been promoted from the position of Private Tutor to the Professorship of Pharmacy and Pharmacognosy at the University of Berne.

We regret to hear that Dr. Thomas Anderson, Director of the Calcutta Botanical Gardens and Superintendent of the Darjeeling Cinchona Plantations, is seriously ill. He left Calcutta some months ago on account of his health.

Dr. Birdwood has published a most valuable and exhaustive paper on the history, botanical and otherwise, of Gum Olibanum, in the last part of the 'Linnean Transactions.'

The plans for the erection of a Pharmaceutical Institute in connection with the University of Marburg have been approved, and the work was to have been commenced at once, but will now probably be delayed by reason of the war.

Meetings of Scientific Societies.

QUEKETT MICROSCOPICAL CLUB.

The Fifth Annual General Meeting of this Club was held on Friday evening last, July 22nd, at University College, Gower Street; Peter Le Neve Foster, Esq., President, in the chair.

According to the Annual Report of the Committee, which was read, the Club still maintains its popularity and success. It numbers over 500 members, and meets for the prosecution of microscopical inquiry and discussion twice a month throughout the year. Mr. Peter Le Neve Foster, in vacating the presidential chair, which he had so ably filled during the past year, delivered a valedictory address, in which he called attention to various open questions in microscopical science as fields well worth investigation. Professor Lionel S. Beale, F.R.S., was elected President for the ensuing year, and Messrs. Henry Lee, F.L.S., Arthur E. Durham, F.R.C.S., Peter Le Neve Foster, M.A., and Dr. Robert Braithwaite, F.L.S., were elected Vice-Presidents; while Messrs. Allbon, T. W. Burr, F.R.A.S., Witham M. Bywater, and Charles F. White, were elected to fill four vacancies on the Committee. The proceedings then terminated in a conversazione.

Law Proceedings.

DAMAGES AGAINST A DRUGGIST.

Court of Passage, Liverpool.

Kelly and Wife *v.* Trilfield.—This was a case in which the plaintiff and his wife sought to recover damages from a druggist in Liverpool, as solatium for injuries sustained by Mr. Kelly in consequence of the defendant administering to Sarah Kelly some noxious drug, by which her health was hurt and destroyed. Dr. Commins was for the plaintiff, and Mr. M'Oubrey for the defendant, who, in answer to the declaration of the plaintiff, had entered a plea of not guilty. The case for the plaintiffs was that on the evening of the 20th March, 1869, Mrs. Kelly went to the defendant's shop and asked for half an ounce of castor oil, for which she took a small glass. She asked him to put in some water to prevent the oil sticking to the glass, but instead of doing that he put in some peppermint. Mrs. Kelly then told him that she did not want peppermint, upon which he emptied the glass, and taking another bottle from the shelf poured in something which appeared to be pure water. He then poured in the castor oil, and covered the glass over with a piece of paper. Mrs. Kelly took the oil home and laid it on the corner of the chimney-piece in her bedroom, where it remained till the morning of the 23rd March, when about four o'clock she got out of bed and swallowed it. She had no sooner taken the oil, and had scarcely time to lay the glass on the table, when she felt a burning sensation in her mouth, throat, and chest. She became sick, and immediately vomited the oil up on the floor, blood coming up with it. Her mouth and throat were excoriated, and the boards of the floor where she had vomited are all blackened with the liquid. For two or three months Mrs. Kelly had suffered much from the effects of the unfortunate mistake, especially during her confinement, which happened five days afterwards. Dr. Commins said they were not in a position to say what the defendant had put in the glass to produce such effects as these, but there was no doubt it had been some strong drug which had been put in instead of the water. The medical evidence was to the effect that either sal volatile or liquor potassæ would have produced the effects seen on the plaintiff's throat. Mr. M'Oubrey, for the defence, stated that the defendant had only put cinnamon water in the glass, and suggested that if Mrs. Kelly swallowed any deleterious drug it must have been some of the mixture she was in the habit of using as a French polisher. The defendant was then called, and said he had carried on business in Liverpool as a chemist and druggist for fifteen or twenty years. He recollected the plaintiff coming to his shop on the 20th March, 1869, and asking for some castor oil. She told him she would have anything but peppermint in it, and he then took down a bottle from a shelf opposite the counter, and put some cinnamon water in the glass. Mrs. Kelly returned on the Tuesday morning and said her mouth was sore, and then she three times pointed out to him the bottle from which he poured the liquid into the glass before he put in the castor oil. This bottle contained cinnamon water. Defendant said there was nothing approaching to liquor potassæ kept on that shelf—in fact he kept none of these alkaline matters near the place where he took the cinnamon water from.—The jury found for the plaintiff, damages £10.

[*** We insert the report of this case as it appeared in the Liverpool 'Daily Post,' but confess that we are unable to perceive from it the grounds on which the jury found for the plaintiff. In the first place, the length of time during which the castor oil was left "on the corner of the chimney-piece," apparently in an open glass, affords room for the possibility of some deleterious material having been added in some way. The account of the effects produced by the supposed "noxious drug," are, at least, vague, and there is no statement of the medical evidence by which they might have been rendered intelligible.—Ed. Ph. J.]

ON THE COMBINATIONS OF CARBONIC ANHYDRIDE WITH AMMONIA AND WATER.

BY EDWARD DIVERS, M.D.

(*Continued from p.* 46.)

Preparation.—Ammonium carbonate may be prepared in various ways:—

(*a.*) By digesting in a closed flask the commercial carbonate, crushed small, with strong solution of ammonia for two hours, or not much less, at a temperature not exceeding 12° C., or thereabouts, the ammonium carbonate is left as a mealy, obscurely crystalline mass. It is to be dried by pressure between folds of bibulous paper; this operation, after most of the mother-liquid has been absorbed by a few changes of paper, being conducted in a chamber as small as convenient, and as far as possible filled by the salt and the paper used to dry it,—every care, at the same time, being taken to expose it as briefly as possible to the free action of the atmosphere in this stage of the drying. The operation is practically complete when the salt no longer makes distinct wet marks on the drying-paper, though it will then still feel damp. If, when the drying is nearly finished, the salt is found to be firmly adhering to the paper when a change is made, the operation has been so performed as to allow of decomposition taking place, through insufficient exclusion of air, either by having adopted imperfect means for protecting the salt while it was between the folds of paper, or by having made the changes of paper too slowly or too many times. In warm weather it is well to surround the chamber with ice.*

(*b.*) By digesting the commercial carbonate (or any other carbonate of ammonium) with strong solution of ammonia in a closed vessel at a temperature of 20°–25° until it is dissolved, and leaving the solution thus obtained in a cool place, with the vessel containing it not thoroughly closed, in order that some of the ammonia may escape, when minute crystals form, converting it at first into a semi-transparent magma, but afterwards becoming distinct, interlacing, slender prisms. One part of the commercial carbonate to four parts by weight of the strong solution of ammonia is a convenient proportion in which to take them. The digestion generally takes about two days. It may happen when the ammonia has not been allowed to escape, and the quantity of carbonate which has been added is relatively great, that a few larger crystals, having quite a different appearance to the others, will form; when this is the case, the solution must be warmed until these crystals have dissolved, and at the same time some ammonia be allowed to escape, and then on again cooling it these crystals will not re-form. On the other hand, when by prolonged digestion at a gentle heat, a very large quantity of the commercial carbonate has been dissolved in the strongest ammonia-water, fortified occasionally by the passage of ammonia-gas in the cold, the solution only yields the ammonium carbonate with difficulty, until most of the ammonia has been allowed to escape from it by keeping it in an imperfectly-closed vessel, and the crystals are then often large, flattened prisms. In separating minute crystals of ammonium carbonate from their mother-liquor, and preparing them for analysis, the same plan is to be adopted as in the previous method. The preparation is somewhat more manageable than the preparation of the mealy form, and the presence of the crystalline lustre serves as a means of testing its success.

* The chamber I made use of was a small glass pan with vertical sides, having another similar pan, or else a beaker, just large enough to glide into it. On the bottom of the pan a thick layer of circular filters, just fitting the pan, were laid; then came the salt, and over this a second layer of filters; on this a pad of tow, and, lastly, the upper pan, weighted, and sometimes filled with ice.

(*c*.) By passing ammonia through a strong solution of the commercial carbonate until it becomes charged with the gas, when crystals of the ammonium carbonate, similar to those produced by method (*b*), will form in small quantity, either while the gas is passing, if the solution be kept cool, or afterwards, on allowing the solution to stand in a closed vessel in a cool place.

(*d*.) By dissolving a sufficient quantity of the commercial carbonate in warm, dilute solution of ammonia, best in a closed or nearly closed vessel, when ammonium carbonate crystallizes out on cooling. If the free ammonia be present in large quantity, the crystals are small; if it be present in very small quantity only, the salt next to be described crystallizes out; while if it be present in not much more than sufficient quantity to prevent this, the crystals of ammonium carbonate are large. I have found this one of the best methods for getting large crystals.

(*e*.) By adding dilute spirit to a solution of commercial carbonate in ammonia-water (or to any solution equivalent to this prepared in any other way), in quantity somewhat less than enough to cause a precipitate, when the ammonium carbonate slowly crystallizes out in long, flat prisms. As with the last method, the size of the crystals is generally less in proportion to the quantity of free ammonia. When strong spirit is added to a concentrated ammoniacal solution of the carbonate, the whole soon partially solidifies through the formation of minute crystals of ammonium carbonate, large prisms sometimes shooting across the mass when the mixture is not too strong in free ammonia.

(*f*.) By dissolving ammonium carbamate in sufficient quantity in water at a gentle heat (30°–35°) in a closed vessel, when, on cooling the solution, and standing it aside for some time, a little ammonium carbonate crystallizes out.

(*g*.) By dissolving ammonium carbamate in sufficient quantity in strong ammonia solution at the ordinary temperature in a closed vessel, and setting the solution aside with the vessel only imperfectly closed, that ammonia may slowly escape, when ammonium carbonate crystallizes out.

(*h*.) By passing carbonic anhydride into strong ammonia-water for some time, taking care to leave large excess of ammonia, and setting the solution aside in a closed vessel, when the carbonate separates in small, usually minute crystals.

(*i*.) By dissolving good commercial carbonate, crushed small, in water at a gentle heat,—best in a closed, or nearly closed vessel,—setting the solution aside to cool and crystallize, decanting the mother-liquid on to a fresh quantity of commercial carbonate, again effecting solution by heat, cooling, and crystallizing, a second time decanting the mother-liquid, and so on, repeating these solutions and crystallizations a sufficient number of times, when, according to the extent to which the water has been treated with the commercial carbonate, either the last solution, after depositing crystals for one or two days, will, on being decanted, and left for a further time in a closed vessel in a cool place, deposit large prismatic crystals of ammonium carbonate, or the solution will, in one night's crystallization, form over the first crop of crystals a second of the ammonium carbonate, and continue for some time to yield more of this substance.* If, instead of waiting for the solution to crystallize, it be treated with ammonia-water, a precipitation of minute crystals of the salt will take place, and convert the whole into a semi-solid mass. This and method (*d*) are the best for obtaining large crystals. The crystals are relatively short and broad when this solution is allowed to crystallize slowly at medium temperatures; but when the solution which has thus been left standing for some days is exposed to the sky for a night in clear cold weather, long flat prisms generally form.

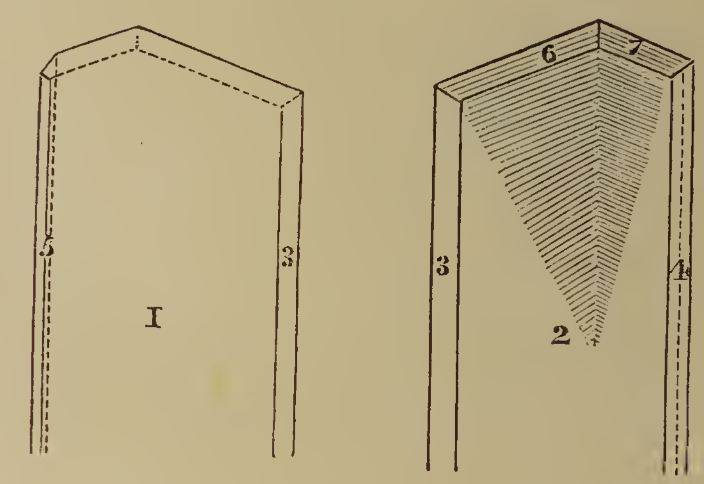
* Details of the action of water on the commercial carbonate will be given further on. It would be inconvenient to go into them here.

Dalton's Method of producing the ammonium carbonate by the wet way has only indirectly succeeded in my hands.

Dalton's Method by the Dry Way.—Dalton gives no further account of this method than that I have set down in the historical notice of his paper.

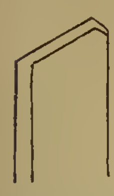
Sensible Properties.—Ammonium carbonate gives out an exceedingly strong ammoniacal odour, due presumably not to itself, but to ammonia as a product of its decomposition. It has an extremely pungent taste, and at once affects the tongue as a caustic to a marked degree.

Form.—Ammonium carbonate takes the form of elongated plates or flattened prisms. Their shape is roughly indicated by the annexed cuts.



The inclination of the side-face 4 to the face 2 does not appear to be the same as that of the side-face 3; nor am I decided whether the side-face 5 is parallel or not to the side-face 3; but the two faces, 4 and 5, I have found it difficult to observe satisfactorily. The faces of the crystals lose their lustre when the mother-liquor is wiped off, and the edges are rapidly destroyed. From the general inclination of the side-faces to the broad face 2, the crystals look like half-forms, or as if the crystal had been formed with its face, 1, on the bottom of the vessel, which is indeed a common position of the crystals. The crystals have, however, the same appearance when formed with both surfaces of the plate free. The end faces, 6, 7, are always hollowed out, and give a distinctive appearance to the crystals.

When large crystals are formed by slow growth, they are so broad in proportion to their length, that they can hardly be described as prisms. But when large crystals are produced in a single night, they are often of great length, shooting across the solution like nitre crystals. One of these I measured, and found it to be 50 mm. long, 6 mm. broad, and about 0·5 mm. thick. Crystals growing over the bottom of the vessel take the broad, short, tabular form; while those produced in the body of the solution assume the slender, flat, prismatic form. When solitary crystals are first seen suspended in the solution, they have a narrow breadth, no sensible thickness, and a considerable length relatively to their minute bulk, and are hardly, if at all visible, except when in a position to reflect light to the eye from one or other of their broad surfaces. A very small absolute bulk of such crystals is sufficient to convert the whole solution into a semi-transparent magma, forming, as they do, equally through all parts of it. When they are very minute, and in not too great quantity, the network they form can be shaken by gently jolting the vessel into a smaller bulk, retaining more or less the shape of the interior of the vessel. Shaken up on to the sides of the vessel, they form masses looking like jelly. Violently shaken up, they subside afterwards to the lower part of the vessel. When the solution filled with these crystals is left undisturbed, the crystals grow, and form a closely interlacing network of slender, apparently four-sided prisms. The ends of small crystals, whether proportionately short or not, are terminated by almost exclusively one face, the other one seen in the large broad crystals being very small, as shown in the margin.



The end faces of large, long prisms are generally very imperfect, but the outline of the broad sides is most like that in the small prisms. Masses of minute crystals, such as are at first obtained by method (*b*), form, when successfully dried, soft, lustrous flakes. When proof spirit is added to a concentrated solution of the carbonate, strong in ammonia, so as to avoid immediate precipitation, minute crystals form, and soon render the fluid semi-solid; shortly afterwards, larger prisms often shoot across the semi-fluid mass. A phenomenon like the last also generally occurs when the semi-solid mass obtained by method (*b*) is cooled in ice, nitre-like prisms shooting across it. When only a very little spirit is used, short, broad prisms sometimes form at the base of the clear solution. A solution not too strong in ammonia, mixed with a suitable quantity of spirit, and left to stand in a covered vessel, becomes filled with interlacing, apparently four-sided prisms.

Behaviour on Exposure.—Ammonium carbonate gets very damp when exposed to the air. A similar change takes place in the half-acid ammonium carbonate, and has been specially pointed out by Deville. Before crystals of the ammonium carbonate can be dried, they lose their lustre, and become semi-opaque and moist, but retain their general shape; when pressed, they break down to a mass of wet acid carbonate. This change is not the result of absorption of moisture from the air, but of the instability of the salt in an atmosphere not charged with the products of its own decomposition; for the action goes on in a stoppered bottle until the air in the bottle is thus affected, and the salt is wet. The change may be thus represented:—

$$CO_2(OH_2)_2(NH_3)_2 = CO_2OH_2NH_3 + OH_2 + NH_3.$$

It is because of this evolution of moist gas that a feeling of dampness in the paper used to dry the salt must not be regarded as proof that some adhering moisture has not been removed from it.

Behaviour when heated.—At about 58° ammonium carbonate is converted into water, carbonic anhydride, and ammonia, when surrounded by an atmosphere formed of products of its own decomposition. When first heated by a water-bath in a retort connected with a tube dipping under mercury, signs of decomposition are apparent by the formation in the retort-neck of drops of fluid and the fibrous crystals already described when the thermometer in the bath registers about 49° or 50°, but the progress of the change is soon arrested unless the temperature is raised, and no marked and continuous change is effected until the water-bath is at a temperature of about 59° or 60°. By maintaining the temperature of the bath at 60° no gas escapes from the apparatus, a moist, solid distillate is formed in the neck of the retort, and the contents of the retort gradually liquefy. Both the residual liquid and the solid distillate contain the ammonia in normal proportion to the carbonic anhydride, but the solid is too deficient in water, that moistening included, to allow of its being represented as an ammonium carbonate, while the fluid in the retort is a solution of the normal carbonate, and, provided the operation is not carried too far, crystallizes out on cooling. The crystals have not been analysed, but they were evidently the normal carbonate. The product of the distillation was analysed.

If the heat be carried some degrees beyond 60°, ammonia escapes during the distillation, and more water rises in vapour with the other constituents. In this case the condensed salt is very moist, but still has not sufficient water to constitute it an ammonium salt of carbonic acid, and, besides, is wanting in ammonia. I shall have again to refer to these products of distillation, and will then give the numerical data of my analyses. The decomposition of the salt by heat is thus represented:—

$$CO_2(OH_2)_2(NH_3)_2 = CO_2 + 2OH_2 + 2NH_3,$$

and is therefore quite distinct from that it undergoes by free exposure to the air.

Behaviour with Water.—Ammonium carbonate is soluble in its own weight of water, or slightly more, at 15°. By cooling the solution contained in a closed vessel, some of the salt crystallizes out again, but mixed with other carbonates.

The saturated solution is of somewhat oily consistence. It smells very strongly of ammonia. Exposed freely to the air it loses ammonia. Heated, it begins to effervesce between 70° and 75°, and boils freely between 75° and 80°, yielding vapours which condense into a moist solid. After boiling for awhile, and then cooling the solution, it is found to be unchanged in properties, except that it is weaker.

A warm saturated solution of ammonium carbonate exhibits the phenomenon of supersaturation and sudden crystallization in a well-marked manner when it is allowed to cool in a closed flask. If the solution does not crystallize while left at rest, it will do so suddenly on stirring it with a glass rod or pouring it out into another vessel.

Behaviour with Alcohol.—Ammonium carbonate is insoluble in alcohol. Crystals of it, treated with rectified spirit, are converted into acid carbonate and free ammonia. An aqueous solution of it is precipitated by alcohol, the precipitate being acid carbonate, or intermediate in composition to this and normal carbonate.

Behaviour with Ammonia-Water.—Ammonium carbonate dissolves in ammonia-water only very sparingly at a low temperature, but, by digestion at ordinary temperatures, the quantity dissolved becomes greater. Strong ammonia-water, added to a concentrated solution of the carbonate, precipitates it unchanged. Ammonia gas, passed into a moderately strong solution, has the same effect. In cases where no precipitate is produced, the mixture will generally deposit some of the salt when cooled in ice. The small solubility of ammonium carbonate in ammonia-water is a fact which is most serviceable in preparing it. Thus, nearly all the methods already given, including, perhaps, that in which the salt is precipitated by spirit from a weak ammoniacal solution, depend upon this influence of ammonia.

Conversion of the Carbonate into Carbamate.—But ammonia has a much more remarkable effect upon ammonium carbonate than that described in the last paragraph. By digesting crystals of the salt with water saturated at a low temperature with ammonia gas for two or more days at a temperature of 20° to 25°, they dissolve in apparently unlimited quantity, and are changed into ammonium carbamate. The mode of proceeding is similar to that adopted in method (*b*) for getting ammonium carbonate in minute crystals. Some of the strongest ammonia-water of commerce is placed in a wide-mouthed bottle, surrounded by ice, and treated with a rapid stream of ammonia gas;* a third of its

* During the passage of the gas the bottle is loosely closed by a cork, perforated to admit the gas delivery-tube, so as to diminish loss by diffusion.

weight or more of crystals of ammonium carbonate are added, the gas still passing; then the bottle is closed with a vulcanized-rubber stopper and gently agitated for a moment, the stopper loosened to allow of restoration of atmospheric pressure by an outrush of the enclosed air, and then tightly inserted again and secured by string; the bottle is then placed where it will be exposed to a temperature of 20° to 25°, and is occasionally agitated. In thirty or forty hours the ammonia solution will have dissolved about half its weight of ammonium carbonate, if so much or more has been added. In any case, though the solvent action of the liquid is not exhausted, it is well to cool the bottle again by ice, and pass more ammonia gas through it, at the same time adding, if necessary, more ammonium carbonate. On opening the bottle for this purpose, after it has been cooled, the internal atmospheric pressure is found to be much less than the external pressure. The solution cooled in ice for hours gives either no crystals or only a few groups of exceedingly minute needles, which the details of the preparation of the carbonate by method (*b*) show almost certainly to be unchanged ammonium carbonate. After the addition of the salt and the ammonia gas, the operation is carried on as before. On again cooling, after thirty or forty hours' digestion, the same appearances present themselves, but a small quantity of minute crystals is now almost certain to appear. The series of operations is to be repeated as many times as are necessary for the solution when cooled by ice, or better by exposure to the sky on a frosty night, to yield the carbamate. When this point is reached, the carbamate appears in the form of beautiful large crystals and crystalline masses along with a few of the minute crystals. If the presence of the crystals be disregarded, and the series of operations, including the addition of more carbonate, be again carried out, the solution, after digestion, yields, on cooling, a large batch of the carbamate. The other crystalline matter does not necessarily increase by repeating the operations, and, when it is present in more than a very small quantity, further digestion with more ammonia suffices to make it appear in less quantity. I have thus converted carbonate of ammonium into carbamate by using only half its weight of ammonia-water, and, after this had been done, there was no sign that the same solution, *plus* ammonia gas, would not have continued to carry on the change in any quantity more of the carbonate.

The solubility of ammonium carbonate in cold concentrated ammonia-water being slight, there can be very little of that added left unchanged. On the other hand, as the carbamate is freely soluble in ammonia-water, much of it remains in solution. No urea could be detected in the solution. The reaction is simple enough:—

$$CO_2(OH_2)_2(NH_3)_2 - 2\,OH_2 = CO_2(NH_3)_2.$$

It may be regarded as being only an instance of the well-known influence of heat in resolving ammonium salts of polybasic acids into the ammonium salts of the amic acids, the use of the ammonia in this case being to prevent a reversion of the change. That ammonia prevents the conversion of carbamate into carbonate I shall afterwards show.

(*To be continued.*)

DEATH FROM AN OVERDOSE OF STRYCHNIA.—AN INTERESTING CASE.

BY CHARLES BULLOCK.

A case of death, resulting from an overdose of strychnia, occurred recently in Pennsylvania under circumstances which render the case interesting and instructive to both medical practitioner and pharmaceutist.

The patient had been labouring under an attack of partial paralysis, and the medical attendant directed the following prescription:—

℞ Strychniæ Muriat. . . . gr.iss
Liq. Ferri Iodidi . . . ʒvj
Syr. Zingiberis q. s. ut ft. f℥iij.
M.
Sig. dose a teaspoonful.

The whole of this prescription was used as directed, and the bottle returned to the druggist, by order of the physician, for renewal of the medicine, the dose on renewal being increased to one and one-half teaspoonful. This was taken with apparent benefit to the patient, until the last dose, exhausting the contents of the bottle, was given. About an hour after, while at a meal, the patient complained of strange sensations, and was soon affected with tonic spasms, which are described by two medical gentlemen, who were called in, as well-marked results of an overdose of strychnia. Proper remedies were promptly used and the spasmodic action passed away, leaving the patient able to speak, but greatly prostrated, and, failing to respond to stimulants, death ensued in a few hours.

The bottle which contained the medicine was produced before the coroner's jury (composed of physicians and pharmaceutists). It appeared to have been drained of its contents to make up the last dose; adhering to the bottle were well-formed crystals, some of them about a line in length, and one-fourth line in thickness. Unfortunately no chemical examination was made to determine whether the crystals were *undissolved* muriate of strychnia or iodide of strychnia. A microscopical examination failed to carry much weight, on account of the destruction of the form of the crystal by washing previous to mounting, the size of the crystal not being accepted in evidence, as crystals of iodide of strychnia were shown nearly as large, made by simple deposition from a warm saturated solution.

The pharmaceutist by whom the prescription was compounded testified, "that he weighed out the muriate of strychnia, threw it into a graduated measure, added the two other ingredients, and stirred them up with a bone spatula until he thought the strychnia had all dissolved, as he could see no undissolved crystals or solid matter." To a question, he replied that he noticed an opalescent appearance, resembling a quinine mixture.

An inmate of the house with deceased testified, "that she was sure that the bottle of medicine was never shaken."

The prescription as above given had been sent to several prominent pharmaceutists, and the compoundings criticized by the jury. In some no chemical change was discernible, in others crystals readily recognizable as iodide of strychnia were floating through the mixture and deposited in the bottom of the bottle. In one case large crystals were contained in the bottle, evidently of the original strychnia salt undissolved.

The jury, after weighing all the evidence, returned a verdict of "Death from prostration, following the accidental administration of an overdose of strychnia.

"The jury further find, from examination of the assistant pharmaceutist, by whom the prescription was compounded, a want of proper attention to, or information in manipulation, which they cannot pass without notice and reprimand, as both efficiency and safety may depend on careful manipulating skill when potent remedies are prescribed.

"They farther find that the ingredients of the prescription are subject to such chemical changes as renders the strychnia contained therein *liable* to be precipitated to the bottom of the bottle containing the prescription; and if the bottle should remain without proper agitation, an overdose of strychnia might result."

So much for the history of the case. We now wish to make some remarks on the chemical and pharmaceutical character of the prescription, and throw out some thoughts on prescribing and compounding, as suggested by this case.

Muriate of strychnia is not officinal in the United States nor British Pharmacopœias, and is rarely prescribed. It is much less soluble than the sulphate, requiring 50 parts of water, at 71° F., for solution (Gmelin's 'Handbook'). The solubility of iodide of strychnia is not found in any authority which I have consulted. It is spoken of as *very insoluble.* My own determinations make its solubility 0·54 parts in 100 parts of water, at 60° F.*

When a drop of syrup of iodide of iron is added to a cold saturated solution of muriate of strychnia, the insoluble iodide of the alkaloid is immediately formed.

I have before me the prescription alluded to in this communication, put up in two ways. In both the muriate of strychnia was previously dissolved in ℥iss of water. In No. 1 the strychnia solution was mixed with the iodide of iron, and the ginger syrup immediately added and well shaken. In No. 2 the strychnia solution was first added to the syrup of ginger, well shaken, and the iodide of iron added. In No. 1 the bottom of the bottle is covered with crystals of iodide of strychnia, and many floating crystals suspended in the mixture. In No. 2 no decomposition is discernible, and after standing four days no deposit has taken place.

On p. 1418 of the U. S. Dispensatory, 13th edition (1870), after quoting from this Journal the experiments of Bouchardat and Gobley, on the insolubility of iodine combinations with strychnia, the authors add: "But though this fact *establishes the impropriety of combining solutions of iodine and strychnia in prescriptions*, yet it by no means justifies the inference drawn from it, that iodine might serve as an antidote to strychnia. Indeed, the contrary has been proved by the experiments of Mr. S. Darby, who found the precipitated iodide of strychnia was highly poisonous to the lower animals," etc.

We have, in the above quotation, information given regarding the insolubility of iodide of strychnia, and the impropriety of prescribing iodine and strychnia solutions in combination.

It is clearly the duty of the pharmaceutist to see that when potent remedies are prescribed in solution that the *solution is complete.* He ought, also, if allowed to dispense such articles, to be informed regarding decompositions liable to occur, and, if possible, guard against mischief likely to result therefrom, or else return the prescription to the writer, with his objections clearly stated. He should also notice when such a prescription is returned for renewal, whether any deposit has taken place in the bottle, and remove it by washing, should such be the case. The question whether it is his duty to mark the bottle "Shake well," when the recipe gives no such direction, is one admitting of different opinions; but we think, when so marked, the error, if any, is on the side of prudence.

We would suggest to physicians, when prescribing a remedy like strychnia in solution to its usual *full dose*, to prescribe it alone, and to give *separately* whatever else may be deemed advisable. We have, in our experience, been made aware of changes unforeseen and unknown to us until the event developed the facts.—*American Journal of Pharmacy.*

[*⁎* Inasmuch as the amount of liquid was three ounces, equal to over thirteen hundred grains, and the hydriodate of strychnine about four grains, it is plain that there was sufficient liquid to keep all of the strychnine in solution.—Ed. Ph. J.]

* Hydrochloric and even acetic acid much increase the solubility of the iodide, without apparent decomposition, when the acids are very dilute.

Chapters for Students.

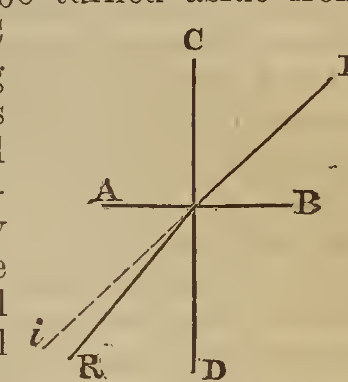
LIGHT—*continued.*

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

7. When light falls upon the surface of a transparent substance, such as a sheet of glass, it is partly reflected from the surface, and the remainder enters the glass. Of the latter portion a certain part, proportionate to the transparency of the glass, is allowed to pass on, is, in other words, transmitted; the remainder is destroyed, it ceases to be light, and is transformed into something else. What becomes of this lost light is not known with certainty.

The light which is transmitted is usually deflected on entering the transparent surface; there is, in fact, only one position which the incident ray can occupy in which it will not be turned aside from following its course. If C were the ray of light falling upon A B, the surface of glass or water, it would proceed straight onwards in the direction C D. But if I, or any line inclined to A B, be the path of the incident ray, it will not go on through *i*, but will be bent in the direction of R.

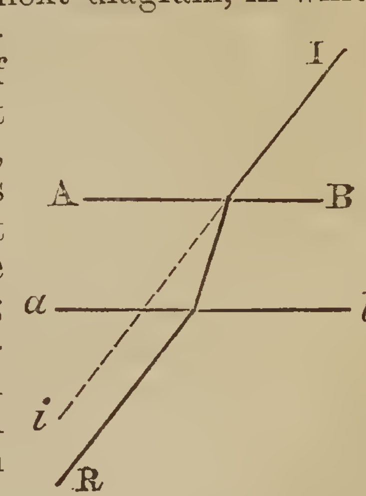


The ray thus turned aside is said to be *refracted.*

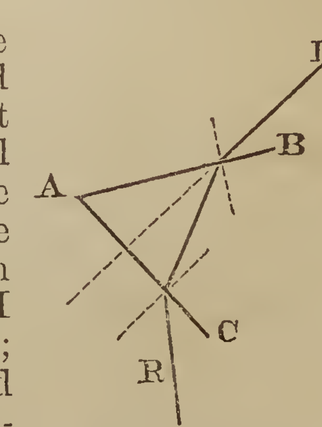
8. When the substance (*e. g.* glass) *into* which the incident ray passes is denser than that (*e. g.* air) *from* which it passes, the ray is refracted, as in the figure, downwards towards the line C D, which is perpendicular or at right angles to the refracting surface.

If R were the incident ray passing from the denser medium glass into the less dense medium air, it would, on the contrary, be bent *away* from this perpendicular in the direction of I.

This is also shown in the next diagram, in which A B and *a b* are the two parallel surfaces of a sheet of glass or other transparent body. The ray I, passing, we suppose, through air, falls upon the surface A B, is bent downwards so as to become more nearly perpendicular; but on emerging again it assumes the direction R, which forms with *a b* an angle equal to that which I forms with A B. The refracted ray R, after emergence, is therefore parallel to the original incident ray I.



9. Now suppose that we have to deal with a wedge-shaped piece of glass, instead of a sheet with parallel surfaces. We shall find that, following the same rules, the course taken by the ray of light will be that shown in the accompanying figure. I is the ray incident upon A B; on entering the glass it is turned down towards the dotted perpendicular; on coming to A C, and emerging from the



glass into a rarer medium, air, it is again bent, but this time away from the dotted perpendicular, and therefore takes the course R. By means, therefore, of such a piece of glass, which is called a prism, the light is brought round a corner.

10. If a beam of ordinary light refracted by a prism, be received on a sheet of paper or other surface, it presents the appearance of a stripe of colours. In the last diagram it will be seen that the direction of the refracted ray I—R is always towards the base or broad side BC of the prism. When the stripe of colours, or 'spectrum' of ordinary light is received on the screen, it will be noticed that the order of the coloured bands is—

RED–ORANGE–YELLOW–GREEN–BLUE–INDIGC–VIOLET

and that the violet end is that which is nearest to the base of the prism, the red nearest to the opposite angle A. The violet is said therefore to be the most refrangible (*i. e.* capable of being most bent by refraction), the red, the least refrangible, and the other colours intermediate in the order given.

11. It was by an experiment of this kind, and by reasoning upon it, that Newton was led to the explanation of the constitution of ordinary sunlight. White light is made up of a number of coloured (and also some invisible) rays, each possessing a different degree of refrangibility. When these pass through a prism, they are bent to the extent peculiar to each respectively, and so undergo *dispersion*, and become perceptible as separate and distinct components; when they are received simultaneously in the eye, without previously submitting to this separation, their combined effect is 'whiteness.' That white light is thus constituted is shown by the experiment already described, and also by the circumstance that if the band of separated coloured rays, produced by sending a beam of white light through a prism, be made to pass through another prism formed of the same material and in a position the reverse of the first, white light will be re-generated. To effect this properly, the two prisms must have an angle A (see diagram) of the same magnitude in both, so that their refracting surfaces may be parallel, when the base of the one is applied to the opposite angle of the other. Under these circumstances the rays which are separated by the first prism are reunited by passing through the second.

12. We are now in a position to understand the production of colour in natural objects. A surface is, for example, red, when it decomposes the light which falls upon it, reflecting only the constituent which gives the impression we call redness, and absorbing all the rest. For a similar reason, on looking through a piece of glass, it appears to be of the colour of the rays which it transmits; the remaining constituents may be reflected or absorbed. Knowledge of these facts helps also to the understanding of the changes of hue which coloured objects exhibit when illuminated by light from different sources. When, for example, a piece of silk appears mauve by daylight, it gives the impression which a mixture in due proportions of red and blue gives. By gaslight the same usually appears red or reddish, from the fact that there is in gaslight so much less of the blue constituent than in sunlight, that when illuminated by the former, the proportion of blue reflected by the silk must be much less, and the red effect predominates. In a photographic chamber illuminated by nearly pure yellow light, all but yellow and white objects appear black; that is, there is no light which they are capable of reflecting.

13. It has already been mentioned that the constituents of sunlight include certain rays which are invisible. They do not produce the impression of light, but the one set of them is capable of heating; the other of effecting chemical decomposition and combination.

If a beam of sunlight is passed through a prism, and the resulting spectrum received upon a screen, it may be found, by the aid of delicate thermometers, or a thermo-electric pile, that the position of greatest heating power is in the dark beyond the extreme point where the red is visible. The position of greatest luminosity is in the yellow portion of the band of light of which the visible spectrum consists; whilst the power of bringing about chemical changes is confined to the other end, the maximum point being found between the indigo and violet. It will, of course, be understood that not only do the luminous parts of the spectrum merge into one another by imperceptible gradations, but that the three forms of action, resulting in heat, light, and chemical activity, are not confined to one narrow portion, but each extends over a considerable proportion of the total length of the spectrum. However, the heating rays are no longer found on reaching the extreme violet; and, in like manner, the rays possessing photographic powers do not extend into the yellow and red.

In a rough sort of way, the subjoined diagram will indicate the relative positions of the constituents of sunlight after they have been separated by the prism.

Reviews.

ON DIET AND REGIMEN IN SICKNESS AND HEALTH. By HORACE DOBELL, M.D. Fourth Edition. Rewritten and much Enlarged. London: H. K. Lewis. 1870.

We have perused, with considerable pleasure, this small volume in its new form. It contains a number of tables of analysis of various articles of food, dietary scales, and alcohol percentages, also numerous recipes; directions for ventilating, heating, disinfecting, and cleansing; together with many practical suggestions for the preservation of health, the prevention of infection and disease, and the management and comfort of a patient and of the sick-chamber.

Although much of the matter is old, many of the suggestions familiar, and most of the rules laid down those of common and every-day practice, yet the collection of these in a form easy of reference, is of some value, and the book cannot fail to be of interest to the general reader.

A new chapter, consisting of a letter and a leading article from the 'Times,' on "London Noise and London Sleep," is worthy of a passing notice, and the author deserves some credit for having brought the subject prominently before the public.

There are few, whether residents in or visitors to London, whose indignation has not been roused simultaneously with their attention, by two "cabbies careering down opposite gutters and holding a conversation across the road at the top of their voices," or by "drunken rollickers, who choose to sing and halloo up and down our streets and squares." The 'Times,' in considering the necessity entailed upon us by the spirit of the age, to move on, not only at the expense, but at the taxation of our nervous energy, demands on the part of the brain-fagged and overworked, that measures should be adopted to allow exhausted nature, at least, the quantum of sleep upon which she may recover herself; and points out how much might be done by the police towards preserving to the hours of night the stillness which is their portion, and to the Londoner, whether he be overworked or not, the opportunity of the undisturbed rest to which, at least, he is entitled. Emphasizing the opinion that public support and encouragement would be given to well-directed efforts of the police, if they would engage in the cause,—we may add, that any agency that would preserve to us the divine nepenthe, against which so perpetual a war is urged in London, is earnestly to be desired. It, at least, would save a frequent disturbance of our equanimity, which alas, but increases the waste of our *vis vitæ*, and robs the candle of life of that brilliancy with which it should burn, in compliment to the necessity imposed upon it to burn quickly.

We wish Dr. Dobell's book all success.

The Unity of Medicine: its Corruptions and Divisions by Law established in England and Wales; their Causes, Effects, and Remedy. By Frederick Davies, M.D., etc. Second Edition. London: Churchill and Sons.

Dr. Davies' treatise reappears opportunely, when another effort is being made to erect a higher and more uniform standard of admission into the ranks of medicine. He gives a rapid history of the healing art from the earliest to the latest times, and endeavours to indicate the critical epochs when medicine became corrupted, as a profession, by the influx of extraneous elements and interests. The union of the physician and apothecary in one person—a result which was brought about towards the end of the seventeenth century—completely destroyed the distinctive character of either office. The apothecary in England and Wales was entitled to visit and prescribe, as well as compound and sell the medicine he had prescribed, provided only that he received no fee. He was thus tempted, says Dr. Davies, to "measure his own worth and his patient's means, in the price and the quantity of medicine he could persuade him to take." From this ill-assorted union of two distinct branches of the healing art have sprung most of the abuses against which medical legislation is now contending; and Dr. Davies sees no remedy for them, but a strict separation of the calling of the apothecary from that of the physician. "It is impossible," says he, "that the great mass of our profession can pretend in one short life to do the work of two;" therefore, let "the part so abnormally united to the physicians' office,—which has never flourished in their hands, which was never sanctioned by any other age or state,—be consigned to those so well prepared to receive it, with honour to themselves and the profession, and with advantage to all." The rapid progress in the efficiency of the pharmacist—a progress attained by the more exacting examinations to which he is subjected—enables the physician to delegate, with increased confidence, the duty of preparing and dispensing drugs to its appropriate hands; while, relieved of work for which he was but partially fitted by training, he will have more time to devote to his already onerous vocation. This reform has been advocated by many recent writers on professional education, among others, by Mr. Huxley, who is quite in favour of dividing pharmacy from medicine, and constituting the votaries of the former into a distinct and honourably recognized and rewarded profession. Dr. Davies' work supplies many cogent arguments, drawn from history and practical experience, for the acceleration of this reform; and, even the reader, who has little personal interest in it, will find himself strongly attached to the reforming party by the force and occasional eloquence of the author's advocacy.

Eczema: its Nature and Treatment, and, incidentally, the Influence of Constitutional Conditions on Skin Diseases. Being the Lettsomian Lectures for the Session 1869–70. By Tilbury Fox, M.D. Lond. London: Renshaw. Pp. 68.

In three lectures, written with the fluency of the journalist rather than the finish of the man of letters, Dr. Tilbury Fox runs over the main features of the most typical of skin diseases. His views are not so much those of the original investigator as of the practised compiler—a compiler, however, who has seen enough for himself to assume the attidude of an eclectic. He retains all that is good in Willan, and rejects all that is unsound in Von Hebra's supplement to that otherwise sagacious observer; while he keeps firm hold of the one true guide to the nature and development of the disease, to wit, "perverted innervation." Appropriately, therefore, he would have recourse to tonics and alteratives in treatment, while he aspires to head that "conservative reaction" in favour of drugs, as against the too sweeping scepticism that has followed their misuse.

There are, in fact, no diseases which make heavier demands on the pharmacopœia than those of the skin; and Dr. Tilbury Fox does good service by laying down such prescriptions as will convert the practitioner from an unwitting ally into an intelligent combatant of their symptoms.

Report on the Quality of the Kerosene Oil sold in the Metropolitan District (New York). By C. F. Chandler, Ph.D.

Reports on the Quality of the Milk Supply of the Metropolitan District (New York). By C. F. Chandler, Ph.D.

Attempted Poisoning by Laudanum.—A singular case is described by Dr. Dobbie, of Glasgow, in the 'British Medical Journal' of July 9th, of a lady who had been insane, and was then labouring under the same disease, having swallowed two ounces of laudanum. The poison was retained for two hours and a half, when she became sick: the vomiting was encouraged by the administration of mustard and water, and the patient was quite well the next morning. The case is remarkable, in that so large a quantity of laudanum was taken on an empty stomach, and by a person unaccustomed to its use, without producing any deleterious effect.

Hæmostatic Collodion.—The following formula is given by Dr. Pavesi ('Union Médicale'):—

Collodion, officinal, 100 parts.
Phenic Acid, 10 parts.
Tannic Acid,
Benzoic Acid, of each 5 parts.

Mix, by shaking.

Explosion of Nitro-Glycerine.—The American papers report a terrible explosion of nitro-glycerine, which occurred in a luggage van in Massachusetts, June 23rd, by which one man was killed, and about thirty injured; also property to the amount of 150,000 dollars was destroyed. Fortunately the train to which the van was attached carried no passengers. The effects of the explosion are graphically described, the buildings in the neighbourhood having been destroyed, and portions of the carriages blown to a great distance.

Obituary.

July 25, at Park Place, Leeds, after a short illness, Mr. ROBERT GOODALL, of the firm of Messrs. Goodall, Backhouse, and Co., wholesale druggists.

It is intended, as soon as the particulars can be obtained, to publish a biographical notice of the late Mr. Orridge, whose services in connection with the Benevolent Fund were so great.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

CITRATE OF MAGNESIA.

Sir,—I hope I may, without appearing to be unnecessarily intrusive, be allowed to correct what looks like a misapprehension of the whole scope of my letter on this subject, by Mr. Hughes, in his letter in last week's number. I cannot at present refer to the letter, but I do not believe it contains any expression that conveys the idea that "the sugar exercises any chemical action on the salts," or on anything; but it will be quite apparent to anybody, that if 20 per cent. of sugar be used by one maker, and 30 or 35 per cent. by another, that the same percentage amount of carbonic acid cannot be given off by both samples. Therefore it is, as I have stated, the amount of carbonic acid which is the indicator of the value of the compound.

F. M. RIMMINGTON.

ANONYMOUS WRITING.

On the subject of "Anonymous Correspondence," I would, in reply to the several writers, observe that your Editorial note of the 16th inst. puts the matter on its right footing. Anonymous writing ought to be the exception, not the rule. Why should a writer, honestly expressing his sentiments, hide his identity by a fictitious signature? I read the letters of those whose names appear and of whom I have any knowledge, either personally or by repute, with a real interest and as the communications of friends. It is not possible, as has lately been proved, that even *great names* can make nonsense pass for reason. The analogy between the correspondents of the secular press, and that of a journal devoted to a special interest, is not complete. The writers in the latter may be considered as members of a confraternity and, as such, willing to be known to their brethren; but a letter to the 'Times,' on a social or a political question, is a very different affair.

I am, Sir, yours faithfully,

Bradford, July 23, 1870. F. M. RIMMINGTON.

Sir,—Allow me, through the medium of your valuable Journal, to second the measure proposed by your correspondent of the 16th inst. viz., "That while the subject of medical reform is being broached, pharmacists should agitate and strive to obtain the privileges belonging to their true position, which they have to study to attain." Let us try to gain that pecuniary advantage from our profession which will sufficiently reward us for our pains in acquiring competence as dispensers and not depend on selling grocery and oils for our means of subsistence, thus making what should be a pharmacy into a general store, where pennyworths of arsenic, treacle, tobacco, and other incongruities are to be had with equal ease. However convenient this may be for customers, it does not require a knowledge of botany and chemistry to wait upon such customers, and they are the most numerous in country towns where medical men dispense their medicines.

I am, Sir, yours respectfully,

JOHN MILLS, A.P.S.

Biarritz, France, July 25th, 1870.

"RULE OF THUMB."

Sir,—In this week's issue of the Journal you state "nothing is more delusive than the eye as a measure of the weight of powders." Why, may I ask, is the eye more liable to delusion in this kind of measuring than in that of *distance*, or any other kind of measuring? Is a rifleman necessarily a good "shot" one day and a poor "shot" another day; or can he in this particular act trust to his eye on Saturday afternoon as well as on Saturday morning; and cannot bulk be measured with as much accuracy as distance? I know a carpenter who never uses his rule for measurements less than six inches, and may not the pharmacist, with a tutored eye, dispense with his scales in the weighing of 1 or 2 gr. powder?

After all, what matters it whether or not the scales are used if the most potent ingredient in these patent medicine powders be no more than sacch. lact.? There is far too much precision required in dispensing ingredients which are almost inert? Besides, there is next to nothing in "*dose.*"

ANTI-HUMBUG IN DISPENSING.

Aberdare, July 23, 1870.

[*** The ease of measuring lines or distance is much simpler than that of measuring irregular solids, such as little heaps of powder. In the actual instance quoted by us the practical effect of guessing was, that an infant would get sometimes half a grain and sometimes a whole grain of calomel; but since our correspondent objects to precision, and thinks there is nothing in dose, perhaps he will not attach much importance to that.—ED. PH. J.]

"*Echo*" informs "R. R." (Leighton Buzzard) that the correct rendering of the sentence criticized at page 60 of the number for July 16th, would be "With Messrs. ——' compliments, soliciting the favour of *Mr. or Messrs.* ——' orders." If *your* is used, the sentence must be in the letter form, commencing "Dear Sir," or "Gentlemen." (For *druggists* read *drug lists.*)

Ignoramus writes, "I have found in my house some curious little things—toys, I suppose; small hollow metal balls, the size of peas. Each ball is fastened, by means of fine wire, to a little capillary glass tube as a handle; they are in a box labelled 'Fil d'Arehal.' Will you, or some of your readers, be good enough to inform me of their properties?" Perhaps some of our readers can give the desired information.

A Minor Associate writes complaining of the M.D. who, in a recent number of the 'Lancet,' criticized the presence of druggists at "Mr. Squire's cutaneous assembly at the Polytechnic," and considers that invidious distinctions should be avoided by those attending such lectures for instruction.

O. J. (Teignmouth) should apply to the Admiralty for information.

C. N.—The following is the formula:—

℞. Savon blanc, 96 grm.
Carbonate de Potasse, 1 grm.
Alcohol (21°), 384 grm.
Mix, and filter the solution.

H. W. Maleham (Sheffield).—Handed to the Secretary.

J. S. (Edinburgh) will find, in the advertising columns of the Journal, particulars as to the price of the index.

C. G. (Leamington).—Parrish's 'Pharmacy,' Pereira, 'Selecta e Præscriptis,' Thomas's 'Medical Dictionary' would probably suffice. We know of no single book containing the information required.

R. J. (Southport).—The proportion of phosphate of iron in the syrup is 1 grain in the drachm; the proportion of hypophosphite of iron in the syrup of hypophosphate is 2 grains in the drachm.

Inquirer (Birmingham).—The proportion of benzoin in ung. zinci benz. is 10 grains to the ounce of lard. (See Vol. XIV. p. 207.)

Spot Stroke (Torquay).—Inquiries are being made as to this matter, and we hope soon to have full information.

H. L. (Brighton) and *J. C. Thesh* (Pontefract) should apply at the War Office.

W. M. Spooner (Witham).—Not on any account.

F. F. (Manchester).—1. Siebe's refrigerator worked with ether answers well. 2. Apprenticeship is not necessary.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to ELIAS BREMRIDGE, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. CHURCHILL, *New Burlington Street, London, W.*

ALCOHOLIC FERMENTATION.

BY BARON VON LIEBIG.

(*Continued from p.* 84.)

It has already been mentioned that many organic compounds are known which undergo, in presence of water, alteration and metamorphosis having a certain duration, and ultimately terminating in putrefaction; while other organic substances that are not liable to such alteration by themselves, nevertheless suffer a similar displacement or separation of their molecules when brought in contact with the former, like sugar in contact with yeast; but without the aid of vital action.

When the molecular work, or the metamorphosis of the cell-contents ceases, its action upon sugar ceases likewise; thus, for example, yeast may be kept for many months in a weak solution of creasote,* carbolic acid,† or other solution containing a certain amount of alcohol and acid, like wine, without any reduction of its efficacy.

It is intelligible that the products formed from the nitrogenous and sulphuretted constituents of yeast in the fermentation of yeast alone, cannot be identical with those formed from it by contact with sugar, because the sugar, penetrating into the cells, reacts upon the contents, and thus the re-arrangement of the particles of nitrogenous substance is effected. Moreover, the liquid filtered from yeast submitted to fermentation by itself is rich in nitrogenous substances, and it is very suitable for cell production.

I have mentioned that yeast loses its power of fermenting when exposed to a temperature of 60° C.; in like manner active fermentation in a saccharine liquid is stopped when the liquid is heated to 60° C., and it does not recommence again on cooling the liquid. Pasteur's admirable method of making wine keep by heating it to 60° C., appears to be in some way connected with this influence of heat upon yeast.

I have observed that during the putrefaction of yeast, the power of producing fermentation in sugar solution is retained for a long time. The point at which putrefaction sets in is easily recognizable when the yeast is mixed with some nitre solution. While fermenting alone or with sugar solution, no alteration of the nitre is caused; but so soon as putrefaction begins, the nitrate is converted into nitrite, and on testing some of the liquid with starch, iodide of potassium, and dilute sulphuric acid, a deep blue colour is produced.

A quantity of yeast was left for five weeks after the commencement of putrefaction, and every four days a portion of it was added to sugar solution. Even after it had passed into an extremely putrid state, it produced fermentation, and then the bad smell disappeared gradually. However, the quantity of alcohol formed became less, and there were formed besides carbonic acid, other products that I have not yet examined.

In reference to the formation and development of the yeast-fungus, Pasteur has made an observation which has given a new direction to the views previously entertained.

It was supposed that yeast was developed like other fungi, which, as parasites, derive their constituents from plant or animal remains, especially that its propagation and multiplication required albuminates, or some derivative of them besides phosphates.

Pasteur's experiments, however, leave no doubt that yeast may develope in mixtures containing tartrate of ammonia, sugar, and the cell-constituents of yeast.

It is astonishing that this discovery has not attracted more attention in regard to a special point, for it comprises a fact of very great significance for physiology, viz., the formation of albuminate in plants, respecting which we are in possession of scarcely anything beyond conjectures; hitherto this has been regarded as one of the greatest mysteries in organic nature.

We have regarded the organic acids in plants—oxalic, malic, citric, etc.—as the intermediate substances between carbonic acid and sugar, starch, cellulose, etc., by means of which the gradual transition from carbonic acid to a plant-constituent is effected; but in the food plants, which contain the largest amounts of albuminates, we do not find any nitrogenous substance besides ammonia that can be connected with the formation of the albuminates.

This problem appeared to be solved by the experiments of Pasteur; for if yeast-cells, placed in a mixture of ammonia, tartaric acid, sugar, and phosphate, could propagate and multiply, it is evident that an albuminate must have been formed from the elements of this mixture, since one of the chief constituents of the yeast-fungus is an albuminate, and in each of the new yeast-cells there must be a certain quantity of freshly-produced albuminate present, without the presence of which no true yeast-cell could have been formed.

Twenty-five years ago I directed attention to the possibility that albumen in plants might be formed by combination of ammonia with sugar, attended with elimination of water.

$$\left.\begin{array}{ll}\text{Sugar . .} & C_{48}H_{48}O_{48} \\ \text{Ammonia} & \quad\;\; H_{18} \quad\;\; N_{6}\end{array}\right\} = \left\{\begin{array}{ll}\text{Protein .} & C_{48}H_{36}O_{14}N_{6} \\ \text{Oxygen.} & \qquad\qquad O_{4} \\ \text{Water .} & \qquad\; H_{30}O_{30}\end{array}\right.$$

$$\overline{C_{48}H_{66}O_{48}N_{6}} \qquad\qquad \overline{C_{48}H_{66}O_{48}N_{6}}$$

The substance here referred to under the name of protein contains the same elements as casein, united in the same proportions, leaving out of consideration sulphur, the precise origin of which I am not able to account for.

The idea of the production of an albuminate from ammonia and sugar was not therefore at all surprising to me, but rather familiar than otherwise; nevertheless, I could not readily conceive such a mode of formation to obtain in a fungus, for it would not be possible without elimination of oxygen from the sugar, while the yeast-fungus grows in the total absence of light, and up to the present time no evolution of oxygen has been observed in the growth of fungi.

On closer consideration of the experiments which preceded Pasteur's chief experiments, and led him to them, it is scarcely possible to suppress some misgivings. Thus, for instance, Pasteur added to a sugar solution some tartrate of ammonia, and, after fermentation, he found less ammonia than he had added, inferring thence that the missing ammonia had entered into combination and contributed to the production of yeast. The details of the three

* Béchamp.

† Dr. v. Pettenkofer.

* In a note on the origin of albumen, Ann. Ch. Ph. li. 287

chief experiments made in reference to the disappearance of ammonia are the following:—

I. 100 grm. sugar, dissolved in a litre of yeast-water, mixed with a trace of yeast, and left to ferment.

The yeast-water contained	·038	grm. ammonia.
The fermented liquid contained	·020	"
Deficiency	·018	"

II. 100 grm. sugar, 10 of fresh yeast, mixed with ·2 tartrate of ammonia. The liquid contained—

Before fermentation	·0185	grm. ammonia.
After fermentation	·0015	"
Deficiency	·0170	"

III. 19·575 grm. sugar, ·525 yeast, and ·475 tartrate of ammonia. The liquid contained—

Before fermentation..........	·088	grm. ammonia.
After fermentation	·071	"
Deficiency	·017	"

In these three experiments, the quantities of ammonia in the fermented liquids were in the ratio, 1 : 2 : 5, and it is rather striking, that the deficiencies were nearly the same in all three instances. It is, moreover, not easily explicable that, in these three experiments, a part of the ammonia should have served for the production of a nitrogenous constituent, while in the fermented liquid there was still a residue of nitrogenous substances, which are admirably suited as food for yeast-cells, and certainly much more so than ammonia; in fact, the fermentation would have gone on just the same in the three mixtures without any addition of ammonia.

The constancy in the loss of ammonia, notwithstanding the dissimilar quantities of ammonia, would appear rather to indicate an error in the method of determination common to all the experiments; but I will not lay any stress on this supposition. The confirmation of the most important thing, viz. the increase of yeast by the ammonia in the fermented mixture, has been left entirely unheeded by Pasteur.

It is clear that if he had added an ammonia salt to one of two mixtures of a known quantity of sugar with the same quantity of yeast-water and a trace of yeast, he should, in the two cases, have found a difference in the quantity of yeast produced. If the ammonia had been applicable for the production of yeast, the mixture with ammonia should have yielded more yeast than the others without ammonia.

The capability of ammonia to serve for the formation of yeast is, therefore, not inferred from the fact that the quantity of yeast was increased in the presence of ammonia, but from the fact, that the determination of ammonia in the fermented liquid showed a loss. The only satisfactory evidence in favour of Pasteur's view, that the ammonia contributed to the formation of yeast is, as already stated, yet to be furnished.

The experiments of Duclaux * seem to admit of the inference, that ammonia has no influence on the formation of yeast. He fermented 40 grm. of sugar with 15 grm. yeast and 1 grm. dextro-tartrate of ammonia, and found that the yeast was reduced from 2·5011 grm. to 2·326 grm., or about 8 per cent., as in Pasteur's experiment without ammonia. But in all liquids that contain material adapted for feeding yeast, there is an increase in the quantity of yeast. However, I will not lay any further weight on these considerations, but will turn to Pasteur's main experiments, by which he believes that the formation of yeast from non-nitrogenous substances and ammonia has been directly proved.

When a mixture of 10 grm. sugar, 100 c.c. water, ·100 grm. tartrate of ammonia, and ·075 to ·080 grm. yeast-ash, was mixed with a trace of yeast, evolution of carbonic acid commenced in a few hours; the sugar was partially decomposed and the yeast increased; ·0062 grm. of ammonia had disappeared (= 5·2 milligrams nitrogen), while the yeast produced weighed ·043 grm., and this should have contained the nitrogen of the ammonia, or upwards of 11 per cent. of nitrogen. Pasteur has described very minutely the progress of this experiment, and I believe it is possible to infer with tolerable certainty from his account, that there was essentially no vinous fermentation, but that a true lactic fermentation took place. There was, indeed, a sensible production of alcohol, but I suspect that the quantity of alcohol was not determined by him, because it was too small. However, 4·5 grm. sugar was decomposed, and it was, for the most part, converted into an organic acid, equivalent to ·597 sulphuric acid. This organic acid consisted chiefly of lactic acid.

I have many times repeated this experiment with great care, and obtained nearly the same results as Pasteur so far as relates to the formation and increase of the yeast. The only alteration that I made in the mixture consisted in heating the liquid to boiling, and allowing it to cool in the vessel before adding the yeast. In another instance I took sugar that had previously been heated to 160° C., at which temperature it is known not to lose its capability of fermenting.* I also found that, after twenty-four hours, some carbonic acid was evolved, and that the greater part of the sugar was converted into an organic acid, the nature of which was not determined.

From one of these mixtures I distilled off 25 c.c., and determined the specific gravity of the distillate to be ·99968, or scarcely different from that of water. By means of Lieben's delicate test, however, alcohol could be detected in it.

There is no doubt that, under these conditions, a decomposition takes place, and that there is some formation of alcohol, which probably originates from the yeast added, although its quantity is so small. But the whole process has no resemblance to that taking place in a sugar solution, to which so much nitrogenous substance has been added, as would correspond to the nitrogen of ·1 grm. neutral tartrate of ammonia (= 15·2 milligrams nitrogen). For instance, in a mixture of 100 c.c. sugar solution, containing 5 grm. sugar and 16 c.c. of a decoction of fresh yeast, there was, after adding a trace of yeast, in eight hours a sensible fermentation; successive bubbles of carbonic acid were evolved slowly but continuously, while the bottom of the vessel became covered with a distinct layer of very white yeast, that increased in thickness until all the sugar was decomposed.

I am fully conscious that, in researches of this kind, a negative argument does not excite any special confidence, for it does not require any particular art not

* 'Comptes Rendus,' lix. 450.

* According to analyses made by Prof. Volhard at the instigation of Prof. Nägeli, the whitest and most transparent crystals of sugar always contain nearly ·5 per cent. of nitrogen.

to obtain the result another experimenter declares he has obtained, while want of skill and care in the execution of difficult experiments are sufficient to cause discrepancies; but I believe that I have not neglected any precaution, and moreover Professor Nägeli, to whom I gave a mixture prepared exactly according to Pasteur's directions, has not been more successful than I was.

Considerations of another kind induced me to discontinue these experiments without losing more time over them.*

It must be noticed that, although Pasteur weighed the deposit formed in his experiments, he has not furnished any evidence that the 43 milligrams obtained was true beer-yeast. He should have brought that deposit into contact with sugar-water, to show that it really consisted of *Torvula cerevisiæ*, and it should have caused sugar to ferment. The microscope is a very untrustworthy instrument for determining the real nature of such things as this. To judge from the proportionately large quantity of lactic acid formed from sugar in Pasteur's experiments, the seeds of *Torvula cerevisiæ* must have given rise to lactic ferment, viz. *Penicillium glaucum*, and the deposit must have consisted of this.

It is surprising that Pasteur claims to have produced beer-yeast in mixtures that did not contain any sulphur. There is no such thing as beer-yeast that does not contain sulphur; its chief constituent is a nitrogenous substance containing as much sulphur as casein does, or even more.

Neither sugar nor tartrate of ammonia contain sulphur, and even yeast ash is generally free from sulphur. That which I used did contain a trace of sulphuric acid, but even if it had contained a considerable amount, the assumption that the yeast plant possessed the capability of decomposing sulphuric acid would have been admissible only if it had been distinctly proved that true beer yeast could have been produced in Pasteur's mixtures. I look forward to this proof with the greatest interest, and, if Pasteur should succeed in obtaining it, we shall have gained an exceedingly important piece of information in reference to plant physiology, either that there is beer yeast not containing any sulphur, or that fungi have the power of decomposing sulphuric acid, and of producing an albuminate from its sulphur, together with ammonia and the elements of sugar or tartaric acid. This is a power which has hitherto been regarded as belonging only to green plants under the influence of light.

The fact that Pasteur, in determining the ammonia in his fermented mixtures, found less than he had added to them, cannot possibly be relied on as evidence that this ammonia served as food for the growth of yeast; for I must again point out, that in no single instance has he shown the formation of true yeast or its increase to be due to the presence of ammonia in the fermenting liquid.†

In carrying out the plan adopted by Pasteur for separating ammonia from fermented liquids by boiling them with calcined magnesia, I have repeatedly obtained less ammonia than the liquid contained; but, in such instances, the deficiency of ammonia was recognizable in the residual magnesia having formed ammonio-phosphate of magnesia in consequence of the presence of soluble alkaline phosphates, which are never wanting in fermented liquids.

Pasteur has also discussed the question as to what becomes of the nitrogen of yeast in fermentation; he says, "In vinous fermentation there is not the slightest formation of ammonia at the expense of yeast." * This statement is, however, inconsistent with that on the previous page, to the effect that a litre of water, containing the soluble constituents of yeast, yielded ·038 grm. of ammonia. I find, moreover, that all fermented liquids contain ammonia, though certainly a very minute quantity. It seems as if nitrogen were excreted in some other form, partly, perhaps, as organic bases. I have been unable to detect leucin in the fermented residues, probably because its amount is too small. Ludwig has found trimethylamin in all the varieties of wine examined by him; and Oser, likewise, has described a very remarkable nitrogenous base, destitute of oxygen, as being a constant product of the fermentation of sugar with yeast. According to his experiments, this base appears to be a constant product of the fermentation of cane sugar.

In the wine districts of France, where many thousands of gallons of wine are distilled in the manufacture of brandy, the residues of this operation would probably be a rich material for investigation, in regard to the non-volatile products of fermentation, and they would probably constitute a source of interesting discoveries. Moreover, if it be the case, as Pasteur states, that for each litre of alcohol produced in fermentation, there is also formed 50 grm. of glycerin, it is possible that glycerin might be extracted from these residues with advantage.

Recent researches on the causes of fermentation and putrefaction have been prosecuted essentially under the influence of the ideas—entertained by Turpin, Cagniard-Latour, Mitscherlich, and others—which prevailed in the minds of many physiologists thirty years ago and have been recalled by Pasteur within the last ten years.

Turpin states, as the result of his microscopic investigation of beer fermentation and acetous fermentation, that "under fermentation is to be understood a joint action of water and living bodies which feed and develope by the assimilation of a constituent of sugar, while, at the same time, eliminating from it alcohol or acetic acid; a purely physiological action that commences and ends with the existence of infusorial plants or animalcules whose life ceases only when the nutritive saccharine materials are totally exhausted."† It is impossible to detect any difference between the fundamental views of Turpin and those of Pasteur.

Inasmuch as Pasteur has again diverted the study of fermentation and putrefaction by microscopists into the old objectless path, the result has been, that the general aspect of these processes has been disregarded, the phenomena that are common to all of them have been overlooked. Observation

* It is well known that in ammoniacal salts of organic acids there is often a spontaneous decomposition accompanied by formation of mould, without any addition of ferment.

† My late friend Pelouze communicated to me, some nine years since, the results of Pasteur's investigations, and I then remarked to him, that I did not perceive anything to induce alteration in my views respecting the cause of fermentation,—adding, that if it were possible, by the aid of ammonia, to produce yeast in fermenting liquids, or to increase its quantity, this possibility would soon be turned to account, and that I would await such a result; but, up to the present time, the industrial preparation of yeast has not altered.

* Page 380.

† Ann. Chem. Pharm. 1839, xxix. 100.

it has been directed to the search for mere details, and has thus become incoherent. This tendency has prevailed so far that special causes are sought for each of these innumerable processes, for each one, in fact, there has been found a particular species of fungus or animal, and this is likewise the case for many diseases, such as cholera, etc. In this way we have attained to such a point, that we are no longer able to comprehend how it is that, in the presence of these enemies, the organic world continues to exist. If we ask the microscopic investigator what is really the nature of the ferments which give rise to lactic, butyric, and other acids, we receive as an answer the names of certain species of fungi!

Though probably no one will dispute the utility of microscopic observations, it is, nevertheless, indispensable to recognize the fact that "causes" are not to be seen, even with microscopes. Observations of that nature are well calculated to define the limits of things that participate in a process, and to direct investigation to the part they take in it; but the supposition that the whole affair is at an end when something has been found of which we have no further knowledge, is sufficient evidence that the true value of physiological facts is misconceived.

All putrefaction-ferments, when left for a time, give rise to the formation of butyric acid from their own elements, and they excite butyric fermentation in other materials which are susceptible of such change, just in the same way that yeast, when left to itself, produces alcohol and excites vinous fermentation when placed in sugar solution. From the fact that, under certain conditions, yeast excites lactic fermentation instead of vinous fermentation, it may be inferred with great probability, that under those conditions, lactic acid is actually produced in the yeast instead of alcohol. Salicin, a glucoside, breaks up in contact with emulsin into saligenin and sugar, but in the presence of yeast and carbonate of lime it breaks up into saligenin and lactic acid. These facts are, I conceive, indications that admit of our hoping to come, by means of properly conducted investigation, somewhat nearer to the causes of these changes.

The production of succinic acid and glycerine appears to be indicative of a fermentation going on simultaneously with the vinous fermentation; it is evidently analogous to the fermentation processes in which lactic acid is formed from sugar or mannite and sometimes butyric acid, from lactic acid. It is possible that the detection of a small quantity of hydrogen in the carbonic acid evolved, might lead to further elucidation. Mannite and glycerine differ only in the amount of hydrogen they contain.

I have regarded the phenomena of fermentation and putrefaction from a totally different point of view, and have considered their elucidation as the bridge by means of which we may arrive at a more exact knowledge of the processes taking place in the organisms of animals and plants.* Who can, at the present time, fail to perceive the significance of these facts, in regard to the conception and explanation of many vital processes? If a change in the locality and relative position of the elementary particles of animal substances, outside the organism, be capable of exerting a very definite influence upon a number of organic substances which are brought in contact with them, if those substances are thereby decomposed, while new compounds are formed from their elements, and if it be considered that the class of substances susceptible of such changes as take place in fermentation, comprises all those which are constituents of the food of man and animals,—who can doubt that the same causes act one of the most important parts in the vital process, or that they have a powerful share in the alterations which the materials of food undergo when they are converted into fat, blood, or constituents of organs! We know, indeed, that there is in all parts of the living animal body an incessant change going on; that living particles of the body are eliminated; that their constituents, whether fibrin, albumen, gelatin, or whatever else they may be, rearrange themselves as new compounds; that their elements unite to form new products. In accordance with our experience we must presume that in virtue of this activity, there is, at all places where it obtains, and corresponding to its direction and intensity, a parallel alteration in the character and composition of constituents of the blood, or of food, coming in contact with such changing particles—that consequently the animal metamorphosis is itself a main cause of the alterations that the food undergoes, and a determining condition of the nutritive process; that with every pathological variation in the metamorphosis of an organ or a gland, or any constituent of them, the action of that organ upon the blood coming in contact with it, or upon the character of its secretion, is also altered; that the action of many therapeutic agents depends on the share they take in the metamorphosis, and that they exercise an influence on the quality of the blood, or of the food, chiefly in virtue of the circumstance that they alter for a time the direction and power of the activity obtaining in the organs, either accelerating, retarding, or stopping it?

UNTO-MOOL.

Tylophora asthmatica, W. and A.

BY M. C. COOKE.

Recently it has been proposed to introduce and cultivate ipecacuanha in India, on a large scale, for medical purposes, as has been done with cinchona. It would be well to inquire, before such a step be taken, whether any of the known indigenous products affords a good substitute for the officinal plant. It is probable that the evidence already collected is insufficient; but it would be comparatively easy to test the value of such drugs as we may name prior to any extensive experiment on acclimatization.

The Natural Order *Asclepiadeæ*, contains several plants with the reputation of possessing emetic virtues, some of them equal to ipecacuanha. Of these, the root of the "mudar," *Calotropis gigantea*, has been named. The emetic properties of mudar root have been vouched for by several good medical authorities, amongst whom may be mentioned Sir W. O'Shaughnessy, Dr. Bonavia, Dr. Hutchinson, Dr. Æ. Ross, Dr. Newton, Dr. Stewart, and others. On the other hand, it is admitted that precaution must be taken to dig the root at the proper season and to prepare it in a certain manner, or it is liable to prove inert.

Then, again, *Secamone emetica*, R. Br., has been mentioned, as regarded by the natives highly for its emetic properties; but the only trial which has been recorded was unsatisfactory, inasmuch as it was almost inert. It is not impossible that, in this instance also, due regard was not had to the season at which it was collected.

The root of *Asclepias curassavica*, L., called 'Bastard Ipecacuanha,' introduced into India, certainly has a reputation in the West Indies and elsewhere as an emetic. Its use appears, however, to be attended by disadvantages, such as powerful action on the bowels, which would militate against its regular use.

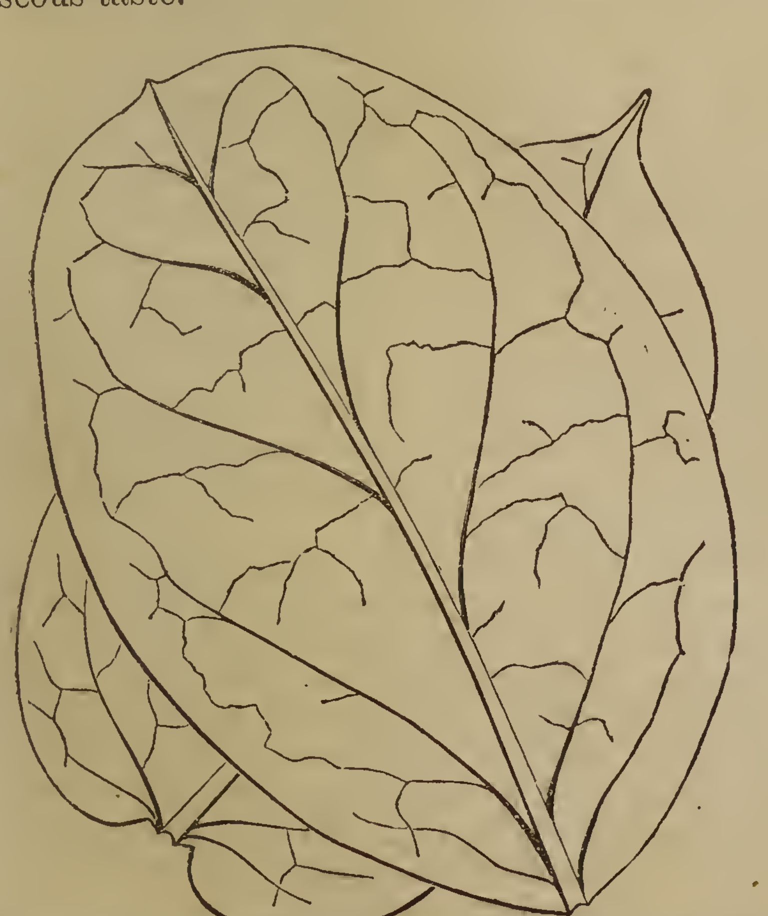
Besides these, *Dæmia extensa*, R. Br., and the leaves of *Hoya viridiflora*, R. Br., enjoy a reputation amongst the natives as emetics, but they do not appear to have been efficiently tested.

Finally, the root and leaves of *Tylophora asthmatica*, W. and A., have been strongly recommended, and this is probably the safest and best of all the remedies here enumerated. The leaves are included in the new 'Pharmacopœia of India' as a primary article, and the evidence goes to show that they are an excellent substitute for ipecacuanha.

This plant is the *Asclepias asthmatica* of Roxburgh, and the *Cynanchum* of other authors. It is called 'Unto-mool' in Bengali, 'Kaka-pulla' of the Teloogoos, and the 'Codegam' or 'Coorinja' of the Tamils. In the Mauritius it is known as 'Ipéca du pays,' or 'Ipéca sauvage.' It is a twining plant, from 6 to 12 feet in height, with opposite, ovate-roundish, acuminate leaves, which are cordate at the base, smooth above and downy beneath; the peduncles are short, with two or three sessile, few-flowered umbels; the flowers are rather large, on long pedicels, externally pale green, with a faint tinge of purple, internally light purple.

This is a very abundant and widely diffused plant in India, being to be met with in nearly all situations, and in flower at all seasons. Is very liable to variation, so as to be difficult to characterize, but may be readily known from an allied species by the reddish or dull pink flowers and the toothed leaflets of the crown.

The *root* is sold in the bazaars in thick, contorted pieces of a pale colour, and a bitterish, somewhat nauseous taste.



The dried *leaves* are from two to three inches in length, entire, ovate-roundish, acuminate at the apex, cordate at the base. The older or lower leaves are scarcely acuminate, and rather rounded than cordate at the base. They have rather a glaucous appearance, with a heavy, disagreeable smell when bruised, and a nauseous taste.

Dr. Kirkpatrick, after remarking that the powdered root and juice are used by the people of Mysore as an emetic, adds, "I have administered this medicine in at least a thousand cases, and found it most valuable. In dysentery, and as a simple emetic, it is in every way comparable with ipecacuanha. The dose is from twenty to thirty grains, with half a grain, or a grain, of tartar emetic, if strong emesis is required. If the dysentery distinctly arise from intermittent disease, quinine is conjoined. The form of the medicine I use is the powder of the dry leaf. If the root were used, the supply would soon be exhausted; besides, I have found it less certain than the leaf. The preparation of the juice would at all times be troublesome and tedious. In catarrhal and chronic coughs it seems to act well. Its efficiency as a substitute for ipecacuanha, not only as a simple emetic but as a remedy in dysentery, asthma, and catarrhal affections, is confirmed by the report of Dr. Oswald, Mr. Moodeen Sheriff, and others. According to the latter, the best treatment of snake-bites consists in producing free emesis by the expressed juice of this plant, and following up its use with diffusible stimulants."

Roxburgh says that "on the coast of Coromandel the roots have often been used as a substitute for ipecacuanha. I have often prescribed it myself, and always found it answer as well as I could expect ipecacuanha to do. I have also often had very favourable reports of its effects from others. It was a very useful medicine with our Europeans who were unfortunately prisoners with Hyder Ali during the war of 1780–3. In a pretty large dose it answered as an emetic, in smaller doses often repeated, as a cathartic, and in both ways very effectually." Other authors add that the natives employ the root as an emetic by rubbing upon a stone three or four inches of the fresh root, and mixing it with a little water for a dose. It generally purges at the same time.

The leaves are considered preferable to the root, —in fact, the leaves only are recommended, in the Pharmacopœia of India. The dose there stated is,—as an emetic, from five-and-twenty to thirty grains of the powder of the dried leaves, conjoined with half a grain or a grain of tartar emetic; as a diaphoretic and expectorant, from three to five grains, thrice daily, or oftener, combined with opium, and other remedies of the same class. It is also stated on the authority of the same work, that this is one of the best indigenous (Indian) substitutes for ipecacuanha. It is easy enough to obtain this drug from India, and it certainly seems worthy of consideration whether it should not also be fairly tried in this country.

OPHELIA CHIRAYTA.

BY FLÜCKIGER AND HÖHN.

This plant is little known in Europe, and is not much used even in England, although it has a place in the British Pharmacopœia of 1867, as well as in that of the United States of 1866. But in India Chirayta has long been in high repute, and it is generally sold in the bazaars. It is also mentioned among the large number of medicinal agents comprised in the 'Systema Medicinæ' of Susrutas about ten centuries before our era. The Sanskrit name is *Kiratatikta*, or the bitter herb of the Kiratas, a half-caste race that had been driven back into the hill country of northern India. It is with good reason, therefore, that this plant has always received attention from English physicians in India, and that it has been included in the Indian Pharmacopœia of 1868.

Strangely enough, Guibourt attempted to refer to *Chirayta* several of the older descriptions and drawings of the *Calamus aromaticus, odoratus*, or *verus* that was brought at an early period from India to Europe. It is true he pointed out the total absence of aroma, so that the remarks of Fée and Royle sufficed to prove the total difference between the odourless *Chirayta* and *Calamus*, although the history of the latter is not yet fully ascertained.

This plant from which this bitter herb is derived —*Ophelia chirata*, Griseb.—was first drawn by Roxburgh in 1814, under the name *Gentiana Chirayta*; subsequently also by Wallich, by Don (as *Agathotes Chirayta*), by Wight, and Cleghorn. It is an elegant annual *Gentiana* of the lower Himalaya, occurring from Simla, and through Kumasu, as far as Nepaul. In its outward appearance *Ophelia Chirayta* closely resembles our *Erythræa Centaurium*, though with several differences.

The Chirayta commonly met with in English commerce is usually of very inferior character, and chiefly consists of stalks deprived of their leaves. The plant that has been examined by Höhn consisted, on the contrary, of well-preserved specimens retaining flowers, fruit, and roots, so that the essential characteristics of that nature could be well observed. For the supply of this material I am indebted to the kindness of my friend Daniel Hanbury.

The woody stems were from 2 to 3 feet long, and ¼ inch thick at the lower ends, cylindrical, with knots at distances of 1½ to 3 or 4 inches, at the upper ends obtusely quadrangular, with wings extending downwards. The colours varied from brownish-yellow to dark purple-red. The branches were more greenish or greyish-brown. The root is sometimes from 2 to 4 feet long, and twice as thick as the stem. It forms generally a simple tap-root, furnished with somewhat scanty fibres. Larger specimens present an angular bending of the root, probably indicating a growth of more than one year. Generally the stem rises isolated from the root, but in some instances I met with plants consisting of several stems. The numerous prolonged branches resemble in their arrangement those of *Erythræa Centaurium*, and towards the upper part they form a thick whorl. The insertion of the leaves and flowers may also be compared to that of the indigenous Gentian referred to above. The lower leaves of *Ophelia* are often 3 cm. in length and 7 mm. broad; the upper ones are very much smaller. All of them are acutely lancet-shaped, smooth edged, cordate at the base, and, like the entire plant, perfectly glabrous. According to the size of the leaves, they present 3, 5, or 7 ribs, of which the central one is the thickest.

The yellow, 4-parted corolla is about 12 mm. long, and rather glandular at the base. The calyx is much shorter than the corona. The fruit is a 1-celled capsule, with two valves at the apex.

* Derived from ὄφελος, useful, in reference to the medicinal virtue of the plant.

The flower possesses the same intense bitter taste that is characteristic of Chirayta. It is only the woody substance of the thickest stems that is not bitter; this contains a considerable pith. Even the branches present in sections a broad ring.

The popular name of this drug in India is *Creyat*, and it has been applied to several varieties of *Ophelia*; but it seems that *Andrographis paniculata*, Wallich (*Justicia paniculata*, Burm.), an *Acanthacea*, frequent in Bengal, is principally understood under that name (or, properly, *Kiratha*). This plant, which is only 1 or 2 feet high, also tastes intensely bitter, but it is distinguishable by its alternate, long-stemmed flowers, with rose-coloured bilabiate corolla. Moreover, the flower forms a panicle.

While *Ophelia Chirayta* is distinguished as *dukhani*, or southern Chiretta or Creyat, the *Ophelia angustifolia*, Don, is, on the contrary, termed *pahari* Chiretta, as coming from the mountains. This variety grows in the same districts as the true Chirayta; but it has leaves that are almost lineal, and the flowers have a white corona, with violet spots, that is shorter than the calyx.

On the contrary, *Ophelia elegans*, Wight, is indigenous to the mountains of southern India, and in the bazaars of that district it is described as inland Creyat. It has blue flowers.

Lastly, the Indian Pharmacopœia mentions the white-flowered *O. densifolia*, Griseb. (*O. multiflora*, Dalzell). All these varieties are described as quite as bitter as the true Chirayta, and as being, in fact, used in the place of it throughout the north-western, central, and southern provinces of India.

These varieties of *Ophelia* correspond in their native country to the allied indigenous European plants which have been introduced into medical use here, and from that point of view their investigation by Höhn presents some pharmaceutical interest. In the Indian Pharmacopœia there is an infusion of Chirayta, and an aromatic tincture with cardamoms and orange-peel.

By extracting the stalks and roots with alcohol of 60 per cent. sugar, wax, chlorophyll, soft resin, tannin, an acid (ophelic), and a pecular bitter substance (chiratin) were dissolved.

The acid was syrupy, and very deliquescent, yellowish-brown, tasting at first slightly sour, afterwards intensely bitter. When warmed it smells like lugian; it dissolves in water with some turbidity (due, perhaps, to resin), completely in alcohol, or a mixture of spirit with ether. It decomposes alkaline solution of copper when warmed with it; also ammoniacal solution of silver with alkalies it darkens; with perchloride of iron it becomes reddish-yellow; with sulphate of copper dirty green; with lead salts yellow, and forms amorphous compounds with acids. Analysis of the lead compound gave $C_{26}H_{20}O_{20}$ as the formula.

Chiratin is a pale yellow, very hygroscopic powder, at the utmost capable only of a granular crystallization; it is very bitter, sparingly soluble in cold water, rather more in hot water, readily soluble in alcohol or ether. It is neutral to test-paper, does not reduce alkaline solution of copper, and gives with tannic acid a copious white flocculent precipitate; formula $C_{52}H_{48}O_{30}$. By the action of acids chiratin is separated into ophelic acid and a yellowish-brown amorphous substance that is not sugar, but tastes bitter, is scarcely soluble in water, readily soluble in spirit, does not reduce copper solution.

Höhn assigns to it the formula $C_{26}H_{24}O_6$, and the name Chiratogenin.

The herb itself gave the same results as the stem and roots.

HYDRATE OF CHLORAL.

BY C. UMNEY, F.C.S.

Reference has already been made in the leading journals of medicine, chemistry, and pharmacy to a compound of chloral with alcohol.

Recently this alcoholate of chloral has found its way into commerce, and has been offered for sale as hydrate, at a much lower rate than the market value of true hydrate of chloral.

It is highly important that the alcoholate should be distinguished from the hydrate, not only because it yields upon decomposition a smaller proportion of chloroform, but because Dr. O. Liebreich and other therapeutists who have experimented with it affirm that its medicinal properties are dissimilar to those of the hydrate.

The object of this communication is to give to pharmacists the details of a quantitative test for determining the chloroform value of any specimen of either of these chloral compounds which may pass through their hands.

a. Hydrate of Chloral.—Take 500 grains of the salt, and dissolve in about 1 ounce of distilled water; transfer to a 1000-grain graduated tube, and make up the measure of the solution to 700 grain-measures; to this add solution of caustic ammonia (·891) until the whole measures 1000 grains. Agitate; immerse the tube in warm water, to assist the reaction, and set aside for twelve hours.

Upon examination, the fluid will be found to have perfectly separated into two layers, the lower being chloroform (from fine specimens of the hydrate nearly colourless), the upper, a deep, sherry-coloured solution of formiate of ammonia.

The volume of the chloroform layer should not be less than 235 grain-measures, which, calculated at the sp. gr. of chloroform (1·497), would give 351·7 grains by weight, a quantity equal to about 70 per cent. (70·3) of the chloral compound employed.

β. Alcoholate of Chloral.—Proceed as in testing the hydrate. The chloroform layer will be about 200 grain-measures, or by weight 299 grains, an equivalent of about 60 per cent. by weight (59·8) of the chloral alcoholate. Such a difference, it must be apparent, is of great importance, as the physiological action of chloral is principally due to its transformation into chloroform in the blood.

An eye accustomed to the rate of solution of the hydrate in water can soon detect the alcoholate by its much less solubility. The hydrate in detached crystals,* resembling crystals of sulphate of magnesia, is a much more soluble form than the ordinary hydrate in masses; it will also produce upon decomposition with ammonia 70 per cent. by weight of chloroform.

The difference in the boiling-point of the hydrate (95° Cent.) and of the alcoholate (116° Cent.) is alone almost sufficient to distinguish one from the other. At any rate, this characteristic, combined with the quantitative chloroform test, is quite sufficient to enable the pharmacist to give with accuracy an opinion upon the purity of any chloral hydrate.

OINTMENT OF MERCURIC NITRATE.

BY R. ROTHER.

One of the most serious imperfections of the Pharmacopœia is its process for the ointment of mercuric nitrate. This is a failure in every respect, the nomenclature not excepted. The ever-recurring difficulties that the officinal formula engenders have caused the accumulation of abundant literature designed to obviate or remove some of these inherent obstacles. But even the enumeration of all the known processes has been of no avail. Most of the modifications that have been suggested are based upon the officinal process itself, and consist mainly of alterations in the proportion of the ingredients or their quality. But the officinal process is in the full sense of the term irrational; likewise must be any other which grounds itself upon this. Therefore, the solution of this profound problem cannot be discovered in the components of the formula, but must be sought for in the operation alone. A review of all the known facts connected with the history of this preparation reveals as follows:—Firstly, since the value of this combination is generally recognized, the title should be distinctive of its character. In this regard the Pharmacopœia completely fails. If the solution of the metal is officinally effected in the contact with the acid at the ordinary temperature, it is positively certain that both mercuric and mercurous nitrate form even in the large surplus of acid shown by the precipitation of mercurous chloride in the presence of chlorhydric acid, consequently the ointment will receive both nitrates from the beginning. Evidently, the lower the temperature at which the solution is made, the greater will be the proportion of mercurous nitrate, in the same ratio the remaining acid, and through it the more powerful the oxidation of the fats. But the intenser the reaction, the more probable will be the reduction of the mercurial salts, and especially the mercurous nitrate, which is eminently dissimilar in its effects and molecular constitution to the mercuric salt. The following equations will sufficiently illustrate the above:—

$$3\,Hg + 8\,(NO_3H) = 3\,((NO_3)_2Hg'') + N_2O_2 + 4\,OH_2$$
$$6\,Hg + 8\,(NO_3H) = 3\,((NO_3)_2Hg_2) + N_2O_2 + 4\,OH_2.$$

When these mercurial solutions come in contact with the heated glycerides, the complicated reaction which immediately ensues commences with two distinct phases. One of these is characteristic only for the so-called non-drying oils; the other is pretty general with all. The first of these is determined by the catalytic action of the nitrogen tetroxide (which is always present in the mercurial solution prepared without heat, and should it not be present, as would be the case by employing a solution containing the mercuric nitrate only, it would, of course, simultaneously result from the mutual decomposition of the nitric acid and the facts), and consists in the transformation of the liquid triolein into its white concrete and crystalline isomere elaidin. But the second, which is characterized by the violent evolution of volatile products, consists, according to the prolongation of the reaction or its intensity, favoured by external causes, and the relative quantity of nitric acid, of the destruction of part of the oleic, palmitic and stearic acid contained in the glycerides that are usually employed.

But the complete dissociation of the original compounds is effected with difficulty. Pure lard, heated with eight and ten times the quantity of strong nitric acid until the latter was dissipated, still was attacked by a fresh portion. In this case, all of the nine volatile acids of the series $C_nH_{2n}O_2$, from acetic to capric inclusive, are produced together with fixed acids of the series $C_nH_{2n-2}O_4$, of which suberic and succinic acid are more abundantly produced from glycerides containing chiefly palmitin. A peculiar and undetermined substance is invariably generated in quantity, and resists the destructive action of the nitric acid with remarkable obstinacy. This is an intensely yellow oil, which saponifies with potassium hydrate, with the formation of a deep red colour; and it is this compound to which the ointment of mercurial nitrate owes its yellow colour. It is supposed that the discoloration of the officinal ointment occurs more particularly when the oxidation of the fatty matter has not been sufficient, and that subsequently the avidity of these bodies robs the mercurial salts of their oxygen and reduces them to the metallic state; but in the officinal ointment the greater part of the mercury no longer exists as normal nitrate, but chiefly as basic nitrate and mercurous or mercuric salts of some of the fatty acids either originally existing in the fat or as products of its decomposition. This is amply evidenced by employing a drying oil, as the oils of cotton or flax-seed, in the preparation of the ointment, which of course, as will be seen, are entirely inadmissible for this purpose. If flax-seed oil, for instance, is heated with nitric acid alone, even until the latter is entirely consumed, no separation will take place; but if to the heated oil the mercurial solution be added, a greenish-yellow agglutinated mass immediately separates, which adheres to the bottom of the vessel and the stirrer too tenaciously to admit of distribution, and moreover hardens on cooling to the consistence of lead plaster. Strong cold nitric acid has no apparent action on this substance; neither have oil of turpentine, alcohol, ether, and carbon disulphide, when repeatedly treated with these solvents in succession; but chloroform dissolves the greater part of it, leaving a greyish, light, flocculent deposit, which agglutinates on the addition of alcohol. Cold strong nitric acid attacks this powerfully, forming a green solution containing abundance of mercuric oxide. At the same time a yellow oily substance separates, which completely dissolves in chloroform—also in ether, but slowly and imperfectly in alcohol—to an intense yellow colour, and saponifies with potassium hydrate to a deep red colour. The original resinous substance, as it separates from the supernatant oily liquid, is but faintly acted on by cold strong nitric acid; but the same acid, when hot, dissolves all but a yellow oil, which separates from the solution, and contains mercury in abundance, as the black precipitate with ammonium sulphide indicates. The first chloroformic solution of the resinous deposit, when evaporated, leaves a reddish-yellow varnish-like residue, which is insoluble in water, but readily saponifies with potassium hydrate to a red solution, whilst a small quantity of mercurous oxide at the same time separates. By the addition of nitric acid to a solution of this soap, a yellow precipitate again occurs.

The separation of this resinous deposit at the very outset of the operation, goes to show how easily the mercurial nitrates are reduced by heat, or, more particularly, by the combined influence of temperature and the reducing property of the organic substances, even in the presence of a large excess of free nitric acid, which seems to indicate, in this instance at least, that the replacement of the hydrogen atom of the acid molecule through the mercurial atom, renders it more unstable in the presence of organic matter, and, therefore a more powerful oxidizer.

The evolution of nitrogen dioxide during the solution of the resinous remnant, insoluble in chloroform would also indicate that the body contained either metallic mercury or the suboxide. This supports the supposition that the mercurous compounds are less stable than the mercuric under similar circumstances. It also affords incontrovertible evidence that in the officinal ointment the smallest portion of the mercury exists as nitrate, and that the greater portion can be present in an indefinite variety of forms. Therefore, the only form in which the metal should be combined is as mercuric nitrate, and the title should designate it accordingly.

Secondly, a portion of the fatty substance which the formula demands cannot be obtained, unless the pharmaceutist prepares it himself, because an officinal neat's-foot oil does not exist in the market, but a rank and disgusting semi-fluid grease, which possesses none of the officinal characteristics. But pure lard can always be readily obtained, and, since it furnishes an excellent ointment, should invariably be used.

Thirdly, the manner of executing the officinal operation is the very embodiment of failure. In this process it is of the utmost necessity to employ vessels of immense proportionate size. It is a point of great importance to retain the temperature of the heated fats within certain limits, which is an exceedingly difficult office to perform after a violent reaction has set in; and even with all these precautions the ointment may overflow or its colour be impaired from reduction of the metal by too great a heat. The production of a good ointment by this process is therefore a matter of chance, and depends upon circumstances that seem rather the good luck of the operator than a well-defined pharmaceutical process.

Now, all these difficulties can be readily overcome by an entire change in the operation itself, regardless of the component elements of the formula. The new process rests upon a scientific basis, whose characteristic feature pervades it in every detail, and which must therefore invariably yield a uniform and definite result. Two parallel operations, separate and distinct, unite their perfect results to one complete and unchangeable whole. The formation of mercuric nitrate is effected with the requisite quantity of nitric acid, and the remainder is completely consumed in the oxidation of the fats. This ensures the ultimate existence of but one compound of mercury in the finished product, and that is, as the title implies, the mercuric nitrate. It likewise admits of the oxidation of the fatty matter to the utmost capacity of all the available nitric acid, so that when the last vestige of this has disappeared the mercurial solution can be mixed with the nearly-cooled product without causing any further reaction. A very decided advantage of this process is that the enormously large vessels can be dispensed with. The nitric acid is added to the melted fat, and the heat continued until brisk ebullition sets in. This occurs mainly in the centre of the mixture, and without frothing. It is, however, of the utmost necessity not to disturb the liquids by stirring. If the reaction becomes too violent, the mixture must be removed a short time from the fire; and if the action slackens too much, it must be replaced. Finally, when all the nitric acid has been decomposed, the temperature can be considerably raised without causing any further effervescence. The boiling then is analogous to the boiling of fatty matters in general.

From the foregoing results the following formula is deduced:—

Take of Mercury................	$1\frac{1}{2}$	troy ounces.
Nitric Acid, sp. gr. 1·42 ..	$3\frac{1}{2}$	,,
Lard (pure)	$16\frac{1}{2}$	,,

Dissolve the mercury in 900 grains of the nitric acid, with the aid of heat, and keep the solution gently warm to prevent crystallization before it is used. Melt the lard in a suitable vessel with a moderate heat; then add the remainder of the nitric acid, and continue the heat, *without* stirring the mixture, as long as moderate effervescence continues; but if this becomes too violent, remove the mixture from the fire, and only replace it when the action slackens too much. Finally, when effervescence ceases and the liquid only boils, even under an increased heat, remove the mixture from the fire altogether; and when it begins to stiffen, add the mercurial solution, and mix thoroughly.—*The Chicago Pharmacist.*

Prevention of "Pitting" in Smallpox.—As a means of preventing the disfigurement attending this disease, a writer in 'Union Médicale' recommends the painting of the pustules, as soon as the eruption appears, with tincture of iodine. The application should be continued for five or six days.

REPORT ON CINCHONA CULTIVATION IN BENGAL.

From C. B. Clarke, Esq., M.A., *Officiating Superintendent, Botanic Garden, and in charge of Cinchona cultivation in Bengal, to the Secretary to the Government of Bengal,—(No.* 188, *dated Botanic Garden, Calcutta, the* 29*th April*, 1870).

Sir,—I beg leave to submit the annual report on the cultivation of Cinchona in Bengal for the year ending 31st March, 1870.

2. The three species of cinchona of which the cultivation has been extended during the year are *C. succirubra*, *C. officinalis*, and *C. calisaya*.

The number of plants of these species in permanent plantations were as under:—

	C. succirubra.	*C. officinalis.*	*C. calisaya.*
March 31, 1869	615,730	312,719	220
March 31, 1870	1,055,100	406,899	4,000
Increase	439,370	94,180	3,780

3. The increase of permanent plantation of *C. succirubra* and *C. calisaya* has been made about Rishap at an elevation of 2500 feet; the increase of *C. officinalis* at Rungbee at an elevation of about 4500 feet.

4. The average growth for the year of the ten measured plants of *C. succirubra* planted in March, 1867, at Rishap, has been 51 inches, which fairly represents the satisfactory general growth of the *C. succirubra* plantations.

5. The average growth for the year of the ten measured plants of *C. officinalis* planted in October, 1864, at Rungbee, has been 12 inches, which fairly represents the unsatisfactory general growth of the *C. officinalis* plantations.

6. The average growth for the year of the ten measured plants of *C. calisaya* planted in June, 1867, at Rishap, has been 52 inches, which represents the average growth of all the plants in the plantation catalogued as *C. calisaya*. But several important varieties are included under the name *C. calisaya*, and the tree variety raised by seed in February, 1867, and planted out in June, 1867, has attained a height of 12 feet in October, 1869, and a tree of this age, lately cut down, has produced two pounds of dry bark.

7. As fully explained by Dr. T. Anderson in his annual cinchona report in Bengal for the year ending 31st March, 1868, the exceeding steepness of the hills, combined with the large rainfall, prevents any tilth on these cinchona plantations. The grass and low jungle having been cut close, the young cinchona plants are planted out in the permanent plantations. The weeds having been merely headed down, not eradicated, grow with great strength in a moist and warm climate, and continual scouring of the young plantations is necessary. This is the chief expense under thissystemofcultivation.

8. *C. succirubra* and *C. calisaya* (tree variety) grow so freely, that by the third year the young trees in the plantations are all locked; they then crush the jungle beneath them, and can take care of themselves, and little further expense upon them is called for.

9. But *C. officinalis* shows no inclination to become a tree at these plantations; it remains a shrub with very scanty foliage, and even on the plantations which are five years old, there continues the same expenditure in scouring.

10. *C. succirubra* and *C. calisaya* are planted about 1200 to the acre; *C. officinalis* about 4000 to the acre.

11. In the fifth year of growth in permanent plantation an acre of *C. officinalis* carries less than one-fourth the bark carried by an acre of *C. succirubra*, and costs more than four times as much annual expenditure. Moreover, the *C. officinalis* then appears disinclined to grow much larger, whereas *C. succirubra* will clearly grow into a considerable tree.

12. I calculate that at present it has not been discovered how to grow *C. officinalis* to economic profit at Rungbee. I therefore stopped its extension in September last, though I was aware of the high quality of the grey bark. The present quantity is large for an experiment; and, as an experiment, a few acres of *C. officinalis* were planted in September last at a somewhat higher level (5000 feet) than the main plantation. Also, in all the *C. officinalis* plantations below the level of 4000 feet (above which level *C. succirubra* does not thrive), *C. succirubra* has been planted between the ranks of *C. officinalis*, and will, doubtless, soon overgrow it.

13. The propagation and extension of *C. calisaya* has been pushed as fast as possible. There is no difficulty in multiplying *C. succirubra* and *C. officinalis* by cuttings, but at Rishap there is found the greatest difficulty and uncertainty in multiplying *C. calisaya* by cuttings. Herr von Gorkom, the Director of the Dutch Government cinchona cultivation in Java, informs me that there the same difficulty with *C. calisaya* is found; but, on the other hand, Mr. M'Ivor, in the drier climate of the Nilgherries, says cuttings strike with perfect success.

14. Herr von Gorkom has sent me on several occasions most valuable packets of *C. calisaya* seed, which germinated excellently; but if it could be discovered how to grow *C. calisaya* by cuttings, I should greatly prefer that method, as by it I am sure of getting exactly the variety which I wish to propagate. Mr. M'Ivor is of opinion, that not merely do the varieties cross freely, but that many hybrids are formed from different species of cinchona.

15. The most valuable bark known in the European market is the *C. calisaya* bark; this species grows admirably at Rishap, and, during the past year, propagation has been almost entirely confined to it. In growing for profit, I believe it will ultimately be found advisable to grow one or two species only on these plantations; and that it is best to discard a species at once which is clearly inferior with us to *C. calisaya* and *C. succirubra*.

16. I have lately brought from the Nilgherries two new kinds of cinchona, one provisionally named *C. mirabilis*, of Mr. Broughton, the other *C. pitayo*. In *C. mirabilis* the bark contains the astonishing quantity of 13½ per cent. of quinine alkaloid, and more than 9 per cent. of crystallizable quinine. *C. pitayo* is a rich bark from Peru, a very high-level species, said to be found growing through the snow.

17. During the year both *C. succirubra* and *C. officinalis* ripened seeds; 5¾ ounces of the former and 5¼ ounces of the latter were distributed. One ounce of seed will raise nearly 50,000 plants.

18. There were distributed from Rungbee during the past financial year cinchona plants as under:—

	C. succirubra.	*C. calisaya.*	*C. officinalis.*
Mr. Werniche, Kursiong ..	2500	50	..
Dr. Jameson, Saharunpore .	1500	260	500
Mr. Robson, Tukvar	..	200	..
Col. Strutt, Kangra Valley .	..	12	..
Total	4000	522	500

19. The amount of propagation having been greatly reduced, a considerable number of the old frames and glass were sold. The receipts for the past year of the cinchona plantation paid into the Darjeeling treasury were as under:—

	Rs.	As.	P.
Rent from land let	1130	0	0
Price of a wardian case	10	0	0
Sale of cinchona plants	156	4	0
Sale of old glass	187	8	0
Total	1483	12	0

20. The total expenditure for the year on the Sikhim cinchona cultivation was Rs. 50,224, being Rs. 18,642 less than the estimate, and Rs. 18,040 less than that of the preceding year.

21. The *C. succirubra* trees stand 6 feet by 6 in the plantations, and, as an experiment in January last, a small portion of the denser plantation was thinned by cutting down three trees out of every four. This was found to produce 300 lbs. of dried bark, worth about Rs. 250 per acre.

22. At the same time a considerable portion of the more advanced trees were pruned by the removal of the lower branches. There was stored from the thinnings and prunings in all 2400 lbs. of dried bark.

23. The only private plantation in Sikhim, which (so far as I know) is extending cinchona planting on a considerable scale, is that of Mr. Lloyd and Colonel Angus, known as the Darjeeling Cinchona Association, and which occupies the north side of the Rungbee valley. This Association now has about 500 acres of permanent plantation of *C. succirubra*, and has cut a considerable quantity of three-year-old bark during the late cold weather, and sold it in the London market.

24. The Government cinchona plantation at Nunklow, in the Khasi Hills, was formed for the supply of cinchona plants to the planters in Assam and Cachar. Seed is now easily transmitted, and I believe the discontinuance of the plantation at Nunklow has been decided upon by Government.

Number and distribution of Cinchona plants in the Government plantations near Darjeeling on the 31*st March,* 1870.

Names of species of cinchona.	Number in permanent plantations.	Number of stock plants for propagation.	Number of seedlings or rooted cuttings in nursery beds for permanent plantations.	Number of rooted plants in cutting beds.	Number of cuttings made during the month.	Total number of plants, cuttings, and seedlings.
C. succirubra	1,055,100	20,000	164,615	None	None	1,239,715
C. culisaya ...	4,000	10,000	8,758	32,274	2,000	57,032
C. micrantha	29,667	None	None	None	None	29,667
C. officinalis, and varieties.	406,899	10,000	205,952	307,853	Ditto	930,704
C. pahudiana	5,092	None	None	None	Ditto	5,092
Total	1,500,758	40,000	379,325	340,127	2,000	2,262,210

C. B. Clarke,
Officiating Superintendent, Botanic Garden, and in charge of cinchona cultivation in Bengal.

Conversion of Angelic into Valerianic Acid.—According to Jaffe, angelic acid is not converted into valerianic acid by means of hydriodic acid. According to Ascher, a temperature of 180° to 200° C. is needed for this transformation, which does not take place at low temperatures. By heating together angelic acid, red phosphorus, and hydriodic acid to 180° to 200° C., for the space of eight hours, a complete transformation into valerianic acid was effected. As our readers will know, angelic acid differs from valerianic acid by two equivalents of hydrogen, which, according to the foregoing account, it acquires from the hydriodic acid.

Determination of the Value of Cinchona Bark.—The methods of determining the value of cinchona bark may be divided into two classes, viz. those which give the total amount of alkaloids all together, without distinguishing between them, and those which give the amount of pure quinine. Those belonging to the former class may, in fact, be regarded as abandoned, because they are calculated to assign the same value to bark containing only modified and uncrystallizable alkaloids as to bark containing a corresponding amount of pure quinine.

The methods most practised for determining pure quinine are based upon the use of ether or chloroform for purifying the quinine to be determined, or, in other words, they represent, as quinine, all the alkaloid soluble in ether and chloroform. It may be stated, without much need of examination, that these methods are calculated to lead to serious errors. For instance, is it not evident that by this use of ether, bark containing only aricine, may be regarded as of good quality, inasmuch as that alkaloid is soluble in ether? Moreover, the inadequacy of these methods may be demonstrated in a manner entirely different. All manufacturers of quinine have been led to abandon them on account of the loss experienced in many instances to a large extent. They have purchased as rich, samples of bark that yielded only small quantities of quinine. At the present time manufacturers have adopted the plan of determining the value of bark by means of a miniature operation, conducted in the same way as the manufacture on a large scale. This, it must be admitted, is the most judicious method, and probably the only one that can be depended on.

Though the method suggested by M. Carles is not open to the objections raised against those formerly in use, we do not consider that it should be preferred to that just mentioned for the purposes of manufacturers. At the same time it may be useful for pharmacists, since it is more accurate than others.

His method consists in determining quinine in the state of crystallized sulphate, after its separation from other alkaloids whose sulphates are more soluble. Moreover, by the use of chloroform as a solvent, and the separation of resins by means of dilute sulphuric acid, it is possible to obtain sulphate of quinine in a very satisfactory state of purity and whiteness.

The chief disadvantage of the method consists in relying too much on a slight artifice, by means of which the soluble sulphate of quinine is converted into crystals by washing with ammonia. This is an operation requiring some dexterity in manipulation. It is also to be regretted that M. Carles has not determined the solubility of the sulphate in the mother liquors obtained in the operation, for since they contain sulphates of other alkaloids, they may also contain some quinine.*

Fatal Case of Poisoning of a Man and a Horse.—In the August number of the 'Journal of Botany' is a short notice of a rapidly fatal case of poisoning by *Œnanthe crocata*. This is an umbelliferous plant of common occurrence in the south of England, and has frequently been eaten by mistake for other allied plants with fatal effects. In the present instance, it was mistaken for "wild parsnip" by a carter, who thought himself afflicted with "scurvy." The man ate some of the root whilst at work, and about an hour after he fell back foaming at the mouth, and black in the face. He died before the arrival of medical aid about half an hour after the first effects, one hour and a half after the ingestion of the poison. On *post-mortem* examination, about "half a small cupful" of the masticated root was found in the stomach. The horse to which the man had given some of the root lived half an hour longer than the man. *Œnanthe crocata* belongs to that group of narcotico-acrid poisons comprising the *Solanaceæ*, and characterized by producing convulsions with delirium. Death may even occur more rapidly than in the above case. It is of interest to note, as the point is one which has been several times observed, that the juice of the plant was yellow in colour. It has been said that the state of the plant with a colourless juice is less virulent in its nature.

---

* Extract from the Report of a Commission consisting of MM. Gobley, Roussin, and Jungfleisch.

The Pharmaceutical Journal.

SATURDAY, AUGUST 6, 1870.

THE POISON REGULATIONS.

In drawing attention last week to the remarks of the 'Pall Mall Gazette' anent the privileges and duties of the Pharmaceutical Society, we were not influenced by any idea of an unkind spirit prompting our contemporary; indeed, we thought he desired rather to utter a kindly warning, more pleasantly expressed than other observations on the same subjects which we have read within the last three months: but straws in the air indicate the course of the wind, and it is sometimes well to mark their direction.

In days gone by, chemists and druggists were too insignificant a class to attract attention from other members of society; invested with privileges, they became worthy of observation. Privileges are never granted without duties being imposed on the recipients, and their fulfilment at once furnishes an object for criticism.

When we are reminded that "all monopolies are to be regarded with distrust, and watched with anxiety in the public interest," that our Society "has public duties and private interests to consult, and the two may not always concur," we cannot fail to recognize the fact that the eye of the press—which we may call one of the great lenses of the public—is upon us.

We know that the public safety can in no way be better promoted than by aiding the education and enforcing the examination of men to whom the dispensing of dangerous medicines is entrusted. The Pharmaceutical Society enunciated that as a principle thirty years ago, and has ever since faithfully, earnestly, and at great cost, laboured to carry it out. When Poison Bills were brought before Parliament based on other foundations than education, every effort was made, and made successfully, to defeat them; but when that principle was adopted, the Society joined heart and hand to promote it.

Now it cannot be doubted that the public, scarcely conversant with the intricacies of the subject, see greater security in what they may perhaps call the "*material guarantee*" of "*Poison regulations.*" We on the other hand regard them as secondary, but still important, means of safety, so important, indeed, that scarcely an opponent of the code proposed by the Council for the consideration of the Annual Meeting could deny that in his own establishment some such precautions were in use. The opposition was not grounded on objection to the regulations themselves, but simply on a dislike to have any system made compulsory. Those who came to oppose forgot apparently that there are, and will be until another generation has succeeded the present, men in business as Chemists and Druggists, whose qualifications have not been proved by examination, and in disinclination to accept for themselves any *possibility* of inconvenience, they gave the outer world reason to suspect that the latter half of the twofold position described by the 'Pall Mall Gazette' had more weight with them than the former. Such an inference was rather strengthened by the assertion of some that it was useless to ordain regulations for chemists if the same rules were not to be compulsory on apothecaries.

We certainly cannot recur to the proceedings of that stormy day with any satisfaction. A discussion quite foreign to the legitimate business of the Pharmaceutical Society was forced on the meeting, and, as we believe, materially influenced the whole course of events.

We do not intend now to enter on the merits of the proposed regulations; ample opportunity will be found for that, between this and next May, to which time the matter stands postponed, but we desire rather to remind our readers that the Pharmaceutical Society is a public body; that it is a part of the State Government, and if it fall short of its duty, a fair question for discussion will arise as to how far it has fulfilled that part of the contract to which it is bound by the Pharmacy Acts of 1852 and 1868. These are points which should be pondered on quietly at home; with pots, bottles, and general shop arrangements at hand, to show what would be the comparative merits or demerits of the proposed system, or what other system could be suggested as an additional alternative to the three already set forth, and for such reasons we invited those who had propositions to offer, to communicate them to us for publication in this Journal and for criticism by others.

THE PETROLEUM ACT.

Our readers will be glad to learn that a Bill to amend the Petroleum Act is now before the House of Lords, and that it contains provisions for exempting the articles sold under the name of "Benzine Collas," and such fancy titles, secured in small bottles and labelled with words of caution.

This is the exemption which was promised by the Home Secretary when the Pharmaceutical Society, accompanied by Mr. Thomas, represented to him the hardship and annoyance to which retailers were exposed.

It was feared that the Government had further postponed the question.

The 'Times' states, in reference to this Bill, that—

"According to the view of the leading persons engaged in the business, its clauses are such as would completely interrupt this important branch of commerce; and strong representations have therefore been made to some of the principal mercantile members of the House of Commons to prevent its being passed without full consideration when it shall come down to that House."

In reporting the accident that occurred at Bradford, of which an account is given in another part of this Journal, the 'Pall Mall Gazette' remarks that "the substance known as benzoline seems to be little less dangerous to handle than paraffin."

It is almost incredible to meet with such ignorance as that displayed by this remark, and it serves in some measure to account for the accidents that happen with the dangerous volatile spirit called benzoline. The case of Mr. Taylor seems to suggest the need for an alteration in the Petroleum Bill now before the House of Lords, and that, in the label to be attached to bottles containing volatile spirit, "Great care must be taken *in bringing* any light near to the contents," etc., the words in italics should be replaced by "not to bring."

The Juries Bill, as amended in Committee, contains the following clause:—

"13. If any overseer, without reasonable excuse to be allowed by the justice or justices having cognizance of the case, insert in the list of persons qualified to serve as jurors prepared by him the name of any person whose name ought not to have been inserted therein, or omit therefrom the name of any person whose name ought not to have been omitted, he shall, on summary conviction, be liable to a penalty for each offence not exceeding forty shillings."

Transactions of the Pharmaceutical Society.

EXAMINATION IN LONDON.

July 29th, 1870.

Present—Messrs. Allchin, Bird, Edwards, Gale, Garle, Haselden, Ince, and Southall.

Thirty-one candidates were examined; the following passed, and were duly registered:—

MODIFIED (as Chemists and Druggists).

Baynes, James, junior . . . . Brighton.
Burn, Thomas . . . . Hartlepool.
Campbell, John. . . . . Bristol.
Dodds, John Henderson . . . . . . Walsall.
Elkington, Charles John. . . . . . Birmingham.
Grindell, John . . . . London.
Hartley, Stephen . . . . Ulverstone.
Holmes, Frederick George . . . . Brill.
Jarvis, John . . . . Pau.
Jones, George Coverdale. . . . . . Bournemouth.
King, Abraham . . . . Bristol.
Metcalfe, Alfred . . . . East Retford.
Oldham, Gervase . . . . Stockport.
Presley, Edward . . . . Bristol.
Siminson, Henry . . . . Kidderminster.
Simmons, Alfred . . . . Redditch.
Thyer, James . . . . Leamington.
Veitch, William, junior . . . . . . Shildon.
Wheeler, Frederick . . . . Guildford.
Wright, William John . . . . . . Tunbridge Wells.
Young, Jonathan . . . . Cambridge.

MINOR (as a Chemist and Druggist).

Banks, Benjamin . . . . Folkestone.

FIRST, OR PRELIMINARY EXAMINATION.

The Certificates of Examination of the undermentioned were accepted in lieu of the Preliminary Examination:—

Amoore, Lewis Perigo. . . . . Hastings.
Atkinson, John George . . . . . . Horncastle.

Provincial Transactions.

EXETER BRANCH PHARMACEUTICAL SOCIETY.

A Special Meeting of the members of the above Society was held on Friday, the 29th July, on the occasion of the receipt of the gift of books presented to the Society at the British Pharmaceutical Conference, held in Exeter last year, by T. H. Hills, Esq., and termed in memory of the late Jacob Bell, the "Bell and Hills' Library Fund."

The following is the list of works received:—5 vols. of Watts' 'Dictionary of Chemistry;' 1 vol. of Fownes' 'Chemistry;' 1 vol. of Attfield's 'Chemistry;' 1 vol. of Hooker's 'British Flora;' 1 vol. of Royle's 'Materia Medica;' their handsome appearance, and the very appropriate design on the cover of each, viz. "Bell and Hills'," etc., elicited expressions of great satisfaction.

After allusions to the generous gift, and to the great advantages to be derived from the addition to the existing library of such works for the younger students, the class which it was especially the intention of the donor to benefit, it was resolved and carried unanimously, "That the thanks of the Society be given for the above valuable works, and that the Secretary be requested to communicate this resolution to T. H. Hills, Esq.

Parliamentary and Law Proceedings.

A BILL INTITULED AN ACT TO AMEND THE PETROLEUM ACTS 1862 AND 1868.

33 & 34 Vict.

Whereas it is expedient to amend the law relating to the sale and keeping of petroleum and other substances of the like nature:

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

1. This Act may be cited as the Petroleum Act, 1870.

2. This Act shall be construed as one with the Petroleum Acts, 1862, 1868, and those Acts and this Act may be cited together as the Petroleum Acts, 1862 to 1870.

3. Section 4 of the Petroleum Act, 1868, shall not apply to petroleum kept by a dealer for sale by retail, if such dealer comply with the following conditions, namely:

(1.) That the petroleum is kept in separate glass, earthenware, or metal bottles, each of which contains not more than half a pint, and is securely corked; and

(2.) That the aggregate amount of petroleum kept by the dealer, supposing the whole contents of the bottles to be in bulk, does not exceed three gallons; and

(3.) That each bottle has attached thereto a label in legible characters stating as follows: "Great care must be taken in bringing any light near to the contents of this vessel, as they give off an inflammable vapour at a temperature of less than one hundred degrees of Fahrenheit's thermometer."

Every dealer who acts in contravention of any of the above conditions shall be liable to the forfeiture and penalty prescribed by section 4 of the Petroleum Act, 1868.

4. Any officer authorized by the local authority may purchase petroleum from any dealer in it, or may, on producing a copy of his appointment, purporting to be certified by the clerk or some member of the local authority, or producing some other sufficient authority, require the dealer to show him all or any of the vessels in which petroleum in his possession is stored, and the place

of the storage thereof, and to give him samples of such petroleum on payment of the value of such samples.

When the officer has by either of the means aforesaid taken samples of petroleum, he may declare in writing to the dealer that he is about to test the same, or cause the same to be tested, in manner provided by this Act, and it shall be lawful for him to test the same or cause the same to be tested, at any convenient place at such reasonable time as he may appoint, and the dealer or any person appointed by him may be present at the testing; and if it appear to the officer or other person so testing that the petroleum from which such samples have been taken has been kept, offered, or exposed for sale contrary to the Petroleum Acts, 1862 to 1870, such officer or other person may certify such fact, and the certificate so given shall be receivable as evidence in any proceedings that may be taken against a dealer in petroleum in pursuance of those Acts; but it shall be lawful for a dealer proceeded against to give evidence to show that such certificate is incorrect, and thereupon the court before which any such proceedings may be taken may appoint some person skilled in testing petroleum to examine the samples to which such certificate relates, and to declare whether such certificate is correct or incorrect.

Any expenses incurred in testing any petroleum of such dealer in pursuance of this section shall, if such dealer be convicted of keeping, selling, or exposing for sale petroleum in contravention of the Petroleum Acts, 1862 to 1870, be deemed to be a portion of the costs of the proceedings against him, and shall be paid by him accordingly. In any other event such expenses shall be paid by the local authority out of any funds for the time being in their hands.

5. The temperature at which petroleum gives off an inflammable vapour shall for the purposes of the Petroleum Acts, 1862 to 1870, be tested in manner set forth in the schedule to this Act.

6. Any petroleum sold or exposed for sale in contravention of section 5 of the Petroleum Act, 1868, shall be liable to be seized, and upon conviction of the person selling or exposing for sale the same to be forfeited.

7. Sections 6 and 8 of the Petroleum Act, 1868, and the schedule to that Act, are hereby repealed.

Schedule.

Directions for Applying the Flashing Test to Samples of Petroleum Oil.

The cup which is to hold the oil shall be of thin sheet iron or of metal blackened on its inner surface; it shall be two inches deep and two inches wide at the opening, tapering slightly towards the bottom; it shall have a flat rim projecting from the edge of the cup, by which it shall be supported in a metallic vessel four inches and a half deep and four inches and a half in diameter; it shall also have a wire stretched across the opening, which wire shall be so fixed to the edge of the cup that the upper side of the wire shall be a quarter of an inch above the upper side of a circular wire, which shall be fastened round the inside of the cup a quarter of an inch below its upper edge. The thermometer to be used shall have a round bulb about half an inch in diameter, and shall be graduated upon the scale of Fahrenheit, every ten degrees occupying not less than half an inch upon the scale.

When the instrument is to be used, the petroleum to be tested shall be poured into the cup till the liquid rises just to the upper side of the circular wire. The outer vessel shall be filled to within an inch of its edge with water, and a small flame shall be applied to the bottom of the outer vessel. When the temperature of the water has risen to 80° the cup which contains the oil to be tested shall be placed in the outer vessel, and the thermometer shall be inserted into the oil, so that the bottom of the bulb shall be immersed about one inch and a half beneath the surface. A covered screen blackened on the inside, and provided with a hole in the cover for the passage of the stem of the thermometer, shall be placed over the apparatus, and shall be of such dimensions as to surround it about two-thirds, and to reach about eight inches above the level of the vessels. The temperature shall be raised gradually, so that it shall require about five minutes to raise the oil from 80° to 95°.

When heat has been applied to the water until the thermometer has risen to about 90° Fahrenheit, a very small flame, such as that from a piece of burning twine, shall be quickly passed across the surface of the oil on a level with the wire. If no pale blue flicker or flash is produced, the application of the flame is to be repeated for every rise of two or three degrees in the thermometer. When the flashing-point has been noted, the test shall be repeated with a fresh sample of the oil, using water at the temperature of 80° as before, withdrawing the source of heat from the outer vessel when the temperature approaches that noted in the first experiment, and applying the flame test at every rise of two degrees in the thermometer.

N.B.—In performing the test, the operator must be careful not to produce any current of air which would remove the vapour from the surface of the oil, either by breathing upon the surface or by any sudden movement.

SULPHUR IN COAL-GAS.

In reference to the determination of a proper maximum for the sulphur impurity in gas, the referees appointed under the Gas Acts of 1868 and 1869 have examined the various methods hitherto proposed for purifying gas from sulphur, as well as those at present in use. The practical adoption of many of these methods is hindered, either because they inordinately diminish the illuminating power of gas, or else because the beneficial effect which they show when tried experimentally is not realized when they are applied on the large scale required in the manufacture of gas.

The present methods of sulphur-purification are so defective, that even doubling their extent in most cases produces no appreciable improvement in the purity of the gas. For example, the production of gas in summer is only one-half what it is in winter, while the purifying surface remains the same; nevertheless the referees find that while thus virtually doubling the extent of purifying material there is no appreciable effect in reducing the amount of sulphur in the gas of any of the Companies. This fact, as regards the three Companies included under the Act of 1868, is clearly shown by the daily testings now in force, which give the following averages of the amount of sulphur at mid-winter and at midsummer.

	CHARTERED.				CITY.		CENTRAL.
	Arundel Street.		Leadenhall Street.	Gray's Inn.	Cannon Street.		Friendly Place.
	Cannel.	Common.	Common.	Common.	Cannel.	Common.	Common.
December, 1869 . .	21·8	27·4	22·8	24·2	9·4	20·4	14·7
June, 1870	22·3	30·3	20·4	25·2	13·4	18·8	13·3

The referees have endeavoured to determine the relative efficacy of each of the separate stages of purification, and of each of the various processes employed by the Companies, as regards the elimination of this impurity. The results already obtained are acknowledged on all hands to be of a most unexpected nature. First, as regards the "scrubbers." It has been currently believed of late that a most efficient means of purifying the gas from sulphur was to be obtained by "scrubbing," or washing with ammoniacal liquor. Indeed, some authorities have publicly recommended that many thousand gallons of the liquor should be pumped into the scrubbers per hour. But the results of the referees' experiments, as yet obtained, show that, whether or not this opinion be theoretically correct, it is totally wrong as regards the practical efforts produced in the scrubbers in general use.*

The experiments were made with the various kinds of scrubbers employed by the several Companies. These scrubbers differ, to some extent, from one another in the arrangement of the scrubbing materials, especially as regards the nature and the distribution of the liquid employed. They also differ as regards the substances with which the scrubbers are filled: in most cases coke, or fragments of brick, being used, while in Mr. Livesey's scrubber (from which the best results were obtained) the substance employed is a network of thin boards of wood, through which, as in the other forms of the scrubber, water or ammoniacal liquor trickles down slowly through the ascending current of the gas. The experiments were conducted on a uniform system, as follows:—Just before the gas entered the scrubbers a small portion of it was drawn off, and made to pass through a box containing oxide of iron, so as wholly to remove the sulphuretted hydrogen; thereafter it was tested for sulphur. In like manner, as the gas emerged from the scrubbers a portion of it was similarly drawn off, and, after being purified from sulphuretted hydrogen, was tested for sulphur. The summary in the second column of this page will suffice for the present to show the results of these experiments so far as they have gone.

Summary of the Results of Experiments for ascertaining the effect of Scrubbers upon the Quantity of Sulphur-compounds in Gas.

	Average of	Amount of Sulphur at Inlet of Scrubbers.	Amount of Sulphur at Outlet.	Increase or Decrease at Outlet.
Great Central Company .	29 expts.	23·55	28·63	+5·06
Imperial Gas Co. (Fulham)	26 ,,	21·18	20·83	— ·35
Ditto (St. Pancras)	4 ,,	24·7	24·8	+ ·1
Ditto (Shoreditch)	3 ,,	26·35	25·30	—1·5
City of London Company .	3 ,,	22·86	25·41	+2·55
South Metropolitan Co. .	5 ,,	33·03	28·98	—4·05
Chartered Co. (Westmin.)	11 ,,	24·62	26·07	+1·45

Here it appears that only in one case did the scrubbers materially reduce the amount of "sulphur" (*i. e.* sulphur-compounds other than sulphuretted hydrogen), and in the majority of instances *more* sulphur was found in the gas when it emerged from the scrubbers than before it entered them! These facts were so unexpected and they are so contradictory of the long-established opinions and practice of gas-engineers,* that one of the gas-engineers tore up the results of his testings (which accordingly do not appear in the above table), thinking that he would only stultify himself by sending in returns which, he fancied, must be due to some mistake on his part, little expecting that they would be amply corroborated by the facts obtained by the other gas-engineers engaged in the inquiry.

There is no question as to the power of oxide of iron and lime to withdraw a large proportion of sulphur from gas under certain circumstances; but it is evident from the facts already obtained in the referees' experiments, that an adequate knowledge of how to apply these purifying materials in gasworks, so as to produce satisfactory results, has yet to be acquired.

As shown by the reports of the testings made by Dr. Letheby at the Corporation's testing-place, previous to the Act of 1868,—and thereafter from the daily testings in the five testing-stations established in conformity with the instructions of the referees under that Act,—the amount of sulphur in the gas of the Chartered, the Central, and the City companies has averaged as follows:—

Dr. Letheby's Occasional Testings—1864–68.

Two explanatory remarks are necessary in connection with these statistics. Firstly, as regards the improvement that has taken place of late years in the purity of the gas of the Central Company. In the earlier years of the above series, the gas of this Company contained more sulphur than that of any of the others; and the improvement which has subsequently taken place is owing to the adoption of lime in the purifiers, instead of the oxide of iron employed by the other Companies. The works of the Central Company at Bow are in a poor locality, where there are numerous chemical and other works, which produce greater nuisances than that which arises from the use of lime in gasworks. But in the works of all the other gas companies, the use of lime as a purifier is inadmissible, owing to the nuisance which it occasions to the neighbourhood when taken out of the purifiers and exposed to the atmosphere. The works of the Imperial Company at Fulham are in a locality more thinly peopled

* The doubt suggested here by the referees involves a monstrous inconsistency, though the phraseology employed is sufficiently familiar. An opinion that is "theoretically correct" cannot be opposed to "practical experience" if the theory referred to be worth anything; but it does happen that "practical men" fail to comprehend, either the meaning of a theory or its applicability to the business they are concerned with.—Ed. Ph. J.

* The title of gas engineers to have opinions on the subject of gas-purification may fairly be said to rest solely on their technical experience in the production of gas, without being at all a result of their familiarity with, or even cognizance of the chemistry of that art, which is indeed very much in obscurity.—Ed. Ph. J.

than that around the gasworks at Bow; but the inhabitants belong to a higher and wealthier class; and when the Imperial Company, two years ago, attempted to adopt lime as a purifier in their Fulham works, the complaints made and the indictments threatened compelled the company at once to fall back upon the ordinary purifying process by oxide of iron.

The other remark necessary for a right understanding of the above statistics is, that in 1867 an improvement was made in the Letheby sulphur-test, which was used in all the above recorded testings; consequently, at any time subsequent to that improvement, the testings would show a greater amount of sulphur, even when the gas remained of the same purity as before.

"CINCHO-QUININE."

BY W. T. WENZELL, CHEMIST.

(*Read before the California Pharmaceutical Society, March 14th*, 1870.)

The article sold under the above name is stated to represent all of the alkaloids naturally contained in Calisaya bark. It is also asserted that all of the cinchona alkaloids possess equal febrifuge and tonic properties; and that quinia only acquired the rank of superiority as a febrifuge by reason of priority of discovery,—a statement which is also incorrect, inasmuch as cinchona was discovered as early as 1810 by Gomez, whereas quinia was discovered ten years later by Pelletier and Caventou. The "cincho-quinine" is said to be composed of bark alkaloids, as follows:—1. Quinia. 2. Cinchonia. 3. Quinidia. 4. Cinchonidia. 5. Other alkaloidal principles present in the bark.

The claims advanced as to its superiority over the sulphate of quinia are, namely, that "cincho-quinine" contains the whole of the active febrifuge and tonic principles of Calisaya bark; that it exerts the full effects of sulphate of quinia in the same dose, without causing cerebral disturbances; that it is nearly tasteless, and less costly than sulphate of quinia. The dose of the preparation is left to the discretion of the physician, with the direction that it may be administered in doses varying from five to thirty grains.

The apparent insolubility of the "cincho-quinine," its slight bitter taste and large medicinal dose (30 grs.), have led me to investigate the true nature of the article presented. "Cincho-quinine" is put up in imitation of sulphate of quinia in ounce bottles. It appears in the form of white friable scales, which are almost tasteless, only a slight bitterness being perceptible. When placed upon reddened litmus paper, and a drop of alcohol added, the blue colour of the litmus was promptly restored. It proved combustible without residue. When dissolved in water, with the intervention of sulphuric acid, the solution tasted analogous to one of sulphate of cinchonia, and the solution, when strongly acidulated with the acid, possessed in very slight degree only the optical phenomena of fluorescence and epipolism. Dr. Bill's test of ferrocyanide of potassium gave the known reaction for cinchonia. "Cincho-quinine" was nearly insoluble in ether. Twenty grains of the preparation were dissolved in water with a sufficient quantity of sulphuric acid, and the solution subjected to Liebig's ether test, which dissolves quinia, quinicia, and cinchonicia, also portions of quinidia and cinchonidia if a large excess of ether be employed. The etherial solution thus obtained by successive washings with ether, left on evaporation and drying a solid residue, weighing about half a grain, possessing alkaloidal properties. This residue, when dissolved in dilute sulphuric acid and water, and treated with Brande's chlorine and ammonia test, will indicate by its green coloration the presence of quinia, quinidia, and quinicia. The test responded in this instance affirmatively. In order to determine which of the alkaloids produced the coloration, one portion of the solution was tested for quinidia by Van Heijningen's test of oxalate of ammonia, and another portion was tested for quinidia by Dr. Vry's test of iodide of potassium, but both gave negative results. Therefore the alkaloid detected by Brande's test is quinicia, which was confirmed by the application of Herapath's optical and chemical tests of the iodo-sulphates of the cinchona alkaloids. One grain of the mixed alkaloids obtained by Liebig's test from "cincho-quinine" by thorough exhaustion with ether, was dissolved in a fluid drachm of water sufficiently acidulated with sulphuric acid. The solution was then mixed with an equal bulk of alcohol, the mixture warmed to about 100° F., and treated successively with tincture of iodine. The several (7) precipitates which appeared on cooling were amorphous resinous substances soluble in alcohol, and did not exhibit in the least degree crystalline structures. The precipitates first obtained were reddish in appearance, analogous to the salt of iodo-sulphate of quinicia; the last precipitates possessed the purplish tint belonging to the iodo-sulphate of cinchonicia. The absence of all crystalline characteristics of iodo-sulphate salts thus obtained from the alkaloids extracted by ether from "cincho-quinine" point conclusively to the absence of quinia, quinidia, and cinchonidia in the sample under examination; and we can safely assert that "cincho-quinine" is in reality only cinchonia containing about 2 per cent. of quinicia and cinchonicia.

"Cincho-quinine," although having the advantage of being nearly tasteless, does not contain quinia, quinidia, and cinchonidia, and therefore does not represent the whole of the active principles of the bark.

It cannot exert the full effects of sulphate of quinia in the same dose, inasmuch as the stated dose of "cincho-quinine" is from 5 to 30 grains.

Although "cincho-quinine" appears to cost less than sulphate of quinia, it does not follow that commercial "cinchonia," sold at four times its value, is a desirable substitute for quinine in an economical point of view.

And, lastly, one very important principle should by no means be lost sight of, namely, that a physician should always know what he is prescribing, and therefore the substitution of a remedy of less efficiency and uncertain medicinal value is altogether unwarrantable and often hazardous.—*Pacific Med. and Surg. Journ., April*, 1870.

SIMPLE APPARATUS FOR RAPID EVAPORIZATION AT LIMITED HEAT, UNDER REDUCED PRESSURE, WITHOUT THE USE OF A PUMP.

BY A. B. PRESCOTT,

ASSISTANT PROFESSOR OF CHEMISTRY, ETC., UNIVERSITY OF MICHIGAN, U.S.

The pump is not always at hand; its use is forbidden for transmission of corrosive vapours; and, moreover, the removal of liquids, in form of vapour, against the weight of the air by muscular power is liable to "exhaust" the operator more effectively than it does the material. I desire to ask attention to some uses of ordinary distilling apparatus for the production and maintenance of approximate vacuum over liquids during their vaporization, in cases where the heat of 120° to 150° F. may be applied.

It is necessary that the distilling apparatus be made capable of air-tight closure, and that the air be removed from it to begin with. Then the degree of exhaustion in the apparatus is in direct ratio to the rapidity of condensation of the vapour produced. And the rapidity of condensation is only limited by the degree and extent of refrigeration employed, with a given extent of evaporating surface at a stated temperature. The air in the apparatus, to begin with, may be expelled through a suitable aperture by steam, which may be generated in the "receiver" of the apparatus or in an attachment thereto.

Take two round-bottomed glass flasks, the one having a capacity four to eight times greater than the other. Adjust the smaller upon a water-bath, the larger at 10 to 15 inches distance from the other, over a sink or large basin, and connect the two with glass tubing and perforated caoutchouc stoppers, so that the connecting-tube shall incline slightly downward from its bend close to the stopper of the small flask. The stopper of the small flask is also to have a second perforation, in which is fitted a straight glass tube, 2 or 3 inches long, its lower end placed even with the lower end of the stopper. The upper end of this tube is very slightly drawn out for a quarter of an inch, and snugly fitted with 1½ inch of firm rubber tubing, the upper half inch of which is closed with a piece of glass rod of same diameter as the body of the tube.

Now put an ounce or two of water in the large flask, and the material to be evaporated in the small flask; close the stoppers perfectly by turning the flasks under them, and leave open the straight tube. Apply, by the water-bath, the limited degree of heat until it is imparted to the contents of the small flask; then move a lamp under the large flask until the water in it has boiled briskly, and the steam therefrom has escaped continuously from the straight tube for some minutes. Now close the straight tube with its caoutchouc cap, at the same time removing the lamp from the large flask. When the latter has cooled somewhat, wrap it smoothly with linen netting or gauze, and lead upon it a minute stream of cold water, controlling the same as required. The liquid in the small flask boils briskly (if aqueous, boiling at 120° or 150° F.), and the refrigeration is governed to prevent too violent ebullition, lest liquid be thrown into the connecting-tube; the degree of applied heat is governed to the same end.

An ordinary glass retort may be substituted for the small flask as an evaporating vessel, and its tubule may be fitted with a perforated stopper, admitting a thermometer. If there is not room in the stopper (of retort or flask) for both the thermometer and the steam-escape tube, the latter may be dispensed with by adjusting the stopper loose for escape of steam, and pressing it tight when the air is expelled. Flat-bottomed flasks favour equable boiling, but they are liable to collapse.

As a *condenser*, I have used, instead of the large flask, a copper vessel, for more ready application of heat without danger of breaking, and for more efficient refrigeration. This copper receiver is made of conical shape, with rounded bottom, a vertical diameter twice its horizontal diameter, and a neck bent to the angle of about 50° with the vertical axis of the vessel. The diameter of the neck is three-quarters of an inch, to receive a retort beak, the joint being covered with a section of caoutchouc tubing. Or it may be fitted with a perforated stopper, to receive the connecting-tube of the flask when evaporation is conducted in the latter.

With linen netting to spread the water over the free surface of the condensers, the evaporation therefrom refrigerates with a comparatively small supply of water. Using a copper condenser of the above-described shape, a vertical diameter of 12 inches, and capacity of 6 pints, attached to an 8-ounce glass retort containing distillation promoters, I have vaporized 4 fluid ounces of water in sixteen minutes at the constant temperature of 128° F. By ordinary care in the expulsion of air and closure of the apparatus, exhaustion can be invariably secured, fixing the water-boiling point at below 130° F.; that is, atmospheric pressure equal to at least 25 inches of mercury may be removed and sustained by availing ourselves of the displacing effect of steam, and the contraction of condensing vapour, in very simple apparatus.

Notwithstanding the illustrations of vacuum by condensation, which abound upon the physical lecture-table, I do not know whether the devices suggested in this note have been tried or proposed for small chemical operations by any one else.* I have recommended them to students, and we have found them satisfactory for various analytical, experimental, and pharmaceutical operations. We have employed them chiefly in such evaporations as are performed for the residue only, or, at least, not for the quantitative recovery of the distillate, in various evaporations of quantitative analysis, in the elimination of non-volatile alkaloids, in determining the organic matter in water, and in preparing fluid extracts. To evaporate at ordinary temperatures by hand-pump exhaustion is especially irksome in those cases when application of 125° to 150° F. is objectionable. And to connect a vessel under which heat may be applied with the air-pump involves quite as much labour as the arrangement of apparatus for exhaustion by condensation. *American Journal of Pharmacy, from American Supplement to Chem. News, Jan.* 1870.

QUALITY AND ANALYSIS OF MILK.

Dr. C. F. Chandler has published a report of the results obtained in an extended examination of the milk supplied in New York, where it appears that the Metropolitan Board of Health takes cognizance of this among questions affecting the public.

The following is an account of the method of analysis:—

1. The water is determined by evaporating a weighed quantity of milk, either alone or soaked up in a known weight of pure, fine quartz sand. The residue is carefully dried at 212° F., and weighed. The loss in weight represents the water, while the residue includes all the solid constituents.

2. The salts are determined by carefully burning off the combustible portion of the solid residue obtained by evaporation, and weighing the incombustible ash.

3. The butter and casein are determined by coagulating the milk with a few drops of acetic acid, boiling, washing the precipitate with water, and finally separating the butter with ether, leaving the casein pure. On evaporating the ether, the butter is left behind, or the butter may be extracted by ether from the residue obtained by the evaporation of a quantity of milk, soaked up in sand.

4. The sugar is generally determined by deducting the sum of the other constituents from 100. It may be directly determined by the polariscope, after the removal of the casein and butter, or it may be determined by an alkaline solution of copper.

THE ADULTERATION OF MILK.—Numerous substances are mentioned as having been used, or as supposed to be used, for adulterating milk. Prominent among these are,—

1. *Water.*—Adulteration with this substance is generally detected by the specific gravity of the milk. Pure milk varies in specific gravity from 1·023 to 1·034, water being represented by 1·000. Milk is heavier than water, on account of the casein, sugar, and salts, which it holds in solution. Butter, on the other hand, is lighter than water, therefore the specific gravity of milk increases with the percentage of casein, sugar, and salts, while it diminishes with the percentages of water or butter. It is found that good milk generally has a specific gravity of from 1·029 to 1·032. In testing milk the lower number is selected as a fair gravity for pure milk; and whenever the gravity falls below this number the milk may be considered as containing an excess of water, and consequently poor in quality or adulterated. An instrument, called a galactometer, has been devised by Dinocourt, for the purpose of testing the quality of milk. It is simply an areometer, so graduated that 100

* This method of producing a partial vacuum was employed by Barry (see U.S. Dispensatory, "Evaporation of Extracts") more than forty years ago in making extracts and volatile oils.—ED. AMER. JOURN. PHARM.

on the scale represents pure milk, or the gravity 1·029, while 0 represents pure water, or gravity 1·000, the space between being divided into 100 parts. The numbers on the scale represent, therefore, the percentages of pure milk.

Skimmed milk, having been deprived of most of its butter, is heavier than whole milk. By skimming the milk before testing it with the galactometer, the error caused by the butter is eliminated. In this case, however, the mark for 100, or pure milk, must be placed lower down on the instrument, as pure milk, having a specific gravity of 1·029, would, after being skimmed, have a gravity of about 1·033. The 100° mark for skimmed milk is, therefore, fixed at this point.

The *lactometer* is a simple tube closed at the lower end, and graduated in hundredths. It is designed to measure the quantity of cream which rises on the milk.

By using the two instruments together, the *galactometer* and the *lactometer*, very satisfactory conclusions with regard to the quality of milk, can be formed. A perfectly reliable method, though more laborious, is to actually determine the percentage of water in the milk, by evaporating a weighed quantity, and carefully drying the residue at 212° F. If a milk loses more than 88 per cent. of water, having less than 12 per cent. of solids, it may be safely pronounced to be adulterated with water.

2. *Chalk.*—This substance is generally supposed to be extensively used to neutralize the acidity in soured milk, and to produce thickness and opacity, thus concealing dilution with water. It is easily detected, as it is deposited on standing, and can then be recognized by its effervescing with dilute acids. I have never detected it in any sample of milk examined. Its presence would also be shown in a milk analysis, by the unusual amount of ash.

3. *Flour, starch, emulsions of almonds, or hemp-seed, etc.*, are said to be used to thicken milk, and neutralize the blue colour caused by dilution. They were not found in any of our samples.

4. *Sugar, gum, dextrin*, and *borax*, to increase specific gravity.

5. *Turmeric and annatto*, to hide the blue colour.

6. *Cerebral matter, sheep's brains*, to thicken watered milk, easily detected by the microscope, and by its depositing a peculiar white sediment on standing.

7. *Carbonate or bicarbonate of soda*, to neutralize acidity. Detected by the increase in the quantity of ash, or, better, by the effervescence of the ash with acids.

297 specimens of the milk supplied to consumers in the Metropolitan district have been submitted to chemical examination. Of these 45 were seized while undergoing the process of dilution with water, 245 were purchased from the retail dealers, and 7 were procured at one of the crowded cow-stables in Brooklyn.

First Series of Analyses.—In the latter part of February, some milkmen were detected in the act of pouring a suspicious fluid, contained in milk-cans, into their milk. They were at once arrested, and taken, with their cans, about 50 in number, to police headquarters. Samples from 45 of the cans, which were placed in my hands for examination, gave the following results:—

2 cans contained water, not any too pure.

2 cans contained water, clouded with a little milk, probably from having been pumped into cans which had contained milk.

4 cans contained water, to which considerable milk had been added, the specific gravity varying from 1·010 to 1·017, representing by the galactometer from 37 to 60 per cent. of milk.

19 cans contained milk, to which considerable water had been added, the specific gravity varying from 1·023 to 1·028, representing from 80 to 97 per cent. of milk.

18 cans contained pure milk, varying in specific gravity from 1·029 to 1·030.

None of the samples contained any adulterant save water. The large proportion of pure milk is accounted for by the fact, that the work of dilution was interrupted by the police.

Second Series of Analyses.—During the months of June and July a systematic examination of milk was organized, the samples being purchased from retail dealers in various portions of the Metropolitan District. 210 samples were analysed, with the following general results:—

1. The specific gravity varies from 1·010 to 1·032, averaging 1·0208.

2. The percentage of pure milk, as shown by the galactometer, ranges from 37 to 110, averaging 72½.

3. The percentage of water varies from 83·57 to 94·17, averaging 89·89.

4. The percentage of solid constituents, the nutritive portion of the milk, varies from 5·83 to 16·43 per cent., averaging 10·11.

5. No adulteration was found in a single instance, save water.

Third Series of Analyses.—During the last four months of the year, a series of more elaborate analyses was undertaken, with a view to determine the percentages of some of the individual constituents of the milk. 35 samples were examined, and the results, which are herewith presented in tabular form, establish the fact that—

1. The cream averaged 7·89 per cent., ranging from 5·20 to 11·80 per cent.

2. The percentage of pure milk, as shown by the galactometer, averaged 82·44, varying from 50 to 112.

3. The butter averaged 3·03 per cent., varying from 1·81 to 3·76.

4. The casein and milk-sugar together averaged 6·46 per cent., ranging from 4·16 to 9·02.

5. The saline and earthy constituents averaged 0·59 per cent., varying from 0·39 to 0·87 per cent.

6. The total solids averaged 10·08 per cent., ranging from 6·73 to 12·32 per cent.

7. The water averaged 89·92 per cent., ranging from 87·68 to 93·27 per cent.

8. No adulteration was found in any case, save water.

Fourth Series of Analyses.—During the month of April, the attention of the Board having been called to the crowded condition of some of the large cow-stables in the Metropolitan District, the Sanitary Superintendent, Dr. Harris, was directed to make an investigation. It was found, on examination, that, although the stables were over-crowded, dark, and damp, and deficient in ventilation, the animals generally presented a good appearance.

The milk of these cows was specially deficient in butter, and in *every* respect poorer than the milk of healthy cows. No other indications of disease could be detected in the milk.

Fatal Accident with Petroleum Spirit.—Shortly after 10 o'clock on Thursday night, Mr. David Taylor, a chemist and druggist at Bradford, was engaged in emptying a thirty-six gallon cask of benzoline into smaller vessels, when a cat, which had been jumping about, knocked over the candle by the light of which he performed the operation. Alarmed and confused by the circumstance, Mr. Taylor dropped from his hand a half-gallon measure filled with benzoline, which, becoming ignited, instantly set fire to the house. A wooden staircase, beneath which the fire arose, was immediately in a blaze, as were also soon after the rooms above. Efforts at suppression were made by the inmates, but in vain. Two local fire brigades went to the spot, and extinguished the fire in about an hour. Soon after they arrived, a police officer, with difficulty and at great peril, rescued from bed in an upper room a child of one year and nine months, but it was found to be dead, either from suffocation or burning. Mr. Taylor estimates his pecuniary loss at £1200 or £1400.—*Pall Mall Gazette.*

Reviews.

Le Livre des Parfums. Par Eugène Rimmel; Préface d'Alph. Karr. Illustrations d'A. de Neuville, Duhousset, Chéret, etc. Paris: E. Dentu; London: Chapman and Hall.

To the lovers of perfumes this elegant volume will be a source of considerable interest and entertainment. Unlike most works on the subject, it does not consist of a mere dry collection of recipes: it is a history of the use of perfumes in all ages, and among various nations. Commencing with the Egyptians, the Jews and other Asiatic people, he describes the customs prevailing among them in regard to perfumes, passing then to the ancient Greeks, Romans, and Orientals, the savages of Africa, America, Australia, etc., the ancient Gauls and Germanic tribes, then, lastly, describing the development of the perfumer's art in more modern times. The remaining chapters are devoted to modern perfumery, and to an account of the materials used by the perfumer, in which there is an excellent statement of their nature, sources and modes of preparation. To give some idea of the immense extent of the trade in perfumes, we quote the following table, showing the quantities exported from France and the rate of increase during the present century.

Year.	Quantity, Kilogr.	Value, Francs.
1827	751,000	5,401,100
1837	886,000	6,401,600
1847	1,275,600	8,928,900
1857	2,706,700	13,533,100
1867	2,626,600	15,759,600

The volume is beautifully illustrated, with a large number of interesting woodcuts and chromotypes. It is to be hoped that the author will soon produce an English edition.

Water Analysis: a Practical Treatise on the Examination of Potable Water. By J. Alfred Wanklyn and E. T. Chapman. Second Edition. London: Trübner and Co., 60, Paternoster Row. 1870.

This is essentially an exposition of the ammonia-method analysis introduced by Wanklyn, Chapman, and Smith. The fact that it has now reached a second edition indicates that the method has been accepted by chemists. The recent and very interesting work of Dr. Angus Smith on the organic matter of the atmosphere, and Dr. Ransome's researches on the breath in health and disease, are both calculated to increase the confidence of chemists in the trustworthiness of the results given by the ammonia-method, inasmuch as both of these observers employed it in the examination of the water which had absorbed the impurities existing in the different specimens of air with which they were experimenting.

Map of the Geographical Distribution of Medicinal Substances contained in the British Pharmacopœia of 1867. By a Lecturer on Materia Medica. London: John Churchill and Sons. (One sheet mounted on cloth, in wrapper.)

It is a well-known fact that even amongst those who have had the benefit of a good education, the knowledge of geography is often very hazy, as every examiner finds when he asks a candidate to point out a certain place on a map,—answers such as America, Asia, East Indies, not being considered by some students too wide of the mark, a few degrees of latitude or longitude being to them of little consequence.

The idea of getting up cheap maps with the geographical distribution of drugs marked on them is a good one, and meets with favour from students, but there is one great drawback to the map before us, that is in the case of substances having two or more geographical sources, only indicating one on the map. Thus, if a student looks at Siam, he will find no mention of benzoin being produced there, but under Sumatra it is mentioned with the note "(*and Siam*)." Ammoniacum he will not find in the Punjaub, but in Persia it is entered for both countries.

Though this map is not so full or so instructive as Mr. Barber's Medico-Botanical Map, yet it will prove useful to students who do not require a knowledge of drugs beyond those contained in the Pharmacopœia.

Obituary.

ALBRECHT VON GRAEFE.

By the death of Albrecht von Graefe, medicine sustains one of the heaviest among her numerous losses this year. He was born at Berlin in 1825, the son of an eminent surgeon, who was himself an oculist of merit. On the conclusion of an unusually brilliant academic career, he accompanied Professor Donders, the great ophthalmic physician of Holland, on a visit to England in 1851, and having derived what benefit he could from observation of British practice, he returned to Berlin, where he shortly afterwards opened the Ophthalmic Hospital, now celebrated all the world over. In 1853 he founded, along with Arlt and Donders, the 'Archiv für Ophthalmologie,' and continued till his death the most frequent and most valuable contributor to its pages. But a few years elapsed when he gave to the world his great discovery that glaucoma, or disorganization of the eyeball, could be arrested by iridectomy. "There can hardly be," says the 'Lancet,' "either in Europe or America, a community of 10,000 people which does not contain at least one individual who is in the enjoyment of vision that has been preserved by iridectomy, and who, if Von Graefe had not lived, would now be unable to see the sun." To ophthalmic medicine this was but the most remarkable of his many contributions, which, originally announced in his own 'Archiv' and other medical journals, won their way into all scientific centres in Europe and America by the attractiveness of a style unexcelled for lucidity and force. Von Graefe owed much of his success as a practitioner to a combined suavity and firmness of manner, which made him at once the physician and the friend of his patients. Probably no special practitioner of his time ever won more gratitude from a wider *clientèle;* certainly none with the exception of Simpson (whose discovery of chloroform made iridectomy possible) has been followed with profounder regret to so untimely a grave.

July 27, after an illness of three months, Mr. Henry Sharp, of Christchurch, Hants, aged 45. He was one of the founders of the Pharmaceutical Society, and Local Secretary for the district.

Hybridization of Cinchonæ.—At the March meeting of the Linnean Society an interesting paper, by Mr. Broughton, chemist to the Madras Government, was communicated by Mr. Howard. Mr. Broughton stated that in the Madras gardens young plants were growing which appeared to be hybrids been *C. succirubra* and *C. officinalis*. In Java also something similar has occurred between *C. Calisaya* and *C. Pahudiana* (= *C. Hasskarliana*, nov. sp. Miq.). In a letter, Dr. de Vrij says:—"The *Calisaya* of Java contains, besides quinine and cinchonine, very often quinidine. The *C. Pahudiana* contains, besides quinine and cinchonine, almost always cinchonidine. In the hybrid of these two I found no quinidine, but cinchonidine and quinine. As the total amount of alkaloids was small, I was unable to ascertain the presence of cinchonine." (The Hague, 1870.) This discovery will doubtless prove of great importance, for by this means the more delicate, but valuable, alkaloid species can be crossed with those that are more hardy but less valuable, and thus valuable and hardy plants will be obtained.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the Editor, 17, *Bloomsbury Square.*

"Rule of Thumb."

Sir,—"Anti-Humbug" has written a very harum-scarum letter upon the above subject. Now, accuracy cannot be humbug. If a pharmacist has certain ingredients ordered to be divided into twelve equal parts, it is his sole duty to *know* that each part is an equal division, independent of inertness or activity of the medicine. He cannot know if he trusts to a fallible organ, like the eye. Really there is such a thing to be observed in dispensing medicines as conscientiousness, and it is also a fact, that the Pharmacopœia recognizes "dose." Rifle-shooting and carpentering are scarcely such delicate matters as the correct administration of a dose of calomel.

Yours, etc.,

Minor Associate.

July 30, 1870.

Sir,—I confess I was somewhat surprised to find, upon looking down the correspondence column of the last issue of the 'Pharmaceutical Journal,' that there was any gentleman who could so unmistakably advocate such a dangerous method as "measurement" by "rule of thumb." Apart from considering the arguments of your correspondent in support of his views, I cannot help thinking that there is a principle involved in the question upon which it is very desirable we should have a clear understanding.

In these times of examination, when so important a part of our curriculum is devoted to determining the student's capacity for *correctly* ascertaining the amount of active ingredient contained in each dose of medicine prescribed; I think that, to allow the exhibition of such a *principle* as that contained in your correspondent's letter to pass unchallenged, is to commit an error, the gravity of which cannot be too fully estimated.

It may possibly be in the power of "Anti-Humbug" in dispensing *accurately* to measure his medicines by "rule of thumb," but is it correct that such a method should be openly recommended; for I cannot see that he lays down any rule by which we are to decide upon the fitness, or otherwise, of our young members to practise this acquirement?

Of the *danger* of allowing young and *unpractised* dispensers to proceed by "rule of thumb," it is, I trust, needless to speak? Is it, therefore, *dangerous* to allow opinions such as these to pass current in our official organ; for it is apparent they may have a doubtful, if not a decidedly injurious effect upon the minds of those who, by reason of their inexperience, are so prone to imbibe erroneous ideas?

Hoping that this may not be considered an unwarrantable encroachment upon your valuable space,

I remain, yours truly,

E. R. L.

Bath, August 1, 1870.

Trade Grievances.

Sir,—May I beg your indulgence for a small space in your Journal, for a few remarks on what are popularly called *trade grievances?* In almost every number of your Journal is a mass of correspondence, chiefly bewailing our unfortunate lot, and suggesting numerous and various remedies; but as yet I am not aware they have been followed by any practical benefit, and, in my humble opinion, if the following suggestions had not, by a strange oversight, been forgotten in framing our new Act, we should have very rapidly advanced from our present position of tradesmen to our true status of professional men; our pecuniary affairs, of course, advancing in the same ratio.

The first *grievance* is one that has been well ventilated in your columns, namely, Counter Prescribing *versus* The Dispensing of Medicines by Surgeons. I would stringently restrain druggists from supplying all but the most simple medicines, except on the written authority of a medical man, and, on the other hand, would insist on that anomalous animal—a general practitioner, being forbidden, under heavy penalties, from dispensing his own medicines. I advocate the abolition of counter prescribing, although, myself, I do a large practice in it, because I consider it to be the root of all dissensions between ourselves and the medical fraternity. England proudly considering herself the first in the march of civilization and science, is, after considerable advances, still wofully behind her Continental neighbours in the matter of medical and Pharmaceutical reform. Why have we need of so many classes of medical men? From experience in five Continental countries I cannot see the necessity. If a "doctor" to prescribe, and a "pharmacien" to dispense, are all that are required in France, Italy, Switzerland, Germany, Belgium, why must we be saddled with apothecaries, surgeons, etc.,—mongrel compounds of druggists and physicians? Perhaps this clause was not inserted, because the Council did not think it politic to grasp too much at commencement, and it is standing over to a more favourable period,—at least I sincerely hope so.

The other *grievance* is the sad inroad made into our business and reputation by the piratical crew of small shopkeepers, herbalists, quacks, anti-vaccinators, Coffinites, etc., who infest us as maggots do cheese, especially in large manufacturing towns, where in any but the principal thoroughfares every tenth house will sell castor oil, sweet nitre, herbs, pills, powders, *et hoc genus omne,* and who thus take away a great part of our legitimate business, and get us into such disrepute with coroners' juries. The remedy for this is very simple, and I was astounded when the new Act came into operation, without a word on this head. I would merely add bodily to our Act the 6th Article of the French Code, which I translate verbatim, for the benefit of such of your readers as may not have seen it.

"Art. VI. It is forbidden for all grocers, and *all other persons,* to make, sell, or keep in stock any salts, composition, or preparations, entering into the human body in the form of medicines, or to make any mixture of simple drugs, for administering in form of medicine, under a penalty of £20, or more if requisite." This clause is beautifully clear and decisive, and if fortunately it had been incorporated in our own Act, we should have been relieved from these parasites, who at present, if they only steer clear of poison, may sell (or rather undersell) their cheap, adulterated drugs, under the very nose of a Pharmaceutical Chemist, who has had heavy demands on his time and money, in order to qualify him to open a shop.

These then, are, in my opinion, the only stumbling-blocks on the road to advancement, and if the Council will only give them the consideration they duly deserve, we may, at some future time, relieve ourselves of the trammels of paints, oils, and colours, and rise to something higher than "the druggist round the corner."

Although very dissimilar to the above, yet intimately connected with it, is your leader in last number of the Journal, in which the writer takes it for granted that the new members have been elected from the provinces merely in opposition to London members, without due regard to merit, or long and valued services. This is not so; a London chemist has not the slightest idea what a country drug business is like, or what are the requirements of a country druggist. The former Council, in effect, chiefly composed of Londoners, would insist on looking at us from a distance through the rose-coloured glasses of money-coining West-End establishments, and, wishing to elevate us too rapidly on a level with themselves, have done us considerable injury, chiefly by neglecting any attempt to rectify the above grievances; this neglect, we are glad to admit, has not been from unwillingness to assist us, but merely from insufficient knowledge on the subject, and as we provincials form the great body of the Society, pressure was brought to bear on country members to ensure the new Council having the proper proportion of provincial representatives it was entitled to.

Apologizing for trespassing so much on your valuable space,

I remain, yours faithfully,

A Country M. P. S.

Pharmacist, or Pharmaceutical Chemist?

Sir,—On the eve of another Pharmaceutical Conference, allow me, through the medium of the Journal, to draw the attention of Pharmaceutical Chemists to the desirability of adopting (as a body) the title of "Pharmacist" or "Pharmaceutist" in preference to that of "Pharmaceutical Chemist."

We very seldom find the title of Pharmaceutical Chemist used by the public, either in verbal or written communications; probably the reason of this is due to its length, the word "chemist" being much more easily written without than with "Pharmaceutical" tacked to it. I think this would be obviated by the adoption of either of the words suggested.

Trusting the subject will be taken up by those capable of bringing it, if thought desirable, to a successful issue,

I remain, yours truly,

W. Milner Thompson.

Navy Dispensers.

Sir,—I cannot agree with your correspondent of the 23rd inst., "J. T. D.," respecting the remuneration to Navy dispensers; he thinks they will be underpaid, and states that a qualified assistant can earn 5*s.* a day, or more.

In order to form a fair comparison we must remember that the Navy dispenser will not require any capital, and in this respect he is on a par with an assistant in civil service life, but not with the man who starts or purchases a business.

Now, Sir, I have been an assistant about eleven years, and am receiving £40 per annum, with board and lodging. Supposing I had been a Navy dispenser for the same period, my pay would be £2. 5*s.* 6*d.* per week, and quarters; deducting 12*s.* per week for rations (which is ample in the service), my pay would be, free of all drawbacks, £1. 13*s.* 6*d.* per week, more by 18*s.* per week than I now receive.

Yours obediently,

An Assistant.

P.S. I have not touched upon the very important item of superannuation.

Free Trade in Surgical Instruments.

Sir,—Having read the article in question, which appeared in a medical contemporary, and also your remarks thereon, I cannot refrain from expressing my astonishment and regret at the extraordinary strong language, of which you justly complain. Surely, such ugly insinuations as the following, "If the public can be combined against the profession, cannot we can retaliate?" and again, "we can very easily endanger their regular trade," cannot embody the spontaneous sentiments and charitable expressions of the honourable profession whom your contemporary assumes to represent. If a few members of the Nottingham Association have ventured to give utterance to their own private feelings, that is no reason why he should fire such explosive missiles indiscriminately at the "enlightened and respectable pharmaceutists" of whom he speaks, and who, if he forgets not, are in possession of vested rights, privileges, and honourable pursuits far more profitable than the "grasping conduct" he alludes to. The days for such a menacing attitude and vain-boasting having gone by, and the overture of a more glorious era having already commenced, I sincerely trust that the magnifying and deceptive spectacles wherein he beheld a Nottingham gnat assume the proportions of a prodigious camel will never be taken up again, and that language so offensive and uncalled for will be avoided in future.

T. C. Jones.

Chalk Farm Road, N.W., August 1, 1870.

Case of Explosion.

Sir,—Some time since, I had occasion to prepare a strong solution of iodine and iodide of potassium, and, having filtered the solution, left the filter paper in the funnel, where it remained until the following morning, by which time it was quite dry; to my great surprise when I took hold of the filter to throw it away, an exceedingly loud report occurred, shattering the paper and funnel to fragments; the wall of the room was marked in various places by the iodine, my face also being covered with iodine stains for weeks. I am quite at a loss to account for the explosion, perhaps some of your readers may be able to throw light upon the subject.

July 27, 1870. F. J. Trauten.

Poison Regulations.

Sir,—The keeping and dispensing of poisons is a subject which can, in my opinion, only be disposed of when some definite plan is accepted by pharmaceutists, and this will require to be easy of application, inexpensive, and effectual. Now, the two first methods recommended by the Council are objectionable, inasmuch as they involve expensive alterations, either by the adoption of distinctive bottles, "angular, fluted, or corrugated," or of a large "poison cupboard," or rather small room to keep poisonous drugs apart from others.

The first of these plans would require either a very considerable number of new and expensive bottles which, in thousands of cases, could be ill afforded; or an amount of room which could be as ill spared, if it could be found at all.

One other proposal remains, viz. "that bottles or vessels used in any shop or dispensary to contain poison, shall be tied over, capped, or secured, in a manner distinguishable from the way in which any bottles or vessels not used to contain poisonous or dangerous articles used in the same shop or dispensary," etc.

To carry this into effect, I can offer a simple, efficient, and inexpensive plan which I have used in my own pharmacy, and with most satisfactory results for several years. It consists in the use of a neatly constructed india-rubber capsule, which goes most readily over the stopper and shoulder of the bottle, fixing itself by its elasticity alone. It can be put on or off instantaneously, and it bears the word Poison prominently on the side. These are the capsules of which Mr. Sandford spoke at the Annual Meeting, but at the time he had not seen them.

A bottle containing *laudanum, tincture of aconite,* or any other dangerous drug, protected by one of these capsules *could* not without *incredible* carelessness be taken down in mistake for a different bottle not requiring protection. Their general adoption by Pharmaceutical Chemists and the chemists and druggists of Great Britain would, I believe, fully meet all the requirements of the Pharmacy Act, and render unnecessary the interference of Government or Parliament, so as to affect the free action of members of the Pharmaceutical Society, which will certainly be endangered if this or some other plan be not voluntarily adopted.

I enclose you two of the capsules which, if fitted on the proper-sized bottles, will enable you to form a judgment on them.

Your obedient servant,

H. C. Baildon.

73, *Princes Street, Edinburgh, August* 2, 1870.

Note.—Subordinate to the safe keeping of poisons, but still one of some importance to pharmaceutists, evaporation is prevented by the use of these capsules in the case of spirituous preparations. I need hardly say how great the loss is from this cause, or that the greater number of liquid poisons *are* spirituous preparations.

"*Navy Dispenser*" (Rochester) should apply to the Admiralty Office.

"*Zeta*" (Liverpool).—Inquiry shall be made.

"*Rees Lloyd*" (Dowlais).—In the press.

"*Physicians' English.*"—Mr. D. Carroll (Framlingham) writes, in reference to the letter of "Echo," in the Journal of July 16th, pointing out that physicians are also liable to the commission of errors in the use of English and Latin.

E. Trinder (Solihull).—Received with thanks.

"*Leno*" (Sheffield) wishes to have a formula for Quinine Balm for the Hair.

M. E. L. (Southport).—Apply at Apothecaries' Hall.

"*A Member*" (Stroud).—Apply to the Secretary.

C. B. A.—Assistants to Chemists and Druggists need not be on the Register of Chemists and Druggists.

"*Flora of Hampshire.*"—In answer to Mr. Brook, jun., of Southville, Mr. Gibbs, of Winchester, writes: "There is no 'Flora of Hampshire' published. There is a manuscript copy of a catalogue of the flora of Hants, by Dr. Bromfield, preserved at Kew; also a 'Flora of Andover,' published by Clarke. I know of several good herbaria of localities, and should be very glad to communicate with Mr. Brook on the subject."

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

The General Index to the first Fifteen volumes of this Journal may be obtained of the Secretary, 17, Bloomsbury Square, price 2*s.* 8*d.*, post free; bound in cloth, lettered, 3*s.* 8*d.*, post free.

The General Index to the Vols. XVI.–XVIII., Old Series, and Vols. I.–IX., Second Series, may also be obtained of the Secretary, price 3*s.* 3*d.*, post free.

NOTE ON THE ALKALOIDS OF THE GENUS ACONITUM.*

BY PROFESSOR FLÜCKIGER.

Aconitine was discovered by Hesse, in 1833. Von Schroff, in 1857, showed that there occur in aconite tubers two different principles, one being possessed of narcotic properties, the other of an extreme acridity. Von Schroff did not himself isolate these principles, but he ascertained that the physiological effects of the aconitine used throughout Germany agreed with those of the narcotic principle above alluded to. On the other hand, "*Pure Aconitine*," made by Messrs. Morson and Son, was stated by Von Schroff to exactly represent the acrid principle, which his physiological experiments had pointed out, in aconite tubers. He further observed, that this acrid body prevails, or even exists exclusively, in the tubers of certain species of *Aconitum* growing in the alpine regions of the Himalayas. These highly poisonous tubers have been known and used in India since a remote period under the names of *Bikh*, *Bish*, or *Ativisha*, and are met with in the bazaars, and also occasionally imported into London. Von Schroff therefore suggested that the Indian tubers might be the source of what he called *English Aconitine*.

Thus there was established in German literature an important difference between German Aconitine and English Aconitine, the two substances being regarded as by no means identical. The name *Aconitine* then was restricted to the former, while the designation of *napelline* (Wiggers), *nepaline* (Flückiger), *acraconitine* (Ludwig), and *pseudaconitine* (Hübschmann), were severally proposed for the so-regarded *English* preparation. Hübschmann, in 1868, first examined the chemical properties of pseudaconitine, which he had obtained from E. Merck, Darmstadt. It is but sparingly soluble in ether, chloroform, and even in alcohol, but crystallizes readily, especially from hot alcohol; it is soluble in hot benzol, does not soften in boiling water, is not coloured by cold sulphuric acid, nor even after the addition of nitric acid. I have been presented by the late Hübschmann with a small specimen of this pseudaconitine, and am enabled to corroborate the above statements. It is a substance which has a burning, not a bitter taste, and does not produce any coloured reaction with concentrated sulphuric, nitric, or phosphoric acid, either cold or hot, alone or combined.

The aconitine sold in Germany has been for many years past mainly prepared by Hübschmann from tubers of *Aconitum Napellus*, grown in the Swiss Alps. An authentic sample of this alkaloid, as furnished by the manufacturer himself, exhibited the chemical characters universally attributed to aconitine. It dissolves in 2 parts of ether, 2·6 chloroform, 4·2 alcohol, but without separating in distinct crystals upon evaporation. Aconitine produces an intense violet colour with hot concentrated phosphoric acid, this characteristic reaction lasting for several days. Aconitine has an extremely bitter, scarcely somewhat acrid taste.

Consequently, there can be no doubt that aconitine and pseudaconitine are entirely different alkaloids, which may be easily recognised and separated, if occurring, for instance, in Bikh tubers. That pseudaconitine is identical with Von Schroff's "English aconitine," I cannot assert positively, although I suppose it to be so.

I was now desirous of ascertaining whether the aconitine of English chemists and manufacturers agreed or not with pseudaconitine. My friend Mr. Hanbury, as well as Mr. Thomas B. Groves, F.C.S., of Weymouth, kindly provided me with samples of commercial aconitine, to which the latter gentleman also added some specimens prepared by himself. At the outset I examined the "*pure aconitine*" of Morson, as at present sold by that manufacturer, and also samples of his product dating from the years 1856 and 1860. All of them were found to agree exactly with Hübschmann's aconitine. Nearly the same may be said with regard to aconitine made by Hopkin and Williams, which, however, produced a less pure coloration with phosphoric acid, and tasted, in aqueous solution, not quite purely bitter, but, at the same time, somewhat acrid. Its watery solution also yields a soft greasy brownish precipitate with platinocyanide of potassium, whilst in Hübschmann's and in Morson's aconitine the platinum salt produces a heavy, white, not at all agglutinating compound. This discrepancy appears to be due to the presence of a very small quantity of impurities in the alkaloid of Hopkin and Williams. I found its chlorhydrate to contain the same amount of hydrochloric acid as that of Hübschmann, and in its physiological effects no difference could be traced.

The samples of aconitine, prepared by Mr. Groves from *A. Napellus*, agreed partly with the products of Hübschmann and of Morson, partly with that of Hopkin and Williams, inasmuch as the coloration produced with hot concentrated phosphoric acid was pure, or less pure violet. The aconitine of Mr. Groves (at least in some of his samples) is remarkable, as it consists of microscopic crystals; all the other samples of this alkaloid, which I had the opportunity of examining, being entirely amorphous. The said chemist was also the first who succeeded in obtaining crystallized salts of aconitine;* I am indebted to him for really fine rhombic octahedrons of nitrate of aconitine.

It must be concluded from the foregoing experiments, that the aconitine used in England, and that found on the Continent, at least in Germany, are essentially one and the same substance.

Yet pseudaconitine exists. In 1868, the London house of Roller and Wiedenmann met there with a "*cheap aconitine*," which they sent for examination to Mr. Merck. When engaged in the present investigation, this substance had disappeared from the market, so that I could not succeed in obtaining any; but the statements of Mr. Merck † are sufficient to show it was pseudaconitine. Unfortunately no further information as to the source of this curious body was to be obtained. I am informed that in London it was said to come from the Continent! This mysterious pseudaconitine being attributed to the Bikh tubers, I prepared an alcoholic extract of the latter, which was examined by Dr. Klebs, Professor of Pathologic Anatomy in our University. It proved to agree in its effects with aconitine, but decidedly *not* with pseudaconitine. I am also informed, most positively, that in London the manufacturers of aconitine *indiscriminately* resort to Indian

* Abstract from the author's paper in the 'Archiv der Pharmacie,' cxci. (1870), 196 to 215.

* Pharm. Journ. VIII. (1866) 122.
† *Ibid.* X. (1868) 248.

or to Continental (Swiss) aconite tubers, for making aconitine. Where then does pseudaconitine occur?

Bikh tubers appear to be collected from several Himalayan species, especially from *Aconitum ferox*, Wallich, but *A. Napellus* also occurs in the Himalayas.* The specimens of Bikh I had the opportunity of examining are not, however, the tubers of the latter species, the appearance of which is extremely characteristic, the tubers being always formed in pairs, each pair united by a short branchlet. All the eastern tubers, which I have seen, are *single*, and mostly considerably larger than those of *A. Napellus*, but simpler, and devoid of rootlets. Their appearance is so uniform that I should not feel entitled to attribute them to several mother-plants. Whether there are Himalayan aconites containing *pseudaconitine* instead of *aconitine* is a question, to the solution of which I am sorry I cannot contribute.

Some other alkaloids have been pointed out by Hübschmann as existing in aconite.† In *Aconitum Napellus* he found *napelline*, differing from aconitine by its solubility in ammonia, and insolubility in ether. The rhizomes of *A. Lycoctonum*, L., the yellow-flowered Aconite, yielded *lycoctonine* and *acolyctine;* the latter, however, finally proved to agree, probably, with napelline. Again, Messrs. Smith, of Edinburgh, in 1863, obtained from tubers of Napellus, *aconelline* which substance is now thought to be none other than narcotine. No subsequent observer has met with it in aconite.‡ Now is the pseudaconitine a peculiar principle, or does it agree, as has been suggested, with any one among the alkaloids I have named? As to napelline,§ its properties, as given by its discoverer, prove at once that it is quite different from pseudaconitine. If aconelline agrees with narcotine, the well-known characters of this latter substance do not allow us to suppose it in any degree similar to, still less identical with pseudaconitine. Lastly, *lycoctonine* having never been carefully examined, I felt obliged to do so, all the more as the late Hübschmann had himself furnished me with it in a state of perfect purity.

Lycoctonine consists of white, needle-shaped crystals, not melting (like aconitine) in boiling water, but only at some degrees above. On cooling, it does not resume its crystalline form until it is moistened with water, when the amorphous mass is quickly transformed into tufted crystals. By melting, lycoctonine loses no water, nor does it combine with water by the act of re-crystallization. Lycoctonine readily dissolves in chloroform, which, after evaporation, leaves behind an amorphous varnish, which again, on moistening with water, becomes very strikingly crystalline. Sulphide of carbon, ether, alcohol, the fat and volatile oils, amylic alcohol, petroleum spirit, largely dissolve lycoctonine. Of boiling water, 600 parts dissolve 1 part of lycoctonine. The solution has an alkaline reaction and bitter taste; it produces fine yellow crystals if bromine water is added. This takes place even if the solution contains but 1 part of lycoctonine in 30,000 water. Lycoctonine is also precipitated by iodohydrargyrate of potassium, the compound crystallizing after some hours. One part of lycoctonine in 20,000 water yields these crystals after twelve hours. The analogous mercuric compound of aconitine always remains uncrystallized. As to physiological effects, lycoctonine is far less poisonous than aconitine.

Lycoctonine is, therefore, a well-defined, peculiar alkaloid, differing from aconitine as well as from pseudaconitine. I hope soon to determine its composition.

The results of the researches here detailed may be summed up as follows:—

1. Aconitine is contained in the blue-flowering European and Himalayan species of *Aconitum*, especially in *A. Napellus*.
2. Aconitine is particularly characterized by the following properties:—It is anhydrous, becomes soft in boiling water, although it only melts near 120° C. The aqueous solution has a bitter taste, free from acridity; it is not precipitated by bichloride of platinum, but produces an uncrystallizable precipitate with iodohydrargyrate of potassium. It dissolves very readily in ether, chloroform, and alcohol, and forms a monochlorhydrate, $C_{30}H_{47}NO_7+HCl$. The nitrate can be obtained in well-developed microscopic crystals. Aconitine imparts a violet colour to hot phosphoric acid which has been concentrated as much as possible in the water-bath.
3. All aconitine from England which I examined agrees essentially with the German (or Swiss) aconitine.
4. There exists, however, a base entirely distinct from aconitine, of uncertain origin, but perhaps derived from the aconite tubers (*bikh*) of Nepal and other alpine regions of India. It may be distinguished as *pseudaconitine*.
5. Pseudaconitine has a burning, not a bitter taste. It is insoluble in water, less soluble in ether, chloroform, and alcohol, but freely crystallizable from these solutions. It is not coloured by hot concentrated phosphoric acid.
6. Napelline differs both from aconitine and pseudaconitine.
7. So also does lycoctonine, an alkaloid peculiar (so far as we know) to the yellow-flowered Aconite (*Aconitum Lycoctonum*, L.). Its bromine compound crystallizes from a dilute aqueous solution, but upon drying is decomposed.

§ The existence of napelline has been doubted by some authors, but has been always decidedly maintained by Hübschmann.

ACETIC FERMENTATION.

BY BARON VON LIEBIG.

In the investigation of physiological or other phenomena where there are both chemical and physiological processes concerned, as in the case of fermentation, the true method of research requires that the chemical and physical laws of both should be ascertained; indeed the utmost we can expect is to arrive at a knowledge of these laws. The explanation of a physiological phenomenon consists, therefore, in ascertaining first what physical or chemical laws it is subject to, and it is the object of further investigation to determine the extent to which they are concerned.

From this point of view I have endeavoured to refer the chemical process of fermentation to a chemico-physical cause, by directing attention to the influence exercised by a substance in a state of molecular motion upon another highly complex substance whose particles are held together feebly and are in a state of tension. If the molecular motion in the one substance be the consequence of disturbed equilibrium, some exercise of work may be ascribed to it, and this would become sensible in the dislocation or severance of the elements of the other substance.

This view has not been generally accepted, and, quite recently, another one has been adopted by which the transformation of organic materials into inorganic compounds is ascribed to the nutrition and growth of inferior organisms. Thus the old idea of vital force, belonging to the last century, has again become current under a new form in the explanation of very simple chemical changes.

"Fermentation," said Mitscherlich,* "is caused by a plant organism, and putrefaction by an animal organism." Then twenty-six years afterwards, Pasteur has described certain species of fungi, some of which produce acetic fermentation, others lactic fermentation or mucous fermentation, while the butyric and tartaric fermentation, that resemble putrefaction, are assumed to be caused by vibrios.

The characters of these animated ferments are very peculiar.

The acetic acid fungus is, according to Pasteur, so much like the lactic acid fungus, that the two are frequently undistinguishable by the microscope. Moreover, the lactic acid fungus is said to resemble beer-yeast.† The action of these ferments is also very varied.

According to Pasteur, acetic acid is the product of *Mycoderma aceti;* but this plant also produces succinic acid,‡ and, in contact with sugar, it gives rise to vinous fermentation.§ According to Pasteur, phosphates and alkalies are necessary constituents of this fungus, while Mulder declares that when burnt it does not leave the least trace of ash.||

The behaviour of the lactic acid fungus is still more remarkable, for its activity is not limited to the production of lactic acid only, and it is capable of producing butyric acid, mannite, mucus and even alcohol.**

If sugar be fermented with beer-yeast, and the fermented liquor be exposed to the air, a layer of mould is formed on the surface, while the alcohol is converted into acetic acid. A portion of that mould, placed in contact with sugar and chalk, causes the conversion of the sugar into lactic acid.

The lactic acid ferment also produces butyric acid under certain circumstances, though the proper butyric ferment is infusorial; it converts sugar, gum and lactic acid into butyric acid. Atmospheric air is detrimental to it, and it is killed by access of air. However, Maddrell and Engelhard found that lactate of lime, although recrystallized twice and therefore containing only a trace of lactic ferment, was remarkably susceptible of butyric fermentation; while in an experiment made specially to determine the point they observed, in opposition to Pasteur's statement, that the butyric fermentation was accelerated by access of air.††

* Ann. Chem. Pharm. xlviii. 126.
† 'Comptes Rendus,' xlv. 903.

§ Thomson, Ann. Chem. Pharm. lxxxiii. 90.
|| Ann. Chem. Pharm. xlvi. 24.
** 'Comptes Rendus,' xlv. 913.
†† Ann. Chem. Pharm. lxiii. 86.

According to Pasteur the butyric ferment can be sown like beer-yeast. He states that in suitable media, such as solutions of sugar, ammonia, and phosphates, it increases, and that butyric acid is formed meanwhile. But if the facts are the same as in the case of beer-yeast, there does not appear much hope of any particular result. The observations of these living ferments are obviously very superficial and contradictory, so that it is barely possible to say that during the last twelve years there has been any advance towards more definite ideas as to their nature and mode of action.

In reference to the part taken by living organisms in putrefaction, Van den Broeck* expresses himself very clearly as follows:—"The microscopic examination of the five animal substances (egg-white, egg-yelk, arterial blood, gall and urine of the dog and oxen) has taught me that there is no connection between their putrefaction and the development or growth of vibrios."

From the moment a piece of muscle is separated from the living body it begins to undergo alteration; after some hours it acquires an acid reaction, the coagulable substances are coagulated, the contents of the muscular tubes become more solid and acquire a clouded appearance with a thickish consistence. The muscle contracts and thickens, or *rigor mortis* takes place; then, after some time, the stiffness ceases, the acidity augments, and offensive-smelling products make their appearance.

If organized ferments have nothing to do with the formation of the first products that appear in the muscles up to the occurrence of *rigor mortis,*—and I believe there is no physiologist who thinks they have,—then it is difficult to understand how the further alterations can be determined by them.

Fungi and vibrios are dependent upon organic material for their development and nutrition, and the cases where they are not met with in putrefying or decaying materials under ordinary conditions are seldom enough. Accordingly, as one observer finds them or not, opinion may shift from one side to the other, but it would be hopeless to expect from microscopic observations an elucidation of the part they play.

If acetic fermentation be understood as the production of acetic acid from alcohol, it is from a chemical point of view the most thoroughly investigated and most accurately known of all kinds of fermentation.

Pasteur has maintained that the production of acetic acid is a process of fermentation, and that it is determined by the *Mycoderma aceti.*

In the cultivation of *Mycoderma aceti* upon alcoholic liquids, the alcohol is converted first into aldehyde, and then into acetic acid. The vinegar-plant acts only when in direct contact with the air, not when it is immersed; it also requires as food phosphates and albuminous substances.†

I have hitherto believed that the production of acetic acid was well understood, and that it consisted simply in the oxidation of alcohol. Finely divided platinum converts alcohol into acetic acid by means of the oxygen condensed upon it. A number of organic substances are known to absorb oxygen from the air and to retain for some time the power of oxidizing other substances, as in the case of platinum.

* Ann. Chem. Pharm. cxv. 79.
† 'Comptes Rendus,' lviii. 142.

Oil of turpentine, ether, aldehyde, or bitter almond oil, that have been shaken with air, will convert sulphurous acid into sulphuric, and decolorize tincture of indigo; even sulphurous acid, and many solid organic substances, will, while undergoing oxidation, determine the oxidation of other substances, organic and inorganic.

This remarkable property was noticed more than thirty years ago by De Saussure* as being possessed by putrefying substances; and it is worth while to recall to mind his experiments. "When vegetable mould, or the humus contained in various soils, or moist seeds that have undergone fermentation, are kept under a bell jar filled with oxygen, this gas is gradually converted into carbonic acid." Though this is not very remarkable, the following fact is very much so:—"If hydrogen gas be mixed with the oxygen it is converted into water. As the hydrogen disappears, half of its volume of oxygen disappears also."

"When carburetted hydrogen, carbonic oxide, or the hydrogen obtained by the action of red-hot iron on water, are, in this experiment, substituted for hydrogen obtained by dissolving zinc with acids, they do not undergo oxidation." Saussure adds, "These decaying substances act upon the mixture of oxygen with hydrogen in the same way as platinum, and those gases which prevent the action of platinum also prevent the combination in this case."

It seems to me nothing can be more evident than that the oxidation of hydrogen in contact with decaying materials and oxygen is a purely chemical process that has been further elucidated by the experiments of Schönbein and by the formation of ozonized oxygen.

The oxidation of ammonia to nitric acid in the presence of alkaline bases and in soils containing much humus is also due to the same circumstance.

Evidently, decaying substances are capable of condensing oxygen from the air and bringing it into such a condition that it can combine with other substances which do not combine with oxygen at low temperatures, except when aided by these absorbents of oxygen.

Let us suppose that, in place of the hydrogen in Saussure's experiment, alcohol vapour were brought in contact with decaying wood or some material acting in like manner, and then we shall have an explanation of the production of acetic acid from alcohol. In consequence of the oxidation of its hydrogen, alcohol is first converted into aldehyde, and this by further oxidation passes into acetic acid. It is known that the theory of acetification was first suggested by Döbereiner in his memoir on "the behaviour of platinum sponge towards air and alcohol vapour;" and that the method introduced by Schützenbach in 1823 for the manufacture of vinegar is based on this theory.

In this operation wood-shavings or fragments of charcoal are used for determining the oxidation. At one of the largest vinegar factories in Germany, the dilute alcohol receives no admixture during the whole operation; besides air and wood-shavings or charcoal, there is no other material concerned, and the fresh supply of dilute alcohol is only mixed with a little of the unfinished vinegar from a previous operation. The proprietor of these works, Hr. Riemerschmied, sent me some of the beech-wood shavings which had been used uninterruptedly for twenty-five years; and in reply to my inquiry as to whether the *Mycoderma aceti* took part in the production of vinegar, he states that, so far as can be seen, the shavings that have been thirty years in use are quite free from that fungus. According to his data, a hectolitre of wine containing 9 per cent. of alcohol, is converted into vinegar within three days.

If the fermentation of acetic acid were determined by the growth and development of the vinegar-plant, it might be expected that this fungus would increase in some proportion to the acetic acid formed when alcohol was used, as well as when fermented liquors were used. This really takes place when wine is used, and especially with fermented beer-wort, which contains nitrogenous material and phosphates that serve as food for the *Mycoderma aceti*. The production of the fungus is a continual source of hindrance in factories where beer-wort is used, since the interstices of the wood-shavings are gradually stopped up by its growth, and thus free circulation of air is prevented so far as to stop the formation of vinegar.

However, the dilute alcohol used in vinegar works does not contain food for the vinegar-plant, and yet acetic acid is produced without its aid. If the spirit contains amylic alcohol, valerianic acid also is formed.

Microscopic examination of the wood-shavings sent me by Hr. Riemerschmied did not show the presence of *Mycoderma aceti*. They had merely the brown colour of decayed wood, and the structure was quite unaltered.

It is entirely beyond doubt that the vinegar-plant is capable of causing the conversion of alcohol into acetic acid, but this effect is not the result of a physiological process. For the conversion of alcohol into acetic acid oxygen only is necessary, and that the *Mycoderma aceti* does not and cannot furnish. Analyses of the air discharged from the vessels where the vinegar is made, show that the oxygen consumed in the oxidation of alcohol is taken from the air, and the only part taken by the vinegar-plant in the process is that of determining the absorption of oxygen; it is active only in virtue of this chemical property, and it can be replaced by a large number of dead materials or parts of plants.*

These well-known facts prove that the production of acetic acid from alcohol is not brought about by a physiological process; acetic acid is not a product of the *Mycoderma aceti*, but a product of oxidation.

(*To be continued.*)

* Bibl. Univ. de Genève, Feb. 1834.

* The comparatively large amount of nitrogenous material remaining after the fermentation of beer-wort or wine-must, containing little sugar, is a main cause of the beer or wine turning sour, for that nitrogenous material has a great tendency to attract oxygen. In German breweries gypsum is added to the boiling wort with the object of reducing the amount of nitrogenous material, and fermentation is carried on at a low temperature to avoid formation of acetic acid.

In the manufacture of spirit from potatoes and maize, sulphurous acid has been found very useful for augmenting the yield of alcohol by preventing formation of acetic acid. The maize is mashed with water containing some sulphurous acid. In Austria and Hungary this procedure has been dealt with as a mystery, and manufacturers have paid large sums for being taught it. I have ascertained, by special experiments, that a moderate amount of sulphurous acid has scarcely any influence on the fermentation of beer-wort or of sugar with yeast.

WATER CHESTNUTS.

BY M. C. COOKE.

The name of "water chestnuts" has been applied to the fruits of several species of *Trapa*, aquatic plants belonging to the Natural Order Haloragaceæ, of which the European species, *Trapa natans*, the "Marron d'Eau" of the French, is said to have furnished part of the food of the ancient Thracians. The three principal Oriental species, if all are really distinct, are—

Trapa bicornis, L.—Nuts with two opposite, recurved, very obtuse horns. The *Lin-ko* of the Chinese. A native of China, where it is carefully cultivated in lakes, ponds, and other receptacles of water.

Trapa bispinosa, Roxb. (fig. 1).—Nuts with two opposite, straight, barbed, spinous horns. The *Singhara* of India. Cultivated in Bengal and other parts of India as high as Kashmir.

Fig. 1. *Trapa bispinosa*, Roxb.

Trapa quadrispinosa, Roxb.—Nuts with two opposite pairs of straight, acute, spinous horns. A native of Sylhet, where it is found floating on lakes and pools of fresh water.

All these species are esculent, consisting chiefly of starch, but it is to the Singhara nut, *Trapa bispinosa*, that most of our observations will apply.

We learn from Colonel Sleeman that the water chestnut is everywhere as regularly planted and cultivated in fields, under a large surface of water, as wheat and barley are on the dry plains. It is cultivated by a class of men called Dheemurs, who are everywhere fishermen and palanquin-bearers, and they keep boats for the planting, weeding, and gathering the Singhara. The holdings or tenements of each cultivator are marked out carefully on the surface of the water by long bamboos stuck up in it, and they pay so much the acre for the portion they till. The long straws of the plants reach up to the surface of the water, upon which float their green leaves, and their pure white flowers expand beautifully among them in the latter part of the afternoon. The nut grows under the water after the flowers decay, and is of a triangular shape, and covered with a tough brown integument.

The people are very fond of these nuts, which are often carried upon bullocks' backs two or three hundred miles to market. They ripen in the latter end of the rains, or in September, and are eatable till the end of November. The rent paid for an ordinary tank by the cultivator is about 100 rupees a year. Sometimes 200 rupees is paid for a very large one, and even 300, or £30 a year. But the mud increases so rapidly from this cultivation that it soon destroys all reservoirs in which it is permitted, and where it is thought desirable to keep up the tank for the sake of the water, it should be carefully prohibited.

Dr. Stewart says that in Kashmir, miles of the lakes and marshes are covered with this plant. The fruit is said to yield the Government of Kashmir £12,000 of annual income. Moorcroft states that Runjeet Sing derived nearly the same share. From 96,000 to 128,000 loads of this nut are yielded annually by the lake of Ooller alone. In the valley it furnishes almost the only food of 30,000 people for five months in the year.

The seeds contain a great quantity of fecula, and are eaten by the natives, either boiled or roasted; when boiled they are said to resemble a chestnut. The seed is also ground into a coarse flour, and cakes are made therefrom. The Chinese species is similarly employed in that country.

The flattened, triangular kernel of this nut or seed is from three-quarters to an inch in diameter, and about a quarter of an inch in thickness, internally white and friable, externally covered by a thin adherent brownish skin. Almost the whole of its substance consists of regular, oval or elliptical starch granules (fig. 2), with a central crack or hilum, sometimes stellate in rounded granules. The form of the starch granules, their regularity, and the character of the hilum, are sufficient to distinguish them from any others that we have seen.

Fig. 2. Starch granules of *T. bispinosa.*

In India the natives consider these nuts cooling, and that they cure bilious affections and diarrhœa. They are also used to form poultices. The red powder which is so freely used at the Hooly festival is made from the starch of these nuts, coloured red with the flowers of *Butea frondosa* or *Carthamus tinctorius.* The drug called "sweet hermodactyls," or *Surinjan shirin*, found in the bazaars of India, consists chiefly of the kernels of *Trapa bispinosa*, and sometimes they are also mixed with *Surinjan tulk*, or "bitter hermodactyls," as an adulteration.

NOTES ON CHALYBEATE WATERS.

BY JOHN MACPHERSON, M.D.

The following notes, though made with the view of determining the relative value of the strong Harrogate chalybeate, of which so much has been of late heard, are of a general nature, and may be useful at this season of the year.

There are exceedingly few mineral waters that contain chloride of iron in solution. Nay, it is usually supposed that chlorine has been erroneously assigned to iron by chemists, whose analyses of waters would show the presence of its chloride. Besides some waters in Java being said to contain chloride of iron, that salt has also been assigned to the following ones, and in the following proportions in the Prussian pint:—

	Harrogate.	Alexisbad.	Bukowina.
	gr.	gr.	gr.
Chloride of iron	1·6	1·083	0·920
Carbonate of iron	1·27	—	0·003
Sulphate of iron	—	0·574	1·966
Total iron	2·87	1·657	2·889
Total mineral constituents.	49·69	4·876	6·220
Carbonic acid	2·8 in.	traces	none

These three are, therefore, undoubtedly strong iron springs; but there are others stronger, without including the almost poisonous vitriol ones, as they have been called; for instance,—

	Wassenach.	Parad.	Muskau.
	gr.	gr.	gr.
Carbonate of iron . . .	3·08	4·8	1·385
Sulphate of iron	—	—	1·526
Total iron	3·08	4·8	2·911
Total mineral constituents.	12·9	12·4	8·673
Carbonic acid	traces	26 in.	traces

From these comparisons it appears that the Harrogate Muspratt well is not unique in being supposed to contain chloride of iron; that it does not contain iron in uniquely large quantity; and also, that it is by no means a pure spring, for after allowing for 22·5 grs. of common salt, which would not probably interfere much with the assimilation of the iron, it contains 27·2 grs. of other salts. Finally, the quantity of carbonic acid is very trifling.

Are strong iron waters like the foregoing ones well adapted for drinking? The general voice is against them, and they are usually employed only for baths. And it may be said that, in spite of all theoretical assertions of their styptic nature, iron waters are of little use for what are popularly termed steel baths, unless they contain a great deal of carbonic acid; for the non-absorption by the skin of solutions of salts in ordinary baths seems to be definitely settled by the recent inquiries of the Société d'Hydrologie, of Paris. Still, notwithstanding the presumption against such a spring as the Muspratt one, the accounts of the practitioners who use it are entitled to consideration. They assert that immense improvement often results from its use. Glandular swellings, low forms of gout, dyspepsia, and fatty heart, have all been found to yield to its influence. Such general statements are too often made respecting all waters, and from Dr. Myrtle's book I am much inclined to think that he has obtained at least as satisfactory results with the Tewit and the Kissingen well, containing as they do only ·14 and ·33 grain of carbonate of iron respectively. And he says of the Muspratt well, that its water must be given with much circumspection, that it is not only most difficult of digestion frequently, but is apt to cause some of the most painful physiological effects common to the ordinary preparations of iron.

If, then, general experience has shown that these strong iron waters are inconvenient for drinking, what strength of iron waters has practically been employed? Waters containing from ·35 to less than 1 gr. in 16 oz. of the carbonate of iron, waters not containing a large amount of solid ingredients and containing a good supply of carbonic acid—such are the waters the efficacy of which has been proved by the experience of centuries. This is well illustrated by glancing at the composition of the most popular chalybeate waters.

	Spa.	Schwalbach.	Pyrmont.
Carbonate of iron .	0·4	0·46	0·42
Other salts . . .	1·65	11·9	17·9
Carbonic acid . . .	20·1	45	40 inches

Or take a few excellent wells, not perhaps so widely known. Königswarth, near Marienbad, in Bohemia, at a height of 2000 feet; Elster in Saxony; Bocklet, close to Kissingen; Rippoldsau, on the whole the best of the Black Forest chalybeates, at a height of 1800 feet; or Liebenstein in Central Germany, as high as Schwalbach, or about 900 feet.

	Königswarth.	Elster.	Bocklet.	Liebenstein.	Rippoldsau.
Carbonate of iron	·65	·48	·67	·59	·67
Other salts . .	5·8	16·12	24·6	10·7	20·6
Carbonic acid .	37·2	32·9	37·3	40·9	32·8in.

All these are specimens of waters in which iron is presented in a shape rendering it easy of assimilation. I shall not enumerate the springs, such as Marienbad, or Franzensbad, or Harrogate, in which the quantity of sulphates or of common salt is so great as to make their action distinctly purgative. Two salt springs appear to have common salt in a desirable proportion. These are—

	Rakotski, Kissingen;	and Louisenwell, Homburg.
Common salt . .	44·7	23
Carbonate of iron	·33	·33
Carbonic acid .	41	32 inches

But even in them, and particularly in the Rakotski, there is too much common salt.

The great defect of our pure chalybeates, such as Tunbridge Wells or Llandrindod, is the want of carbonic acid to render the waters sparkling for drinking, or useful for baths. The warm chalybeates of Bagnères de Bigorre are also deficient in gas.

Perhaps the places where the best carbonated iron baths can be had are Schwalbach, Pyrmont, Liebenstein, Königswarth, Franzensbad, Elster, and St. Moritz. I believe that the new baths at Spa are good, but they do not contain the largest amount of gas.

With reference to St. Moritz, it is probable that its curative effects depend more on its climate during three months of the year and on its baths, than on its not powerful chalybeate. Those who are in search of stronger chalybeates than it affords would do well to go south and visit St. Caterina, at the same elevation as St. Moritz, or St. Bernardin, a few hundred feet lower, both with a large amount of carbonate of iron and of carbonic acid; or, if they will descend a little towards Italy, they will find two of the best chalybeates in existence, with a large supply of iron and carbonic acid, and minute quantities of carbonate of soda and of common salt—Rabbi at a height of about 1800 feet, and Pejo perhaps 100 feet higher. Proceeding further and fairly into Italy, he will find the more polished Recoaro, with less potent waters, however. The whole five are in beautiful scenery. The analysis of the waters of Pejo gives about 1 gr. of carbonate of iron, with carbonate of soda, 8·6; carbonate of lime, 1·8; common salt, 2·9; total mineral constituents, 15 gr.; carbonic acid, 31 inches: while Rabbi has 0·91 of carbonate of iron; carbonate of soda, 6·4; carbonate of lime, 2·3; common salt, 2·2; total mineral constituents, 12·6 gr.; carbonic acid, 29 inches. It is scarcely possible to have better combinations.

The war which has broken out since these lines were penned will compel those who will not venture into Switzerland and the Tyrol to make the most of our own chalybeates. At their head in England stand Tunbridge Wells and Harrogate, Llandrindod in Wales, Lisdunvarna in Ireland. Pannanich Wells, near Ballater, is almost the only chalybeate in use in Scotland. A host of such springs were formerly in repute in the three kingdoms.—*Medical Times and Gazette.*

ON THE COMBINATIONS OF CARBONIC ANHYDRIDE WITH AMMONIA AND WATER.

BY EDWARD DIVERS, M.D.

(*Continued from p. 96.*)

II. *Half-acid Ammonium Carbonate.*

History.—Rose first definitively obtained this salt in 1839,* but I think Hünefeld† came across crystals of it on cooling the aqueous alcohol from which he had distilled some commercial carbonate; for he described some of the crystals obtained by this cooling as rhombic plates, and, as crystals of the half-acid carbonate can thus be prepared, it is probable these were some.

H. St. Claire Deville obtained it in a different way in 1852, and gave an account of its crystalline form.‡

Preparation.—The half-acid carbonate was obtained by its discoverer by distilling some commercial carbonate at a gentle heat in a retort, the mouth of which was joined to a tube dipping under mercury, until the contents of the retort had become entirely liquefied, and setting aside the liquid thus obtained in a closed vessel to crystallize.

Deville dissolved commercial carbonate in concentrated ammonia-water at a temperature of about 30°, and

* Poggendorff's 'Annalen,' vol. xlvi. p. 373. Also Taylor's 'Scientific Memoirs,' vol. ii. p. 98.

† In 1836. Journ. für Prakt. Chemie, vol. vii. p. 25.

‡ 'Comptes Rendus,' vol. xxxiv. p. 880. Ann. de Chimie [3], vol. xl. p. 87.

set aside the solution to crystallize with or without the previous addition of alcohol. This method is not very satisfactory.

To the methods given by Rose and Deville I have to add two others quite different. The first and most important one is the last method given for preparing the normal carbonate. A concentrated solution of commercial carbonate in warm water is made in a loosely-closed vessel, and left to crystallize; the operation is repeated again and again with the mother-liquor and more of the carbonate of commerce, until in place of the compact crop of crystals at first obtained, a bulky and loosely-arranged crop of thin plates is produced; this and those succeeding it are crops of the half-acid carbonate.

By using not too great a charge of commercial carbonate, and allowing the crystallization to go on, in a place not too cold, crystals form and grow slowly to a considerable size; or large crystals may generally be obtained by decanting the mother-liquor, after twenty-four hours' standing, off the first or second crop of half-acid carbonate, and leaving it undisturbed in a closed vessel for some weeks.

A modification of this method is to heat some commercial carbonate in a retort with just enough water to cover it, at a temperature not exceeding 60°, until all is dissolved, then cooling the solution, and setting it aside to crystallize, when it yields the half-acid carbonate mixed with acid carbonate.

Pelouze and Frémy state, in their 'Traité de Chimie,'* that the half-acid carbonate, identical with that obtained by Rose, may be procured by cooling a solution of commercial carbonate to about 0°, and this statement reappears in one of our standard English works on chemistry. It is utterly at variance with my own experiments on the subject. When the solution has been strong enough to crystallize, the crystals obtained at 0° have always proved to be the acid carbonate. And further, if a solution which has deposited crystals at 0° is heated up with more of the commercial carbonate, and again cooled, the crystals which form are still those of the acid carbonate. Pelouze and Frémy are besides in this statement in direct opposition to H. St. Claire Deville, who, in his paper "Sur la Forme et la Composition des Carbonates Ammoniacaux,"† says that prismatic flattened crystals of the acid carbonate are produced by greatly cooling a solution of the commercial carbonate.

The other new process is the distillation of the ammonio-magnesian carbonate, the products being a fluid distillate, giving crystals of the half-acid carbonate, and a solid directly deposited in the neck of the retort of which the more remote parts are also this carbonate. Further details of the distillation will be afterwards given.

To ensure success in preparing the half-acid carbonate for analysis, similar precautions to those recommended for preparing the normal carbonate should be taken, and, as in the case of this salt, when the crystals are small a feeling of dampness in the drying-paper must be disregarded, and the operation arrested as soon as the crystals cease to make wet spots on bibulous paper pressed against them for a few moments.

Sensible Properties.—Half-acid ammonium carbonate has a very pungent ammoniacal taste and smell, but the pungency is less intense and persistent than that of the normal carbonate.

Form.—It occurs in the form of thin, elongated, six-sided plates, or, when these plates are left to grow in their mother-liquor, of flattened, right rectangular prisms, terminated by the faces of a rhombic octahedron.

Measurements of the angles of the crystals are given in Deville's paper in the 'Annales de Chimie.'

Chemical Composition.—Results of the analyses of the half-acid carbonate have been published by Rose and Deville in their respective memoirs already referred to. Rose deduced from his analysis the formula—

$$(CO_2)_3(OH_2)_5(NH_3)_4,$$

and Deville has adopted the same formula. My own experiments have led me to adopt a different formula, and the results of my analyses point unmistakably to the formula having four atoms of water. It must be taken into consideration that in no case can the samples analysed be quite dry, as the decomposition by which ammonia is liberated also sets free water; because the presence of this water must lower the numbers found for both the carbonic anhydride and the ammonia, thus making the numbers for the former correspond closely to the calculated number, in spite of the decomposition which the salt has undergone, and those for the latter show a greater deviation from the calculated number than the actual loss of the ammonia itself would cause.

The results of Rose's analyses correspond closely with the numbers calculated for a salt containing five atoms of water:—

Rose's Analyses.

	I.	II.	III.	IV.
Carbonic anhydride .	—	45·35	44·61	44·69
Ammonia	23·69	—	—	—

As I have already said, when speaking of the normal carbonate, the accuracy of the results of an analysis of such changeable salts depends very much upon the success in preparing them for analysis. Rose makes no mention of the method he adopted for getting the salt in the dry state undecomposed, or of his success in doing so; yet it will be seen, on examining his results, that the ammonia is slightly in excess of, while the carbonic anhydride is actually less than, the calculated quantity,—a somewhat anomalous result, admitting the accuracy of his analyses.

If it be assumed that the salt analysed, which was in very thin plates, retained some of the mother-liquor, this difficulty respecting the results will be removed; for the mother-liquor from the crystals was itself a solution of *normal* carbonate, according to Rose. This assumption we are justified in making; for it has been shown by Deville's results that other analyses recorded in Rose's paper prove that the crystals employed must have contained mother-liquor in their interstices. And in further support of this assumption, we have also Deville's testimony, that the half-acid carbonate can hardly be obtained at once dry and undecomposed.

Turning now to Deville's deduction of the same formula as Rose's, from the results he himself obtained, we shall not find it, I think, more satisfactory than that of the German chemist. He gives the annexed table of his analyses, the samples—none of them dry—being drier in the order of their numbers. (The water was determined directly.)

Deville's Analyses.

	I.	II.	III.	IV.	Mean.
Carbonic anhydride .	41·4	46·8	46·6	47·8	45·65
Ammonia	21·1	23·7	24·2	23·6	23·15
Water	37·5	29·5	29·2	28·6	31·20

The practical accuracy of these analyses, as such, cannot be impugned; they were performed with great precaution to avoid sources of error, and the three constituents were all determined by a single operation in each case. Now, their mean results correspond closely enough with the percentage numbers for the five-atoms-of-water formula. But then we are certainly not right in taking these mean results as a true indication of the composition of the salt. We can only properly take the mean results of a series of analyses as likely to be more accurate than the results of a single analysis, after we have satisfied ourselves that the unavoidable and undetected imperfections in the performance of the operations are as likely to have influenced each result in one direction as in the opposite. With the present series of analyses, we know

* Vol. ii. p. 483.

† Ann. de Chimie [3], vol. xl. p. 87.

this not to have been the case; but that, on the contrary, every sample used contained adhering water, and one more than another; and further, that every sample might have lost ammonia, while none could have had it in excess. Obviously, therefore, it has been wrong to take, as has been done, the mean percentage quantities of the constituents as the nearest approach to the quantities in the pure salt.

I shall now endeavour to show that the several results obtained unequivocally indicate, when taken in conjunction with each other, that the salt examined was a half-acid carbonate, having *less than five* atoms of water. All the samples, save the last, show but very slight evidence of loss of ammonia, and even in this the ammonia need only to have been 24·6 instead of 23·6 to be in the right proportion to the carbonic anhydride. All the samples were damp; but as the first sample yielded 8 per cent. more water on analysis than the second and third samples, equally free from decomposition, but better dried, no other conclusion can be come to than that either the first sample was a very wet one indeed, or else that a more hydrated half-acid carbonate breaks up, while in a moist state, into water and a less hydrated one,—which no one contends for, and which, from the facts of my own analyses, I cannot admit. In the second and third samples, the water is nearly 2 per cent. less than the calculated quantity for five atoms; and yet both had practically suffered no decomposition, and both were damp. How is it possible, therefore, from these results, to deduce for the salt the formula with five atoms of water? In the fourth sample, the water is even $2\frac{1}{2}$ per cent. less than the calculated quantity; but then this sample was somewhat decomposed. It is not too much to suppose that, as the first sample contained 8 per cent. more water than the others, these, moist as they were, still retained $2\frac{1}{2}$ per cent. of moisture. And I contend that, had the drying been carried on uninterruptedly, instead of in four stages, as was done, and with due protection of the salt from the free action of the air, more water might have been absorbed from the wet salt, without such a loss of ammonia as would have rendered the indication of the analytical results ambiguous. Even, however, as they stand, the results indicate the salt with four atoms, in a slightly decomposed and moist state; and in this state they are described to have been. They contain, in this moist state, only $2\frac{1}{2}$ per cent. too much water for this formula. I consider, therefore, that Deville's analyses in reality require the adoption of the formula with which my own analyses so closely agree.

It may be added that, when considering the relations and analogies of this salt, a fifth atom of water is found to render its composition peculiar, if not abnormal.

Chemical Behaviour.—I have little to say of the behaviour of the half-acid carbonate under circumstances capable of affecting it. The change it undergoes into acid carbonate, when exposed to the air, is quite analogous to that undergone by the normal carbonate:—

$$(CO_2)_3(OH_2)_4(NH_3)_4 = 3\,CO_2OH_2NH_3 + OH_2 + NH_3.$$

It is the difficulty of preventing this change, which renders so very doubtful the accuracy of Rose's analyses.* When heated, its crystals melt, and are decomposed. It is soluble in a little more than five parts of water at 15°; less water than this first becomes saturated, and then slowly decomposes the undissolved salt, leaving behind acid carbonate. Its solubility is, therefore, as nearly as can be stated, that of the acid carbonate it may be said to contain; 272 parts containing 158 parts of the acid carbonate, or about three-fifths of their weight. For the acid carbonate is soluble in 8 parts of water, and, therefore, three-fifths of a part in about 5 parts. A solution saturated at 20° evolves sufficient carbonic anhydride to repel the stopper of a bottle containing it; and, gently heated, effervesces copiously. A saturated solution, cooled, gives good crystals of acid carbonate. It is also decomposed by spirit, acid carbonate being left undissolved. Ammonia has, no doubt, an action upon it, compounded of its respective actions upon the normal and acid carbonates. In short, the half-acid carbonate seems to be intermediate in its other chemical properties, as it is in composition, to these carbonates.

When the half-acid carbonate is obtained by treatment of the commercial carbonate with water, the mother-liquor from the crystals is equivalent in composition to a solution of normal carbonate, with or without a slight excess of ammonia. And Rose also found that the mother-liquor from the crystals formed by his method was a solution of normal carbonate. From this somewhat remarkable fact the half-acid carbonate seems to be totally insoluble in a concentrated solution of normal carbonate. An explanation of this fact on another assumption will, however, be given in another part of this paper.

I may here mention one fact of interest concerning crystals of the half-acid and normal salts, viz., that they appear to act on the glass, both English and German, of the bottles and flasks in which they are stored for some time, destroying the transparency of its surface. I have not observed the solutions of these salts to do so.

* On allowing the crystals of half-acid carbonate to decompose in a limited quantity of air, Deville has observed crystals of acid carbonate form, which he thinks belong to a different system from that of the ordinary crystals of acid carbonate. ('Comptes Rendus,' vol. xxxiv. p. 880.)

PHARMACEUTICAL NOTES.

BY ALBERT E. EBERT.

Not the least duty of the pharmacist, though one more honoured in the breach than the observance, is his obligation to communicate to his fellows of the craft such improvements in manipulation, in apparatus, and in the convenient arrangement of his shop as his every-day experience behind the counter must occasionally suggest. How much practical, *desirable* information is hid under a bushel by this sin of omission we can only conjecture; but if the thousands would communicate their personal experience, it cannot be doubted that a valuable fund of useful knowledge would accumulate. The following suggestions are made with no great claim for their originality or importance, but, since they are based upon actual experience, they may be of utility to others as they have been to us.

Test-tubes, indispensable for their legitimate purpose, will often answer another useful end. For effecting solutions of small quantities of the alkaline or metallic salts, especially when the solvent is of a viscid nature, we have found the test-tube a valuable auxiliary,—more convenient in use than the mortar, less wasteful, and effecting the solution with greater dispatch. We proceed by dropping the salt into the tube, adding a portion of the vehicle, and applying heat, with constant shaking of the tube. Solution quickly follows; the warm liquid is added to the remainder of the vehicle, previously placed in the vial, and the whole is mixed by agitation.

Of course, the dispenser will see that this method of procedure is not applicable where the quantity of the salt exceeds its solubility in the whole liquid at ordinary temperatures, as crystallization would occur. This relation of salt to solvent is often met with, and then the only resort is to the mortar, in which the salt may be rubbed to powder before its mixture with the liquid, and the attachment of a "shaking label" to the vial. Solid extracts may be brought into solution by the same means with great facility.

The moral effect of such a display of chemical ware before the admiring eyes of the patient may be considered, in some rare instances, as equally beneficial with the product of the combined skill of the physician and pharmacist.

In spreading plasters extemporaneously, convenience requires, and neatness demands, an uncoated marginal edge. This is usually secured by pasting strips of paper along the edges of the skin, and removing them after the spreading of the plaster is effected. It is just here that a practical difficulty frequently arises. The paper edges are liable, from drying of the paste, to adhere so strongly that either paper or skin will give way upon an attempt at their removal; the application of water will then be necessary to soften the attachment, and the final result may be expected to present a daubed and uncleanly aspect. This difficulty may be entirely avoided by applying to the paste-brush a little glycerine before the adjustment of the marginal strips.

Coating of Pills.—A prevailing fashion in pharmacy, or rather among prescribers, is the use of sugar-coated pills. This is very detrimental to the practice of legitimate pharmacy, whatever may be its effect upon those who swallow the pills. An extemporaneous process of sugar-coating is a desideratum for which our colleges of pharmacy should unite in offering a prize. In the absence of this, a very excellent substitute may be found in resin. This substance is easily applied, gives a hard, tasteless surface, a handsome appearance, and has a decided tendency to protect the pills from change. The coating cannot interfere with their medicinal action, for it is readily dissolved by the fluids of the stomach. The process of coating is easy and expeditious, and no apparatus is required.

We proceed as follows, keeping prepared a solution of resin in ether, one part of resin to ten parts of the fluid. We return the pills, after they have been rolled to shape, to the mortar in which their ingredients were mixed, pour over them a little of the resinous solution, give the mortar a few twirls, and roll them out upon the platform of the pill-machine or pill-tile. By the time the label is prepared the pills will have become sufficiently dry to allow boxing. A little dusting powder, preferably lycopodium, should be dusted over them, and the work is done.

Speaking of pills, an idea occurs which is worth suggesting to the manufacturers of pill-machines, namely, that these convenient implements be made to cut thirty pills instead of twenty-four. The former number of pills is much more frequently prescribed than the latter. A great improvement would be the placing of numerals before each groove, so that the operator may not be obliged to count the grooves whenever a fractional number of pills are to be divided.

While making suggestions, we will continue by adding that there is a great need for vials, especially for half-, one-, and two-ounce vials, with lips suitable for dropping liquids. With the ware of the market at present, it is almost impossible for an expert to be successful in dropping; so what must be the experience of invalids and nurses in this respect? The defect may be easily remedied by making the lips of vials for such uses broad and *thin*. If we insist in demanding such improvements as we are suggesting, manufacturers will be eager to supply them.—*The Chicago Pharmacist*.

GLUCOSE.

We learn from the 'Grocer' that glucose is fast becoming an article of commerce. Some large parcels have been already received from the Continent, and, unless the lowness of the price obtained for it proves to be a bar to its free production, considerable quantities may be expected. It is offered in the form of huge blocks or cakes, but when specially prepared for the use of brewers, it undergoes a process of crushing that reduces it into small particles resembling grains of malt. It is not allowed by the Excise authorities to enter a brewery in a liquid state. By some brewers, especially those interested in the production of pale sparkling ales, it is preferred to either malt or sugar for obtaining sound and wholesome liquors, in which there is none of that acidity, impurity, or treacly sweetness which may be frequently detected in ales and beer brewed from the common classes of raw sugar. With confectioners, who require the addition of an almost colourless preparation for their more delicate manufactures, it is gradually taking the place of sugar.

CHEAP AERATED BEVERAGES.

The following analyses and remarks are taken from an article with the above title in the 'Food Journal' for August:—

"*Lemonade.*—A good and pure lemonade should show on analysis nothing but sugar and citric acid, and should have a pressure in bottle of at least 60 lbs. to the square inch. Six samples were tested with the following results:—

No.	Contents of bottles.	Citric Acid.	Sugar per bottle.	Tartaric Acid per bottle.	Sulphuric Acid.	Copper or Lead.
				grs.		
1	9 oz.	None	Nearly 1 oz.	9·21	None	None
2	½ pint	,,	About ½ oz.	20·46	,,	,,
3	8½ oz.	,,	,, ,,	17·50	,,	Trace.
4	8½ oz.	,,	,, ¾ oz.	17·50	,,	,,
5	½ pint	A little	,, ,,	40·00	,,	Large trace.
6	,,	None	,, ,,	20·60	,,	Trace.

"Thus we see that in the cheap lemonade there is rarely a trace of lemon-juice at all, the syrup being compounded of sugar, tartaric acid, and essence of lemons. In four cases out of six, poisonous metallic contamination was abundantly evident. The aeration was very imperfect, except in the case of No. 4, but even in that sample it fell far short of the proper amount. The lemonades were all more or less turbid, and, under the microscope, revealed myriads of organized germs and cells with a bright nucleus."

"*Ginger Beer.*—In the common ginger beer, we find that the rule is to reduce the sugar and the ginger to the minimum possible quantity, adding cream of tartar and capsicum to contribute the sharpness and pungency so in vogue with the drinkers of the article. The beer is also commonly contaminated with iron, we presume from the boilers in which it is made. Six samples of this beverage were also tested, with the following results:—

No.	Contents of Bottle.	Acetic Acid per bottle.	Cream of Tartar per bottle.	Total Solids.	Metals.
1	½ pint	2·63 grs.	2·0 grs.	187·6 grs.	Iron.
2	,,	7·75 ,,	3·6 ,,	137·1 ,,	,,
3	,,	11·00 ,,	4·0 ,,	226·0 ,,	Copper.
4	,,	9·60 ,,	4·0 ,,	172·5 ,,	None.
5	,,	2·30 ,,	3·5 ,,	244·5 ,,	,,
6	,,	5·60 ,,	2·7 ,,	205·4 ,,	,,

"This table shows that in all the beers acetic acid had been formed, and some, such as 3 and 4, were very bad in this respect. These same numbers are also to be distinguished by an extra dose of cream of tartar, while No. 3 was found to contain copper, presumably from the vessels used in manufacture. One bottle smelt so strongly of petroleum that its contents were undrinkable."

SEWAGE IRRIGATION.

The following letter from Mr. J. J. Mechi, of Tiptree Hall, on the above subject, has appeared in the 'Times,' under the heading "Waste":—

"Every well-wisher to the country who reflects upon the great sewage question, and its present condition, must feel humiliated by our national and willing helplessness and shortcomings as regards the disposal and utilization of this our vast food-producing treasure. The blundering from beginning to end has been immense. Our sanitary reformers, in their laudable desire to preserve our health, abolished our cesspools, poisoned our rivers, and deprived us of the only cheap and effective means for fertilizing our fields and filling our stomachs.

"A jury of Chinamen would pronounce us guilty of suicidal insanity, for in China their 400 millions of people depend mainly on human sewage for the production of their food,—they do not, like us, purchase birds' dung from Peru, or import the antiquated dust and ashes of foreign men and animals. Every one in Britain believes in the sheepfold, but about the man-fold, which is superior in its effects and results, there has been complete apathy.

"The voluntary principle has been tried and failed. Farmer So-and-So, near a town, declines to have the nasty stuff on his land, and so has obstructed its use. Some wholesome despotism, in railway fashion, by Acts of Parliament, has authorized Corporations and Boards of Health to take land for the purpose of receiving the sewage. London is, however, still an exception to this wholesome rule. We have expended four millions sterling in sewers to convey it into and to poison and obstruct our noble Thames, and have, for this worse than useless purpose, to pay a rate of threepence in the pound for some thirty or forty years, besides the heavy annual working expenses. Ratepayers are naturally indignant that such a valuable food-producing material should be wasted. The Thames Conservators have taken action by Parliamentary powers to prevent solid matters passing into the river. It must, therefore, go on to the land. But the extent of land required, who shall pay for it, and when it is to be paid for or liquidated, are important and difficult questions. Ratepayers very reasonably object to be mulcted in the cost of land which must improve greatly in value, and will, with the sewers, become a great boon to future generations.

"It appears to me that the rule which compels Boards of Health or Corporations to repay the whole cost of sewage in a few years, in addition to the interest and annual working expenses, is too stringent; and that, looking to the permanency of the works, the period of repayment should be considerably extended. The same remark holds good as to the purchase of land required to receive the sewage. It is the fear of imposing heavy rates for an early repayment that causes Corporations or Boards of Health to limit their purchase of land to a *minimum*. Why should they not be allowed to mortgage the land for long periods, thus easing the present ratepayers, and transferring a fair portion of the burden to posterity, who, by the improved value of the land, will be better able to bear it? Reliable evidence shows unmistakably that the rental and value of sewaged land increases year by year, and will continue to do so until it reaches its *maximum* of fertility. The sewaged Edinburgh meadows, the average annual value of which has risen to £27 per acre, prove this; land near Croydon, worth in its unsewaged state about 30*s.* per acre, was let when sewaged for £5 per acre, and now (the first seven years' term having expired) it is let, with an addition of 250 acres, at £9 per acre per annum, thus proportionately multiplying the value of the fee simple.

"A very large area would be required for the utilization and purification of the London sewage. We know that London consumes daily the annual available produce of 20,000 acres, and a similar quantity is required weekly for London horses.

"The average manurial power of Britain is equal to only two sheep or two human beings per acre. At that estimate London sewage should fertilize 1,750,000 acres. Such an area is, of course, at present out of the question; but taking the accepted impression that we should allow 100 human beings to each acre (or fifty times our general manurial power), even at this rate 35,000 acres would be required. To purchase this land at £50 per acre would cost £1,750,000; to prepare it for the reception of sewage by drainage, levelling, pumping, etc., would bring the probable cost to nearly £2,500,000.

"The Metropolitan Board of Works would hardly dare to exact a rate sufficiently large to liquidate this amount in a short period. The right of mortgaging during a century would remove the difficulty, or probably taking powers to resell the land when improved, reserving the powers of sewaging, etc.

"At all events, the recent action in Parliament of the Thames Conservancy will compel us to fertilize the land, rather than poison and choke our noble river."

Silk and Sunflowers in Mauritius.—We gather from the last annual report of the Royal Society of Arts and Sciences of Mauritius, that they had received a communication from the "Silk Supply Association," asking whether silk could be grown in the island, and laying down as a principle, that wherever the mulberry-tree will grow, there silk can be produced. The Society referred the question to a committee, who report unanimously that "not only can the mulberry be cultivated and the silkworm reared in Mauritius, but that an establishment founded on certain principles (which they indicate) would implant the industry of the silk-grower on a firm basis in the island." The committee feel so confident of success, that they offer to undertake the management of the establishment; and we notice that a specimen of silk grown in Mauritius, and reeled more than twenty years ago, was valued at 30*s.* a pound in the London market last January.

Another plant, the sunflower (*Helianthus annuus*), is to be cultivated, and seeds have been distributed among persons willing to undertake the task. It is popularly believed that plantations of sunflowers tend to improve local climates, by neutralizing the effect of marsh air and checking the liability to intermittent fever; and in some parts of Holland and the South of France the growth of sunflowers has been encouraged as a means of sanification. The same motive has led to the experiment now making in Mauritius, where some of the planters remark that, apart from all other considerations, the seeds of the sunflower yield a valuable oil and are much relished by poultry.

A climbing plant, known to botanists as the *Telfairia* (or *Joliffia*) *Africana*, was formerly abundant in Mauritius, but has, for some as yet unexplained reason, completely disappeared from the island. The plant being useful as well as ornamental, growing to a great height and bearing seeds which yield a rich sweet oil, is to be reintroduced; and at the request of the Governor, Sir Henry Barkly, a supply of seeds has been forwarded from Zanzibar by Dr. Kirk.—*Athenæum, July 30th.*

Clark's Water-Softening Process.—It appears that the patent for this process has expired, and that anybody can use it now that likes to do so. Seeing that the London water companies have us entirely at their mercy in the matter of water supply, it would be only a gracious act if they were to determine henceforth to apply Clark's softening and purifying process to the whole of their respective supplies. If the companies decline this spontaneous manifestation of regard for their customers, it may be worth while for the Home Secretary to remember this point in his promised legislation upon the recommendations of the Royal Commission on Water Supply.—*Lancet.*

Adulteration of Carbonate of Soda.—The 'Antwerp Journal of Pharmacy' calls attention to the practice of adulterating carbonate of soda by mixing with it a proportion of sulphate of soda. At first sight the admixture is not apparent, though the two salts differ essentially from each other, both in their crystallization and their chemical properties. The fraud is one that may easily be detected by a chemist.

The Pharmaceutical Journal.

SATURDAY, AUGUST 13, 1870.

PHARMACEUTICAL EXHIBITIONS.

The practice of holding periodical exhibitions appears to be gaining favour not only in this country, but also in America, for a circular just received from Mr. J. Faris Moore, announces that at the eighteenth annual meeting of the American Pharmaceutical Association, to be held in Baltimore, on the 13th September next, there will be an exhibition of objects relating to Pharmacy and the Collateral Sciences. It adds that the exhibition has become a prominent and interesting feature of the Association's annual meeting, constituting an exponent of the progress of chemical and pharmaceutical industry, besides affording an excellent opportunity for the manufacturer and wholesale dealer to make his name and goods known to the trade.

Following the precedent established at Nottingham and Norwich, the Liverpool Local Committee of the British Pharmaceutical Conference has decided to hold an exhibition of objects relating to Pharmacy, or having a special interest for members of the drug trade, during the meeting which is to commence on Tuesday, the 13th of September, under the presidency of Mr. Stoddart. The central position of Liverpool, its commercial importance, and the proximity of large chemical manufactories, constitute special reasons for holding such an exhibition there. The objects which it is desirable should be represented are—

1. Novelties or improvements in pharmaceutical processes, including apparatus and utensils for evaporation, distillation, pulverization, displacement, filtration, etc. Applications of gas and steam are especially desired. Models or drawings will also be eligible.
2. Instruments intended for use in chemical investigations, such as apparatus for volumetric analysis, spectroscopes, polarizing apparatus for testing the purity of pharmaceutical preparations, etc.
3. Microscopes, microscopic accessories and objects.
4. New medicines and medical appliances, as galvanic and electro-magnetic machines, enema-syringes, etc.
5. Illustrations of general business fittings and arrangements for dispensing.
6. Improved dispensing appliances, as bottles, boxes for pills and powders, labels, etc.
7. Poison bottles, poison labels, etc. Illustrations of precautions against mistake, either by dispenser or patient.
8. Improved preparations for the administration of medicines. This class would include methods for disguising nauseous remedies by means of capsules, also the various coatings of pills, also improved suppositories and pessaries, liquors and other substitutes for alcoholic tinctures. Artificial mineral waters.
9. Specimens of drugs or chemicals remarkable for fine quality, or for other reasons. Illustrations, botanical or mineral, of the sources of medicines.
10. Foreign preparations, proprietary or otherwise.
11. Illustrations of adulterations, and the means of detecting them.
12. Improved dietetic preparations.
13. Books, English or foreign, relating to pharmacy or the collateral sciences.
14. Historical relics, having an interest in connection with pharmacy, or its cultivators, as portraits, autographs, etc.
15. Any improvements within the scope of the drug trade, or consistent with it, but which are not embraced by previous classes.

The following Regulations are to be observed —

Objects for exhibition are to be delivered at Liverpool free of carriage on or before September 8th, advice being sent at the same time by post, and an invoice of their value, stating whether intended for sale or not; and descriptive accounts written on one side of the paper only should accompany all articles sent. The Committee will take charge of unpacking and re-packing articles sent for exhibition, but whilst every care will be taken, they cannot be responsible for damage. The Committee reserve the right to decline any objects they may consider unsuitable.

A report upon the Exhibition will be prepared by a Special Committee, and published in the 'Proceedings of the British Pharmaceutical Conference,' and intending exhibitors should apply at once to the Hon. Secretary, Mr. E. Davies, Royal Institution, Liverpool.

A similar exhibition is now being held at Newcastle, in connection with the British Medical Association, and, among other objects of interest to medical men, new drugs, chemicals, and preparations of food are represented by several well-known pharmacists.

CHEMISTS' WEIGHTS AND MEASURES.

For some time past considerable activity has been manifested by the local authorities of Islington, in reference to incorrect weights and measures, and recently eighty-four persons were fined. In most instances there appears to have been no intention to defraud, but it is worth noticing that there were no less than sixteen chemists among those who were fined. It appears, according to a statement in the 'Grocer,' that one of those who suggested greater activity on the part of the inspectors was a chemist, and that he was also one of the first victims of the course he had suggested.

THE YEAR-BOOK OF PHARMACY.

We acknowledge the receipt of a specimen-page of this projected work, and are glad to find that there is a steady progress towards its actual publication. The Executive Committee of the British Pharmaceutical Conference reported last year, at the Exeter Meeting, that, in considering whether the compilation and issue of such a work would be desirable, it was felt that since similar works, in connection with various sciences, are published in most other countries, and are found to advance knowledge beneficially, Great Britain should not be without such a yearly report. It was the opinion of the Committee that the publication of a work of the kind would further the best interests of pharmacy and pharmacists. It was considered that the necessary funds for the publication of this 'Year-Book' would be obtained if some five hundred new members joined the Conference, and we understand nearly that number of additions has already been obtained. With such a desirable object immediately before British pharmacists, we anticipate a still larger accession to the ranks of the Conference at Liverpool.

The 'Year-Book' is to include notices of all pharmaceutical papers, new processes, preparations, and formulæ published throughout the world.

THE BRITISH MEDICAL JOURNAL.

It is with great pleasure we learn that Mr. Ernest Hart has been unanimously elected editor of this journal, which is the organ of the British Medical Association. As might have been expected, Mr. Hart's claims were recognized and strongly urged by many leading members of the medical profession, and we congratulate the Association on having secured the services of so talented an editor to fill up the vacancy caused by Mr. Jonathan Hutchinson's resignation.

In another part of the Journal will be found the Act for regulating the Sale of Poisons in Ireland. It is simply an extension of the Act applying to Great Britain.

Mr. H. Alder Smith has been elected Resident Surgeon to Christ's Hospital, in the room of Mr. Stone, resigned. Mr. Smith was formerly a pupil in the Laboratory of the Pharmaceutical Society, and we are glad to find that the distinction he gained as a student there and elsewhere is being followed by practical success.

Mr. Porter, who was killed at the Hastings Sewage Works last week, was formerly a student in the Laboratory of the Pharmaceutical Society.

The 'Times' is authorized to state, in answer to frequent inquiries, that the North German Government does not object to admit British medical men as volunteers in their army hospitals, provided that they speak German fluently, that they have the licence to practise medicine and surgery in the United Kingdom, that they have the permission of their Government to serve as medical volunteers in Germany, and that they will place themselves unconditionally at the disposal of the North German Government.

The 'Lancet,' in speaking of the Second Report of the Rivers Pollution Commissioners, says that "the public, now fully sensible of the folly of turning the *débris* of our food and bodily waste into our rivers and the sea, polluting them to an extent which made their condition destructive of public health and comfort, have been fascinated with a fiction that alum, blood, and clay possessed the charm of preventing contamination, and, at the same time, became the medium of restoring to the land those fertilizing agents which had been extracted in the formation of food." It adds, that these illusions are made to disappear by Dr. Frankland's investigation of the subject,—the general conclusions he has arrived at being those stated in our notice of the Royal Commissioners' Second Report* just presented to Parliament.

The Société de Pharmacie have named a commission, consisting of MM. Jungfleisch, Coulier, Baudrimont, Limousin, and Regnauld, to inquire into the causes of the accidents which occur in the preparation of oxygen by heating chlorate of potash with peroxide of manganese.

The 'Medical Times and Gazette' announces, in reference to the suggestion for a memorial to the late Sir James Clark, that when it was brought to the notice of his family a desire was expressed by them that it should not be carried out. Although they feel deeply the kindness of the proposal, they consider it doubtful whether such a memorial would have been wished for by Sir James, inasmuch as he did not approve of the practice of subscriptions for such purposes. While thanking those who entertain the desire, the family hope that their friends will not be hurt by a request not to move further in the matter.

The drawings of *Cinchonæ*, made under the superintendence of Dr. Mutis at the end of the last century, are about to be published. It will be remembered that they were discovered by Mr. Clements R. Markham in an outhouse in the Botanical Garden at Madrid, together with some of Dr. Mutis' MSS., a part of which was published under the title of 'The Cinchona Species of New Granada,' for her Majesty's Stationery Office, in 1867, by Mr. Markham.

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL,

August 3rd, 1870.

MR. SANDFORD, PRESIDENT, IN THE CHAIR.

MR. HASELDEN, VICE-PRESIDENT.

Present—Messrs. Atherton, Bottle, Bourdas, Brady, Edwards, Groves, Hills, Reynolds, Savage, Stoddart, and Woolley.

The minutes of the last meeting were read and confirmed.

Mr. Woolley desired to move that the portion of the minutes referring to the grant of an annuity to Dr. Redwood should be excepted from confirmation, but, it being ruled that according to the Bye-laws, Section 6, Clause 3, "All resolutions carried at the meetings of the

* See Pharm. Journ. No. 4, p. 67.

Council, except such as relate to the Bye-laws, shall be acted upon without confirmation," he was deemed out of order. Mr. Woolley thereupon lodged a protest against the funds of the Society being dealt with in such a summary manner as that in which the grant to Dr. Redwood was voted.

The following letter, received by the President from Dr. Redwood, was read:—

"*To the President and Council of the Pharmaceutical Society of Great Britain.*

"Gentlemen,—Although I deeply regret the decision of your Board by which I have been removed from the position I so long occupied as Editor of the 'Pharmaceutical Journal,' I must beg to express to you my thanks for the liberal spirit in which you have acknowledged the services I have endeavoured faithfully and zealously to render to the Society from its first formation, and which I shall still hope to find some means of continuing to render.

"I am, yours truly,

"T. REDWOOD.

"*August* 1*st*, 1870."

It was moved by Mr. Bottle, seconded by Mr. Savage, and

Resolved unanimously—That the President be requested to forward to Mrs. Orridge, on behalf of this Council, a letter of sympathy and condolence in her recent bereavement, and that a minute thereof be entered in the Transactions of the Society, as a recognition by the Council of the valuable services rendered to the Society by the late Mr. B. B. Orridge, and more especially so in furthering the objects of the Benevolent Fund.

A letter from the Medical Department of the Privy Council Office was read, confirming the appointment of the two Examiners for Scotland, Henry C. Baildon and Alexander Noble, nominated at the last meeting of the Council.

The Report of the Finance Committee was presented, showing on the General Fund account a balance in the Treasurer's hands of . . . . . . £986. 5*s*. 9*d*.
And submitting for payment accounts, etc., amounting to . . . . £711. 16*s*. 6*d*.
On the Benevolent Fund Account, a balance of . . . . £560. 11*s*. 11*d*.

Resolved—That the Report be received and adopted, and payments made.

Resolved—That the Treasurer be requested to purchase the following Government Securities:—
Consols. Benevolent Fund Account . £461. 12*s*. 10*d*.
New Three per Cents. General Fund Account . . . . £1200. 0*s*. 0*d*.

And for this purpose the £1000 on deposit account at the Bankers' was ordered to be withdrawn.

The Report and recommendations of the Library, Museum, and Laboratory Committee having been read, it was

Resolved—That they be received.

Resolved—That the Report of the House Committee be received and adopted.

On the recommendation of the Committee for the appointment of Sub-Editor of the 'Pharmaceutical Journal,' it was

Resolved—That Francis Passmore be appointed, at a salary of £150 per annum.

The Report and recommendations of the Benevolent Fund Committee having been read, it was

Resolved—That the sum of Ten Pounds be granted to a Member at Oxford.

The Board of Examiners reported that one Candidate presented himself for the Senior Bell Memorial Scholarship, and seven for the Junior.

The former failed to obtain the requisite number of marks in his examinations to establish his title to the Scholarship.

The Junior Scholarship was awarded to Henry Churchill, with free Laboratory instruction and materials for the Session 1870–71.

SESSIONAL PRIZES.*

The Board reported that during the past Session twenty-nine Candidates had passed the Minor Examination in honours, of whom eleven had competed for the Prize of Books.

On the report and recommendation of the Board, the prize was awarded to Edward Alfred Webb.

The Professors presented their respective Reports of the results of the competition for the Prizes offered by the Council, which, having been read, the following awards were declared:—

CHEMISTRY AND PHARMACY.

Bronze Council Medals . . Equal { Charles Fryer.
Frederick Hamilton Peck.
Certificate of Honour . . Henry Forster.

BOTANY AND MATERIA MEDICA.

Bronze Council Medal . . Edward Alfred Webb.
Certificates of Honour . . Frederick Hamilton Peck.
Charles Fryer.
Certificates of Merit . . . . Henry Forster.
John Pim Jackson.
Everton Sainsbury.

PRACTICAL CHEMISTRY.

Bronze Council Medal . . Charles Fryer.
Certificates of Honour . . George Bult Francis.
Thomas Fütcher Best.
William Raffle.
Everton Sainsbury.
Edmund Henry Metcalfe.
Certificates of Merit . . . . Edward Alfred Webb.
Frederick Hamilton Peck.

The Professor of Botany reported that four Herbaria had been received in competition for the Prize.

The following awards were made:—

Silver Medals . . . . Edward Rammell.
Edward Alfred Webb.
Certificate of Honour . . Alexander Wood.
Certificate of Merit . . . . Charles John Stansby.

Notice of Motion.—Mr. Savage, Mr. Brady,

That in the Sessional Examination in future Silver Medals be awarded for the first prize, and Bronze Medals for the second. Certificates of Honour and Merit as heretofore.

Resolved—That the following, being duly registered as Pharmaceutical Chemists, be respectively granted Diplomas stamped with the seal of the Society:—

Adams, Frank . . . . Stoke-on-Trent.
Bland, Thomas Frederick . . . . Stourbridge.
Clarke, Richard Feaver . . . . . . Torquay.
Cotterill, Samuel . . . . Southampton.
Gibbs, James . . . . Bedford.
Griffiths, Waldron . . . . Harrow-on-the-Hill.
Hartt, Charles Henry . . . . Torquay.
Howie, William Lamond . . . . . . Edinburgh.
Jackson, John Pim . . . . Leeds.
Mason, Robert William . . . . . . Rugby.
Pilley, Henry Thomas . . . . Lincoln.

* The Sessional Prizes and Certificates will be distributed at the Evening Meeting on the 5th October next. Successful candidates will be expected to attend. An Address to the Students will be delivered by Mr. Schacht, of Clifton. Ladies are invited to be present.

Pitts, Phineas Reynolds ...... Hingham.
Raffle, William .... South Shields.
Robson, James Crosby .... Darlington.
Romano, Frederick William Richard .... Rio Grande do Sul.
Thompson, William Milner .. Thirsk.
Walton, Jonathan Sparke .... Haydon Bridge.
Webb, Edward Alfred .... Clapham.

Resolved—That the following Pharmaceutical Chemists be and are hereby elected Members of the Society:—

Bland, Thomas Frederick .... Stourbridge.
Clarke, Richard Feaver ...... Torquay.
Dewson, Frederick Stokes .... Birmingham.
Hanson, Thomas .... Bombay.
Pitts, Phineas Reynolds ...... Hingham.
Robson, James Crosby .... Darlington.
Romano, Frederick William Richard .... Rio Grande do Sul.

William Thomas Phillips, of Carmarthen, having paid his subscription for the current year (due 1st of January last), and a fine, was restored to membership.

Resolved—That the following Registered Chemists and Druggists be elected Members of the Society:—

Balcomb, John .... Cheltenham.
Bowden, William .... Patricroft.
Clarke, Thomas Allen ...... Horncastle.
Hopkinson, Thomas .... Grantham.
Johnson, Joseph Garwood .. Barnsley.
Kingsford, Frederick ...... 54, Piccadilly, London.
Knowles, Charles W. ...... Thorne, Yorkshire.
Lockwood, George Alfred .. Sheffield.
Newham, Benjamin .... Sheffield.
Place, William Byron ...... Betley.
Riches, Thomas .... Torquay.
Sharples, George William .. Blackpool.
Shipley, William .... Ashbourn.
Stockman, Frederick ...... 200, Essex Rd., London.

The following, having passed the Modified Examination, and being in business on their own account, were elected Associates, with the privileges granted by Sect. 20, Pharmacy Act, 1868.

Clift, Martin Luther .... London.
Jarvis, John .... Dunstable.
Searle, William George ...... Manchester.

The following, having passed their respective Examinations, were elected Associates of the Society:—

Minor.

Butterfield, Edward .... London.
Butterworth, Albert .... Sowerby.
Bowen, John William .... Handsworth.
Braddock, Henry .... Oldham.
Carroll, Denis .... Dublin.
Clark, Walter Beales .... Leicester.
Diaper, Albert .... Bury St. Edmund's.
Green, Marryat H. .... London.
Habgood, Henry .... Wells.
Haydon, William Frederic .... Blandford.
Hogg, Joseph Fawcett .... North Shields.
Keightley, Joseph .... Tunstall.
Longley, John William ...... Leeds.
Margetts, George William .... Fakenham.
Page, William Henry .... London.
Storey, Edward Henry ...... London.
Sumner, Benjamin T. .... Horncastle.

Modified.

Atkinson, Leonard .... London.
Bates, John Freer .... Manchester.
Dawney, Charles .... Exeter.
Deane, Frederick Dawson .... Jersey.
Dodds, John Henderson ...... Walsall.
Grindell, John .... London.
Jenkins, David .... Bridgend.
Johnson, Henry .... Barnsley.
Moyle, Joseph .... London.
Organ, Edward .... Bristol.
Perkins, John Jaquest .... Stafford.
Rowell, John Childs .... Reading.
Scott, Joseph .... Worcester.
Smith, John Charles .... London.
Squire, James .... Lewes.

The Secretary reported that the Local Secretaries appointed at the last meeting of the Council for Aberdare and Oxford had declined to accept office; whereupon it was

Resolved—That the following be appointed:—

Pratt, Joseph, for Aberdare.
Tuck, John, for Oxford.

The Registrar was authorized and directed to remove from the Register of Chemists and Druggists the name of Edward Charles Whisken, of Welchpool.

The consideration of the precautions necessary for the "Sale and Keeping of Poisons" was again deferred.

Proceedings of Scientific Societies.

BRITISH PHARMACEUTICAL CONFERENCE.

The Secretaries of the Pharmaceutical Conference have issued a circular announcing that the seventh Annual Meeting will be held in September next, at Liverpool, in the Royal Institution, under the presidency of Mr. W. W. Stoddart, F.C.S., F.G.S. On Tuesday, the 13th, at 10 A.M., the President will deliver an address; the reading and discussion of papers on pharmaceutical subjects will then commence, be continued in the afternoon till 4.30, and be carried on during Wednesday; an adjournment from 12.30 to 2.0 taking place each day.

Members intending to be present are requested to communicate with the Local Secretary, Mr. E. Davies, Royal Institution, Liverpool, who will give all information concerning lodging and hotel accommodation, etc.

"The facilities for communication with Scotland and Ireland, as well as all parts of England, render it probable that this meeting will be very numerously attended.

"There is much connected with the trade of Liverpool which cannot fail to be interesting to strangers. The river Mersey, with its line of docks, five miles in length; the great works at Birkenhead; the large warehouses, fitted with the latest mechanical appliances; the quay sides, covered with the various produce of all climes; and the numerous charitable institutions on the river, offer a class of attractions almost peculiar to Liverpool; while its shipbuilding yards, foundries, chemical, and various other works on an extensive scale, and its vicinity to the mining and manufacturing districts, enable it to meet the tastes of all classes of scientific men. The proximity of Chester and the coast of North Wales places many interesting spots within easy reach."

An exhibition of objects relating to pharmacy will be held this year in connection with the meeting of the Conference. Such exhibitions are found to stimulate pharmaceutical industry, promote original research, and supply a personal element of interest to the transactions of our Association. The central position of Liverpool, and its high commercial importance, will probably induce a large number of pharmacists to exhibit on this occasion.

Gentlemen engaged upon any investigation, are reminded that papers are expected to be sent in to the Secretaries fourteen days before the Annual Meeting, accompanied by a short abstract for insertion in the local and other newspapers.

Authors are specially requested to send the titles of their papers to either of the General Secretaries two or three weeks before the Annual Meeting. The subjects will then be extensively advertised, and thus full interest be secured.

Members disposed to accept any of the unaccepted subjects suggested for investigation in the list sent to them in the early part of the year; work on any subject suggested by themselves; propose any subject for investigation by others; forward for analysis specimens of drugs and chemicals whose examination might tend to throw light on the question of adulterations and impurities; propose the recognition of any Pharmaceutical Association and reception of its delegates by the Conference; nominate gentlemen for membership, or make any suggestions or propositions, are requested to advise the Secretaries.

The objects of this Association of Pharmacologists and chemists and druggists are:—

(1) To increase the common stock of pharmaceutical knowledge, and

(2) To promote community of interests among those engaged in pharmacy.

In addition to the existing means of attaining these ends, the Committee will in future issue to members an Annual Report on the progress of pharmacy,—a Year-Book, containing notices of all pharmaceutical papers, formulæ, etc., published in the various scientific journals of Europe and America. For the annual subscription of 5s., each member will thus receive a tangible *quid pro quo* in addition to the yearly volume of 'Proceedings.' The necessary funds for accomplishing this object can probably be obtained without making any charge in addition to the present subscription, if *five hundred new members be added to the ranks.*

The Executive Committee call on every chemist and druggist to offer his name for election, and on every member to make an effort to obtain more members. Nominations will be received by either of the officers.

Copies of letters of invitation to membership will be sent to any member willing to sign and forward them to friends interested in pharmacy.

HUNTERIAN MEDICAL SOCIETY.

August 3.

At a Special Meeting held in the Theatre of the London Institution, Baboo Gopaul Chunder Roy delivered a lecture on the state of medicine in India prior to the British rule. The President of the Society, Mr. Jonathan Hutchinson, introduced the lecturer, who stated that he had come to England as a candidate for an appointment in the India medical service, but had found, on his arrival, that no examination was to take place. He then referred to the high state of civilization which existed in Eastern countries in very early ages. There was good reason for believing that astronomy had its origin in India, and in that country medicine attained, at an early period, a high degree of development. An advance, however, was arrested by the Mohammedan conquests; and therefore Hindoo science, remaining as it did at the point where it was centuries ago, presented a strange contrast with modern science. The physicians of India had sprung from two of the castes—the Brahmins, who were the most highly educated and from whom the priests were chosen, and the Boyshos or traders, who were not allowed to learn Sanskrit or to reach the higher education of the Brahmins. Medicine and surgery were distinct; the latter being entrusted to barbers, whose operative skill was very limited. Medicine was from very ancient times divided into anatomy, materia medica and the treatment of diseases. The study of anatomy was very imperfect, in consequence of the prejudices against handling dead bodies. What knowledge of anatomy the Hindoo possessed, was gained from the dissection of goats; and an acquaintance with the human skeleton was obtained by allowing bodies to remain in water till the bones and ligaments alone were left. The umbilicus was supposed to be the centre of the vascular system. The blood was regarded as a mixture of humours. The materia medica attracted attention at an early period; and the articles were described with a view to their dietetic as well as to their therapeutic properties. Mercury, arsenic, iron, and several other mineral remedies were known in Hindoo medicine many centuries ago. Gold dust entered very extensively into the formulæ; perhaps not so much for the sake of increasing the therapeutic value of the medicines as their cost. Sesquioxide of iron was the chief basis of tonic remedies. Arsenic had been long used in the treatment of intermittent fever. There were a large number of remedies belonging to the vegetable kingdom in use in India from remote ages, some of which, as bael, chirayta, etc., had been adopted in the 'British Pharmacopœia.' Baboo Chunder Roy recommended a careful investigation of Indian medicinal plants; believing it probable that among them would be found some valuable remedies for the prevalent diseases of the country. In works on the practice of medicine, the description of symptoms was very exact, but the treatment was empirical. In fevers, low diet was enjoined; the patient was kept for forty-eight hours without medicine; then bitters and purgatives were administered; and then, if the fever persisted, arsenic in divided doses. This treatment rarely failed to arrest the disease in ten days; but it left the patient's constitution in an impaired state. Surgery was in old times entrusted to barbers, whose practice was limited mostly to the treatment of ulcers, abscesses, etc. But for ages there had been persons who performed the operation for depression of cataract, cupping (by means of cow's horns), bleeding (in the calves of the legs), etc. Hygiene had long held a place in the Hindoo system, being mixed up with religious rites. Washing in the Ganges was thus made a religious ceremony. The flesh of the ox was forbidden, on account of the use of the animal in agriculture, and of the cow in yielding milk; and that of the pig on account of the filthy habits of the animal. Dry earth had been long used for removing offensive smells. Change of climate, in the form of pilgrimages to distant lands, had long been a remedy in chronic diseases. With all this, there was ignorance of some of the fundamental principles of hygiene. Poison and pure air were in the same category; and a Hindoo sick-room was rigidly closed at all points. Turning, next, to the British rule, the lecturer referred to the influence of a surgeon, Mr. Broughton, in establishing the East India Company in India in the last century. The idea of founding an English medical university in Calcutta arose in 1836. At first there was great difficulty, on account of the religious prejudices, in obtaining students; and goats and dry bones were for some time the only objects on which anatomy could be studied. The necessity for dissection was at last strongly felt; and it was a memorable event when Baboo Modoosudun Gupto first broke through the prejudices of his race, and dissected a human body. From this time, medicine advanced; a hospital was founded; and degrees were given by the University. Baboo Chunder Roy complained that the degrees in Medicine of the Indian Universities were not recognized in England. They were obtained only after stringent examination; and in not one instance where the native holders of them had come to England to undergo the competitive examinations for the Indian Medical Service, had there been a failure. It had been said that the preliminary training was deficient; but it should be remembered that Sanskrit stood in India in the place of Latin, and that English itself was a foreign tongue to the Hindoos. He complained of the low estimate in which the native graduates of the Indian Colleges were held, and trusted that means would be taken to remove the stigma of inferiority which was attached to them.

ROYAL SOCIETY.

May 19, 1870.

Experiments on the Effects of Alcohol on the Human Body.

BY DR. E. A. PARKES AND COUNT C. WOLLOWICZ.

An important series of experiments on this subject has been made conjointly by the authors. Their object was to ascertain the physiological and dietetic effects of alcohol on the human body in a state of health. The plan of observation was as follows: For twenty-eight days a man, an intelligent healthy soldier, remained on a diet precisely similar as to food and times of meals in every respect, except that for the first eight days he took only water (in the shape of coffee, tea, and simple water); for the next six days he added to this diet rectified spirit, in such proportion, that he took in divided quantities, on the first day 1 fluid ounce of absolute alcohol; on the second day 2 fluid ounces; on the third 4 ounces; and on the fifth and sixth days 8 ounces on each day. He then returned to water for six days, and then for three days took each day half a bottle (12 ounces) of fine brandy, containing 48 per cent. of alcohol. Then for three days he returned to water. There were thus five periods, viz. of water drinking, alcohol, water, brandy, water. And for ten days before the experiments were commenced, the man, a beer drinker usually, abstained from any alcoholic liquid for ten days. The food taken was all weighed, it was the ordinary diet. The general results obtained may now be very briefly summed up. It would seem first of all that, other conditions remaining the same, the weight of the body is unaffected by the taking of alcohol. With regard to temperature, we are told "that the general result from all observations surprised us (the observers), considering the numerous experiments on men and animals in which the temperature has been found to be lowered by alcohol." The tendency, indeed, was rather in the opposite direction, especially with the brandy. The alcohol was, however, never pushed far, because the object was not to induce any narcotism, but to ascertain its dietetic value; and the discrepancy involved in the observations of Drs. Parkes and Wollowicz may be in part further explained by the fact that the individual experimented upon possessed a perfectly healthy resisting, and not a diseased or weakened organism. The diminution of temperature by large and narcotic doses is not disputed; all that our experimenters affirm is that with a small amount of alcohol, and a good supply of food, the temperature is not diminished. The effects on the circulation described are very interesting. The pulse was not only more frequent and fuller when alcohol and brandy were used, but the increased frequency was persistent after the omission of the alcohol. The pulse had not reached in six days the point which was proper to it before the alcohol was given.

The first day of alcohol gave an excess of 4, the last 23 per cent. in the beats of the heart, that is, an excess of 13 per cent. as a mean of six days. This, on calculation, amounts to an excess in the daily work of the heart equal to lifting 15·8 tons one foot during the first two, and 24 tons during the last two days of the alcoholic period. On the fifth and sixth days after the alcohol was left off, when its elimination was complete, the heart showed in the sphygmographic tracings signs of unusual feebleness; and when subsequently brandy was given, it was clear that it was acting upon a heart whose nutrition had not been perfectly restored. The observers say that it is evident that in the man experimented upon, the amount of alcohol the heart will bear without losing its healthy sphygmographic tracing is small, and it must be supposed that eventually some disease of the heart will follow the excitement induced by large doses of alcohol. The action on the kidneys of a moderate amount of alcohol is not marked; the amount of water eliminated is rather increased; no change takes place as regards the nitrogen when the ingress of nitrogen is constant,—certainly it is not diminished in amount. This conclusion is antagonistic to the observations formerly made on the point, which indicated that nitrogen is retained in considerable amount in the body under the exhibition of alcohol, which in this way increases assimilation, and when food is deficient saves the tissues from waste.

Little change is also effected in the phosphoric acid, the chlorine, and the free acidity of the urine. The elimination of nitrogen by the bowels was not lessened. The elimination of alcohol by the lungs was marked; indeed a good deal must have been got rid of in this way,—by the skin considerable, by the kidneys slight. Drs. Parkes and Wollowicz think that, though not excessive at any one time, the exit is longer continued than Anstie and Dupré suppose.

Special note was taken of the effect of alcohol on digestion and appetite. It seems that in the man under observation some point near two fluid ounces of absolute alcohol is the limit of useful action on appetite. It might have been found to be less, had the experiments been continued. Further, although large doses interfered with the appetite, they did not interfere with or retard primary digestion, as far as could be seen, nor the normal chemical changes that result in the elimination of nitrogenous excreta, phosphoric acid, and the like. In a word, no evidence was forthcoming to show that alcohol either saved or exhausted the tissues; that is to say, the good or evil ascribed to alcohol in this direction was not observed by Dr. Parkes and Dr. Wollowicz in the healthy man. It may be, of course, different in disease. The effect on the nervous system was shown only by subjective symptoms,—headache, heaviness, loss of cheerfulness and alacrity, torpor and sleepiness; and narcotism was induced by an amount of alcohol less than 4 and nearer 2 ounces daily, and the experimenters conclude that the narcotism, the loss of appetite, and the increased frequency in the heart's beats, are related to the common cause, viz. implication of the nervous system. The general inference of the experimenters on this point is that something under 2 fluid ounces of alcohol could be taken daily without harm by the man under observation. The following are the final conclusions given by Dr. Parkes and his coadjutor. "It will be seen that the general result of our experiments is to confirm the opinion held by physicians as to what must be the indications of alcohol in health and disease. The effects on appetite and on circulation are the practical points to seize; and if we are correct in our inferences, the commencement of narcotism marks the point when both appetite and circulation will be damaged. As to the metamorphosis of nitrogenous tissue, it seems improbable that alcohol in quantities that can be properly used in diet has any effect; it appears to us unlikely (in the face of the chemical results) that it can enable the body to perform more work on less food, though by quickening a failing heart it may enable work to be done which otherwise could not be so. It may then act like the spur in the hide of the horse, eliciting force, though not supplying it." The experimenters, whilst recognizing further the great practical use of alcohol in raising a failing appetite, exciting a feeble heart, and accelerating a languid capillary circulation, are strongly impressed with the need of moderation and caution in its use. They do not deal with diseased conditions, but only a state of health, and do not refer at all to the action of wine or beer.

The Academy of Sciences at Paris will bestow this year a prize of 5000 francs for the best essay, "On the Use of Electricity in Medicine," and two prizes in botany, each of the value of 3000 francs.

Pencils of Sulphate of Copper.—M. Herbelin, of Nantes, rubs a crystal of sulphate of copper on a moist stone covered with fine sand, until a pencil is produced. —*Répertoire de Pharmacie.*

Parliamentary and Law Proceedings.

INDIAN DRUGS.

In the course of his speech upon introducing the Indian budget to the House of Commons last week, Mr. Grant Duff said that the revenue from opium had fallen off largely, but that, on the other hand, there had been an increase in the excise from spirits, drugs, etc., known as the Abkari revenue. Very frequent inquiries about the forest service were made at the India Office. The experiment they had been making of selecting young men by a competitive examination, and then giving them a thorough training in the great forest schools at Hanover and Nancy, bade fair to produce excellent results, and to give them a real forest school in India. That was all the more important because, although the natural products were not yet made anything like so available to mankind as they ought to be, the increased tendencies of all art and science in our times to produce specialities and encourage specialists were depriving them, to a great extent, of the assistance they used to receive in that field from various classes of their officers, and above all from their medical men. The examinations for the special Forest Service showed increasingly careful preparation. The accounts they received of the young men studying on the Continent were good, while those who were in India were thought likely to turn out very useful officers. Although the receipts had largely increased, there had also been a proportionate increase in the expense, but in a new service that was only what might be expected, and it might go on increasing for some time without raising any presumption against the ultimate pecuniary results of the plan. In fact, much more than mere pecuniary results were at stake: climatic changes of a very dangerous kind were threatening, or in some instances had actually occurred, and the evils that had to be met could only be checked by the direct action of the Central Government. The excellent results of the cinchona cultivation had been laid before the House. Peru and Ecuador had given increased facilities for combating fever, one of the worst enemies of man in India; they had already two millions and a half of cinchona plants growing there. It was now the turn of Brazil to enable them to combat acute dysentery, a hardly less formidable foe. Measures had been taken to send out from Kew, from Edinburgh, and also directly from Brazil, the ipecacuanha, which is now considered almost a specific against that terrible malady. Lately the Government of India had been devoting some attention to the Rhea or China grass, an abundant Indian product, which, if a machine could be obtained that would detach the fibre from the stalk in an easy and satisfactory manner, would become of great economic importance; rewards to the amount of £5000 had been offered by the Indian authorities for such a machine. The opening of the Suez canal seemed likely to exercise a favourable influence on the tea cultivation of Northern India. Turning to another very important Indian product, it was gratifying to observe that India last year sent nearly as much cotton to our shores as the United States and Brazil combined. There was satisfactory evidence that the cultivation of the poppy was spreading very extensively through China, although the old vigorous edicts against it remained unrepealed; but there was not satisfactory evidence as to how far that extended cultivation was the result of the withdrawal of much of the pressure that prevented the Chinaman from indulging in his favourite luxury, and of a consequent increase of consumption; or whether it implied that the Chinese opium was now used by many who formerly used the Indian opium. For anything yet known, Indian opium might still find a very profitable market in China. The estimated revenue from opium in 1870–1 was under seven millions, whereas in 1867–8 a smaller opium expenditure produced an opium revenue of nearly nine millions.

Mr. Eastwick said that one of the most prominent reasons for retrenchment was the precariousness of the opium trade. Sir Richard Temple, in his statements, merely spoke of the extension of opium cultivation in China, and entirely overlooked the exportation of opium from Persia. A few years ago that country did not export any opium; but last year it exported four thousand chests, worth about half a million sterling. It had been analysed and found to be nearly equal to the opium of India, whilst it had the further recommendation of paying no duty, so that the profit was enormous. He should not be surprised if that branch of the trade doubled or quadrupled in a year.

AN ACT TO REGULATE THE SALE OF POISONS IN IRELAND.

[*14th July*, 1870.]

Whereas it is expedient for the safety of the public that due provision should be made to regulate the sale of poisons in Ireland:

Be it enacted by the Queen's most excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same as follows:

1. The several articles mentioned in the Schedule A. to this Act annexed shall be deemed to be poisons within the meaning of this Act; and the King and Queen's College of Physicians in Ireland may from time to time, by resolution, declare that any article other than those mentioned in the said schedule and in such resolution named ought to be deemed a poison within the meaning of this Act; and thereupon the said College shall submit the said resolution for the approval of her Majesty's Privy Council in Ireland, and if such approval shall be given, then such resolution and approval shall be advertised in the 'Dublin Gazette;' and on the expiration of one month from such advertisement the article named in such resolution shall be deemed to be a poison within the meaning of this Act.

2. It shall be unlawful to sell any poison, either by wholesale or by retail, unless the box, bottle, vessel, wrapper, or cover in which such poison is contained be distinctly labelled with the name of the article, and the word "poison," and with the name and address of the seller of the poison; and it shall be unlawful to sell any of the poisons which are named in the first part of Schedule A. to this Act annexed, or which may hereafter be added thereto under section one of this Act, to any person unknown to the seller, unless such person is introduced by some person known to the seller; and on every sale of any such article the seller shall, before delivery, make or cause to be made an entry in a book to be kept for that purpose, stating in the form set forth in the Schedule B. to this Act annexed, the date of the sale, the name and address of the purchaser, the name and quantity of the article sold, and the purpose for which it is stated by the purchaser to be required, to which entry the signature of the purchaser and of the person (if any) who introduced him shall be affixed; and any person selling poison otherwise than is herein provided shall be liable to a penalty not exceeding five pounds for the first offence, and to a penalty not exceeding ten pounds for the second or any subsequent offence; and for the purposes of this section the person on whose behalf any sale is made by any apprentice or servant shall be deemed to be the seller; but the provisions of this section which are solely applicable to poisons in the first part of the Schedule A. to this Act annexed, or which require that the label shall contain the name and address of the seller, shall not apply to articles to be exported from Ireland by wholesale dealers, nor to sales by wholesale to retail dealers in the ordinary course of wholesale dealing, nor shall any of the provisions of this section apply to any medicine

supplied by a duly qualified apothecary nor apply to any article when forming part of the ingredients of any medicine dispensed by a duly qualified apothecary, provided such medicine be labelled in the manner aforesaid with the name and address of the seller, and the ingredients thereof be entered with the name of the person to whom it is sold or delivered in a book to be kept by the seller for that purpose; and nothing in this Act contained shall repeal or affect any of the provisions of the Act of the fourteenth and fifteenth years of the reign of her present Majesty, intituled "An Act to Regulate the Sale of Arsenic."

3. The provisions of the Act of the twenty-third and twenty-fourth years of the reign of her present Majesty, intituled "An Act for preventing the Adulteration of Articles of Food or Drink," shall extend to all articles usually taken or sold as medicines, and every adulteration of any such article shall be deemed an admixture injurious to health.

4. Every penalty recoverable under the provisions of this Act shall be recoverable in a summary way, with respect to the police district of Dublin metropolis subject and according to the provisions of any Act regulating the powers and duties of justices of the peace for such district or of the police of such district, and with respect to other parts of Ireland before a justice or justices of the peace sitting in petty sessions, subject and according to provisions of the Petty Sessions (Ireland) Act, 1851, and any Act amending the same, and shall be applied according to the provisions of the Fines Act (Ireland), 1851, or any Act amending the same.

SCHEDULE A.

Part I.

Arsenic, and its preparations.
Prussic acid.
Cyanides of potassium and all metallic cyanides.
Strychnine, and all poisonous vegetable alkaloids and their salts.
Aconite, and its preparations.
Emetic tartar.
Corrosive sublimate.
Cantharides.
Savin, and its oil.
Ergot of rye, and its preparations.

Part II.

Oxalic acid.
Chloroform.
Belladonna, and its preparations.
Essential oil of almonds, unless deprived of its prussic acid.
Opium, and all preparations of opium or of poppies.
Preparations of corrosive sublimate.
Preparations of morphine.
Red oxide of mercury (commonly known as red precipitate of mercury).
Ammoniated mercury (commonly known as white precipitate of mercury).
Every compound containing any of the poisons mentioned in this schedule, when prepared or sold for the destruction of vermin.
The tincture and all vesicating liquid preparations of cantharides.

SCHEDULE B.

Date.	Name of Purchaser.	Name and Quantity of Poison sold.	Purpose for which it is required.	Signature of Purchaser.	Signature of Person introducing Purchaser.

Chapters for Students.

CHEMICAL NOTES TO THE PHARMACOPŒIA.

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

ACIDUM NITRICUM.—[§ An acid, prepared from nitrate of potash or nitrate of soda, by distillation with sulphuric acid and water, and containing 70 per cent. by weight of nitric acid, HNO_3.] Specific gravity 1·42.

The reaction which occurs in the retort is similar to that in which hydrochloric acid is produced:—

$$KNO_3, \text{ or } NaNO_3 + H_2SO_4 = HNO_3 + KHSO_4, \text{ or } NaHSO_4.$$

Absolute nitric acid differs from hydrochloric acid in being, at ordinary temperatures, not a gas, but a fuming liquid of sp. gr. 1·51; this was the preparation of the B. P. 1864; it is, however, extremely unstable, undergoing decomposition spontaneously in the light, and in many respects inconvenient, and was, therefore, replaced in the present edition by a weaker acid. Nitric acid poured over copper filings evolves dense red fumes, consisting chiefly of nitric *per*oxide:—

$$4HNO_3 + Cu = Cu''2NO_3 + 2H_2O + 2NO_2.$$

If previously diluted with water, nitric oxide is the gas evolved:—

$$8HNO_3 + 3Cu = 3(Cu2NO_3) + 4H_2O + 2NO.$$

Nitric oxide is a colourless gas, but when it meets oxygen either alone or mixed with other gases, as in atmospheric air, it forms an orange-red vapour:—

$$\underset{\text{Nitric oxide.}}{2NO} + \underset{\text{Oxygen.}}{O_2} = \underset{\text{Nitric peroxide.}}{2NO_2}.$$

Nitric oxide forms, with ferrous sulphate, a dark-coloured solution, upon the formation of which depends the usual test for nitrates:—Dissolve the substance in water, add a small crystal of sulphate of iron, and shake up till partly dissolved, then pour into the inclined tube sufficient pure and strong sulphuric acid to form a separate stratum at the bottom. The line where the two liquids meet is marked by a purple or brown coloration if a nitrate (or nitrite) is present. Nitric acid is an example of what are known as *oxidizing agents;* it readily and freely gives up part of its oxygen. This arises from the strong affinity of the hydrogen in it, and the weaker affinity of the nitrogen for oxygen; so that when brought into contact with bodies greedy of oxygen, oxygen separates from it, water is formed, and one of the oxides of nitrogen. This is the reason of its deflagration when poured upon hot charcoal, the decolorization of indigo and other reactions, *e.g.* when nitrate of ammonia is strongly heated:—

$$NH_3.HNO_3 = \underset{\text{Water.}}{2H_2O} + \underset{\text{Nitrous oxide.}}{N_2O}.$$

Also its reactions with copper already described, and resulting in the evolution of nitric oxide and peroxide.

The sesquioxide of nitrogen, or nitrous anhydride, is evolved when it acts upon white arsenic:—

$$\underset{\text{Arsenious anhydride.}}{As_2O_3} + 2HNO_3 = \underset{\text{Arsenic anhydride.}}{As_2O_5} + H_2O + \underset{\text{Nitrous anhydride.}}{N_2O_3}.$$

The whole of the oxides of nitrogen are tabulated below:—

Nitrous oxide, or laughing gas . . . . . . N_2O
Colourless.

Nitric oxide (formerly binoxide of nitrogen) . . . . N_2O_2, or NO
Colourless, but reddens in the air.

Nitrous anhydride . . . . N_2O_3
Red fumes, condensible to blue liquid.

Nitric peroxide . . . . N_2O_4, or NO_2
Red-brown fumes, condensible to orange liquid or crystalline solid.

Nitric anhydride . . . . N_2O_5
Colourless, crystalline, easily decomposed.

The nitric acid of the B. P. should leave no residue on evaporation, showing that it contains no nitrate of potash or soda; and should give, *when considerably diluted*, no precipitate with chloride of barium or nitrate of silver, showing freedom from sulphuric and hydrochloric acids. It is necessary to add water, for the undiluted acid will throw down many salts, such as nitrate of barium, which are soluble in water, but not in the concentrated acid. 9 grams of nitric acid, B. P., are neutralized by the addition of 100 cubic centimetres of the volumetric solution of soda. 1000 c.c. of vol. sol. of soda contain 40 grams of $NaHO$, and will neutralize 1 molecule of HNO_3, or 63 grams. 100 will therefore neutralize $\frac{1}{10}$th of 63 or 6·3 grams. This is the amount of HNO_3 in 9 grams of the official acid; it is equivalent to 70 per cent.; for

9 : 6·3 :: 100 : 70.

The British Medical Association.—The Thirty-eighth Annual Congress of the British Medical Association was inaugurated yesterday by the usual preliminary proceedings of the Council, and more formally by the general meeting of the members in the Lecture Room of the Literary and Philosophical Society, on which occasion Dr. Charlton, of Newcastle, signalized his accession to the Presidency for the year by the delivery of an address almost equally interesting to the general public and to the medical profession, inasmuch as it was devoted to the great subject of Hygiene and to what may be called the politics of the profession. This latter subject elicited sympathetic response from the Association, which has already distinguished itself in the promotion of medical reform, while it is still leading the van against obsolete pretensions and the obstructiveness of vested interests. The address furnishes a convenient abstract of the aims, principles, and achievements of the Society to which Newcastle is this week extending its heartiest welcome and warmest hospitality.—*Newcastle Daily Chronicle.*

Accident at the A B C Sewage Works at Hastings.—The Hastings sewage works* have become the scene of a melancholy disaster. As in the case of the London main drainage, the sewage of Hastings is received into a large tank or reservoir, where it is stored until the state of the tide allows of its discharge. The Hastings Sewage Manure Company, who work what is termed the A B C patent, under an arrangement with the Native Guano Company, have established their works just over the spot where the great intercepting sewer discharges into the tank. The tank itself is of considerable extent, and is entirely subterranean, having an entrance or man-hole at each end. Late on Friday evening cries of distress were heard proceeding from the tank, into which two of the workmen were known to have descended. Mr. Porter, who acted as chemist to the manure company, was on the premises at the time, and unfortunately sacrificed his own life in an unsuccessful attempt to rescue them. He descended the shaft leading to the tank, and a man who accompanied him saw him fall.

An inquest was held, on Monday afternoon, on the bodies of the two workmen, when the jury returned a verdict of "Accidental death from inhaling noxious gases," but no evidence was produced to show how these gases were generated. A similar verdict was returned by another jury in the case of Mr. Porter, whose body was recovered later.

* See Pharm. Journ. No. 1, p. 5.

Blood Pictures.—Dr. Day, of Geelong, Australia, the improver of the guaiacum-tests for blood and other animal fluids, confirms the discovery of Neumann, that the picture or network formed by human blood can be distinguished under the microscope from that which is formed by the blood of other animals. He says he has repeated the experiment, which is "wonderfully simple," almost every day for the last two months, with invariable success. A small drop, not a mere speck, of the blood is to be placed on a microscopic slide, and carefully watched, at a temperature of 10° or 12° Réaumur (=54·2° to 59° Fahr.), until the picture or network formed by its coagulation is developed. Human blood speedily breaks up into a "small pattern" network; the blood of other animals (calves, pigs, etc.) takes a longer time, and makes a larger pattern; but the blood of every animal seems to form a characteristic "picture." Dr. Day has examined the blood of calves, pigs, sheep, rabbits, ducks, hens, several kinds of fishes, etc., as well as that of man, and has found the results to be trustworthy and constant.—*British Medical Journal.*

Arsenic.—The use of arsenic in a very large number of skin diseases has led to a conclusion that its specific effects upon such diseases have been greatly exaggerated. In a large number of selected cases no benefit has been apparent. As a tonic in neuralgia, rheumatism, and ague, it is an excellent remedy.—*Annual Report of the Hankow Medical Mission, by F. Porter Smith, M.B.*

Obituary.

The death, at the age of 75, of Baron Charles von Hügel is announced. He was Austrian plenipotentiary at the Court of Belgium, and well known as an Austrian explorer and founder of the Horticultural Society at Vienna. He died at Brussels on the 2nd of June. Baron von Hügel was author of 'Botanisches Archiv der Gartenbaugesellschaft des Oesterreichischen Kaiserstaates,' Wien, 1837; and of 'Orchideensammlung im Frühjahr 1845,' Wien, 1845, which enumerates 1080 species. Some of the plants collected by him in Australia in 1833 were enumerated, and the new species described by Bentham, Fenzl, Schott, and Endlicher, in the unfinished 'Enumeratio Plantarum quas in Nov. Holl. collegit C. L. B. de Hügel,' Vienna, 1837.

BOOKS RECEIVED.

Observations on Therapeutics and Disease. By Donald Campbell Black, M.D., L.R.C.S. Edinburgh. London: John Churchill and Sons. Glasgow: James Hadden. 1870.

The Food Journal. No. VII. London: J. M. Johnson and Sons, 3, Castle Street, Holborn.

The Practice of Perfumery: a Treatise on the Toilet and Cosmetic Arts, Historical, Scientific, and Practical; with Chapters on the Management of the Hair, Skin, and Teeth. By R. Jones Owen. London: Houlston and Sons.

The Laboratory Guide: a Manual of Practical Chemistry for Colleges and Schools, specially arranged for Agricultural Students. By Arthur Herbert Church, M.A. London: Van Voorst.

Trade Grievances.

Sir,—In the admirable letter of "A Country M. P. S." on the above-mentioned subject two suggestions are given, and, so far, very good; but I think that there might have been a third, which is, "that all Registered Chemists and Druggists be equally exempt with Pharmaceutical Chemists from serving on juries;" or, what would be better, "that all who are M. P. S. or A. P. S. be exempt."

If the latter suggestion became law, every chemist in the country would become connected with the Society, just the same as every surgeon is a member of his college.

Again, I do not see why the Pharmaceutical Society should not be called the Royal College of Pharmacy, and so Members become entitled to the initials M.R.C.Ph., and Associates A.R.C.Ph. The difference between Pharmaceutical Chemists and Chemists and Druggists would be much the same as it is between the Fellows (F.R.C.S.) and Members (M.R.C.S.) of the College of Surgeons.

I remain, Sir, yours obediently,
W. B. C.

Manchester, August 8th, 1870.

Sir,—It was with some surprise that I read in the Journal of the 6th an article written, under the title of "Trade Grievances," by an M.P.S. The writer of this letter, I think, must have been in a somewhat passionate frame of mind, or he would hardly have recommended the adoption of the sixth article of the French code to our English law. It is well that the desire of the Pharmaceutical Society for educational progress has not led it to wish to take from shopkeepers the right of selling simple drugs, as salts, senna, etc. In not attempting this, the Society has shown that whilst in restricting the sale of poisons it has been anxious to protect the public welfare, yet it has not wished to prohibit the sale of simple remedies merely to enrich the class of tradespeople whom it represents. In stigmatizing small shopkeepers who deal in the above class of drugs as pirates, parasites, etc., I think our friend has far exceeded the bounds by which he would have been restrained, had he considered justice, good taste, and courtesy.

Although wishing as ardently as "A Country M.P.S." that the sale of drugs should be confined to our class, yet it is not by the aid of the law that I would see this done, but by the gradual enlightenment of the public mind, which will lead people to see the propriety of purchasing even the simpler drugs from an educated tradesman.

In conclusion, I would just remark that, should any Act so stringent as the one advised be passed, in all common English fairness, grocers and wine merchants will demand that we, too, be compelled to leave off the sale of the many articles which belong especially to their department.

I am, Sir, yours truly,
Walter B. Clarke, A.P.S.

15, *Belvoir Street, Leicester.*

Sir,—"A Country M. P. S." should not worry himself about his "grocer" neighbours who sell salts and senna, unless prepared for fair play, for I should be glad to "spot" the small town pharmacist who does not sell tea, spices, starch, and the numerous articles fairly within the province of the grocery trade. The French pharmaciens are undoubtedly blessed by having Art. 6 to protect them; but no free-trading Englishman can be debarred from selling "that which goeth into the mouth," though it steal away the brain. "M. P. S." has but a poor opinion of himself if he fears the competition of shopkeepers who can only sell scheduled poisons by affixing a patent medicine stamp thereon; so much for the Pharmacy Act and the five-shilling patent medicine licence. We note, on *paper,* the advancing strides of chemistry, and the superior position of pharmacists, whilst it is well known that grocers who *have sold* drugs are now "registered chemists;" time, of course, will settle the many sham druggists now afloat, but until the present generation die off, or this grievance is looked after, the existing state of things must continue. Of course, the well-educated pharmacist will, as a rule, carry more weight with the public than will a second-class man, but it must not be forgotten that "birds of a feather" will sympathize with each other, and No. 2 frequently drives ahead of No. 1, whose pride, as a superior and scientific man, brings him to beggary, especially in small country places.

Just a word about "Rule of Thumb," or guessing, there is more "cry than wool" about your correspondents' letters, for who would weigh out separately a dozen 1 grain calomel powders, or not do so in the case of the same number of ʒij magnesia powders? A practical man will judge correctly, and never be in doubt as to the best method of dispensing physic.

Just another word. I am a country pharmacist, and to make a fair return am *obliged,* by the necessities of "small mouths to be filled," not to do as I would wish, but to provide my *clientèle* with the minor articles of grocery, and encroach also upon the preserves of the painter, perfumer, butcher, wine merchant, etc. etc., without squeamishness, thankfully and cheerfully.

I am, Sir, faithfully yours,
J. Houlton.

Poison Regulations.

Sir,—I regret to find that the "Poisons Regulations" are rising to the surface again; I had hoped they were submerged with a millstone upon them.

Notwithstanding the suggestion of the 'Pall Mall Gazette,' that our Society has public duties and private interests, which may not always concur, it so happens with chemists that public duty and private interest do absolutely concur; for a chemist's success mainly depends upon public appreciation, and that depends upon the care and attention of the individual, the public having quick discernment in these matters.

Your obedient servant,
John Beaton.

Kilburn, August 8th, 1870.

W. C. Fry (Taunton).—The work mentioned is a very good one for the purpose.

"*Studiosus*" (Knaresborough) writes to ask which is the best modern work on the general treatment of diseases in cattle and horses, and its price.

A. B.—(1.) The tap would be injured after a time. (2.) The solution would probably become contaminated by the metal.

W. Young (Harrow Road).—Received with thanks.

C. L. R. wishes to be informed where he can procure a work on entomology, in which "the general structure of insects is fully explained, and the conformation of their minute parts as seen in the microscope is adequately illustrated."

"*Zeta*" and "*Quercus.*"—The new edition of Bentley's 'Manual of Botany' will be ready in October.

"*Cortex*" (Manchester).—(1.) Scheele's green comes within the meaning of the Act. (2.) Apply for information to the Registrar.

G. J. Thomas (South Molton) should consult his solicitor.

"*Chemist*" should apply to the Inland Revenue Office.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

The General Index to the first Fifteen volumes of this Journal may be obtained of the Secretary, 17, Bloomsbury Square, price 2*s.* 8*d.*, post free; bound in cloth, lettered, 3*s.* 8*d.*, post free.

The General Index to the Vols. XVI.–XVIII., Old Series, and Vols. I.–IX., Second Series, may also be obtained of the Secretary, price 3*s.* 3*d.*, post free.

ACETIC FERMENTATION.

BY BARON VON LIEBIG.

(*Continued from p.* 124.)

The various decompositions of organic substances may, as I believe, be grouped in three distinct classes.

The first class comprises those forms of fermentation which give rise to alcohol, lactic acid, or butyric acid, and the putrefaction of animal materials. These processes, once commenced, continue to go on without further aid by atmospheric oxygen.

The second class comprises acetic fermentation, nitrification, also the fermentation of urine. Here atmospheric oxygen plays a definitely determining part.

The peculiarity in the fermentation of urine, or one form of it, was first observed by Gay-Lussac. He found that fresh urine might be kept for months without decomposition in a clean glass vessel entirely filled, but if the vessel was half-filled with air, oxygen was absorbed by the urine, and a corresponding quantity of urea was converted into carbonic acid and ammonia. This decomposition was limited by the quantity of oxygen, and it commenced again when fresh oxygen was supplied until eventually all the urea was transformed.

This decomposition of the urea is accompanied by an oxidation of the colour constituents of the urine, and a small quantity of acetic acid is formed at the same time.

The special peculiarity of this fermentation is that two processes take place together, an oxidation and a breaking up; while one or more constituents of the urine are being oxidized they act, by virtue of that change, like a ferment such as beer-yeast upon cane sugar; urea associated with the elements of water breaks up as sugar does, without otherwise taking part in the oxidation. Fermentation of this kind takes place also in animal materials when access of air is not prevented during their putrefaction.

The fermentation of dextrin in beer-wort presents a phenomenon entirely similar.

In the course of a long series of experiments that have been conducted in my laboratory by Dr. Lermer, I have had an opportunity of confirming the observations of Musculus, that by the action of diastase, starch is only partially converted into sugar.

In mashing malted barley the starch is acted upon by a large excess of diastase; but at the utmost the sugar produced corresponds only to one-half of the starch present. A sample of malt which gave 74 per cent. of sugar when heated for twelve hours with dilute hydrochloric acid, yielded only 34 per cent. of sugar when mashed until the iodine reaction was no longer produced. A solution of dextrin does not undergo fermentation when mixed with beer-yeast; but when some sugar is added to the mixture, great part of the dextrin is converted into alcohol and carbonic acid just as the sugar itself is.*

In this case the influence of the motion communicated to the sugar atoms by the action of yeast appears very evidently to have been extended to the dextrin, upon which yeast has no action. Before the dextrin could break up into alcohol and carbonic acid, it must have been converted into sugar.*

Excepting beer-yeast and the vinegar plant, which can easily be collected in quantities and purified, the other ferments are scarcely known in regard to their chemical relations; but it is to be hoped that by more thorough investigation their peculiarities and their influence in the production of lactic acid, butyric acid, etc., may become explicable in the same way as the decomposition of sugar in vinous fermentation, or the production of acetic acid by *Mycoderma aceti*.

If chemical causes determine the action of yeast-cells in vinous fermentation, it might be expected that external chemical actions would exercise some influence on the progress of the fermentation. There are, indeed, many observations as to the influence of chemical agents upon the fermentation of sugar, and though some of the results I have obtained were already known, the confirmation of previous statements is of some interest.

A trace of oxide of mercury entirely stops the action of yeast upon sugar,† and it acts in the same way upon yeast-water. If this is mixed with a little of the freshly precipitated oxide, then filtered, and mixed with some solution of cane sugar, it will be found that no grape sugar is formed.

Salts of copper exercise the same influence upon fermentescible mixtures. The yeast takes up the copper salt and becomes green. In that state it has no action on sugar.

Persalts of iron colour yeast dirty yellow; after two or three days this colour disappears and then a slow regular fermentation sets in.

In order to avoid repetition, it may be stated that in the following experiments the mixtures operated upon contained in each instance 5 grm. of sugar with the same quantity of washed yeast, and that, with all additions included, the total volume was always 100 c.c. To some of these mixtures were added various substances, in order to ascertain their influence on the fermentation; one had no admixture, and that served as a standard for comparison.

When the fermentation took place unequally in these mixtures within a given time and under the same conditions, that could be readily ascertained by determining the quantity of sugar remaining at the end of the experiments; if, for example, there was less sugar in the standard mixture that had received no admixture than there was in others, it is evident that the fermentation must have been retarded in the latter cases.

The sugar determinations were generally made by Fehling's method, or by a new method which gives very accurate results, and in which cyanide of mercury is used.

The chlorides of sodium and potassium appear to promote fermentation somewhat. In mixtures containing these salts there was about 5·5 per cent.

* 300 c.c. of a mash containing 8·449 grm. of sugar was mixed with 10 per cent. of yeast and left to ferment at 18° C. After the lapse of six days all the sugar had disappeared; the alcohol then contained in the liquid was ascertained to be 6·942 grm. According to the amount of sugar, it should have been only 4·317 grm.

* After fermenting 385 c.c. of beer-wort containing 22·86 grm. of sugar, it was found to contain 18 grm. of alcohol, but according to the quantity of sugar it contained, only 11·683 grm. should have been formed. The excess of alcohol in this and the preceding experiment can only have originated from dextrin. The quantity of dextrin decomposed in fermentation appears also to be very much dependent upon the temperature of the wort during fermentation. 500 c.c. of the same wort fermented at 8° C. gave 13·897 grm. alcohol; while according to the quantity of sugar in the wort, 14·37 grm. of alcohol might have been formed.

† Colin.

more sugar decomposed within sixteen hours than in the standard mixture.

Caustic potash, soda and ammonia, added to the mixture in such quantity as to render the liquid strongly alkaline, did not hinder fermentation; but a much longer time elapsed before the evolution of gas became evident, since the carbonic acid was taken up by the alkalies until bicarbonates had been formed.

Fermentation is remarkably retarded by chloroform. After adding 30 c.c. of a clear, filtered solution of chloroform in warm water, several mixtures were left to ferment for fifteen or eighteen hours, with the following results as regards the sugar decomposed:—

	I.	II.	III.
Mixtures with chloroform	0·240	1·240	4·00 grm.
„ without „	1·670	2·230	4·34

The mixture I. was tested for sugar eighteen hours after fermentation, II. fifteen hours after, and III. forty hours after.

Against 100 parts sugar decomposed in the standard mixtures, there was in I. only 14 per cent. decomposed, within the same time, where chloroform was present; in II. there was only 55 per cent. decomposed.

As chloroform is very sparingly soluble in water, if it may be assumed that the solution contained its own volume of chloroform vapour, it would only amount to one-third of the volume of the mixtures, so that the action of chloroform may be regarded as very powerful. A few drops of chloroform added to one of the mixtures, stopped the fermentation completely.

My experiments as to the influence of quinine upon fermentation are confirmatory of the results obtained by Dr. Kerner and others. Small quantities retard, while larger quantities entirely stop fermentation. With an addition of 0·2 grm. sulphate of quinine, the mixture contained 4·75 grm. sugar after forty-eight hours, while in the standard mixture the whole of the 5 grm. had been decomposed.

In neutral solutions nicotine appears to accelerate fermentation somewhat. With an addition of 0·5 grm. hydrochlorate of nicotine, the sugar decomposed after fourteen hours was as 11 : 10 in the standard mixture, so that one-tenth of the sugar remained in the unmixed solution of sugar; after thirty-six hours the quantities of decomposed sugar were as 29·5 : 26·5, or in the same ratio as before. Therefore in both instances the acceleration was apparently the same.

The influence of strychnine is peculiar. On addition of small quantities, fermentation is at first accelerated, then it is retarded. The mixtures containing strychnine evolve much more gas during the first six hours than the standard does; they froth considerably more and readily rise over the top of the vessel.

In two mixtures, containing respectively 0·01 grm. and 0·1 grm. hydrochlorate of strychnine, the quantities of sugar decomposed within four hours were to the quantity decomposed in the standard as 15 : 14 : 13; after eighteen hours they were as 24 : 24 : 25·7, so that it would seem there was acceleration during the first four hours and a retardation subsequently.

This retardation is more recognizable when the addition of strychnine is increased. On adding 0·2 grm. of the salt, there were decomposed in two mixtures—

With strychnine . . .	3·09 grm. sugar.	
Without „ . . .	3·68	„

Creatin appears to retard fermentation, while creatinine appears to accelerate it, and at the same time the creatine is partially converted into creatinine.

An exceedingly minute quantity of prussic acid suffices to retard fermentation and to stop it altogether. In a mixture containing 0·018 grm. dry acid, the quantity of sugar decomposed within sixteen hours was only 0·6 grm., while on the standard there was 3·4 grm. decomposed, or six times as much. With a large quantity of prussic acid there was no fermentation.

The action of the organic substance in yeast-water upon cane sugar is not hindered by prussic acid. When yeast-water, mixed with a few drops of the acid and a solution of cane sugar, is left for some hours, a certain quantity of grape sugar is found to have been formed. On saturating the liquid with oxide of mercury, filtering, and heating the filtered liquid after addition of caustic soda, a grey precipitate of metallic mercury is produced. It is only grape sugar that has this property of reducing an alkaline solution of cyanide of mercury.

However, prussic acid has a remarkable influence upon yeast-water: it has already been mentioned that yeast-water left in contact with the air becomes turbid and deposits a white sediment. Frequently there is also a layer of mould formed on the surface. This alteration appears to be entirely prevented by prussic acid. Yeast-water mixed with a mere trace of prussic acid remains for weeks perfectly clear; there is no sediment formed nor any appearance of moulding.

Schönbein has already noticed the retardation caused by prussic acid, and one of its most remarkable features is that the capability of yeast to produce fermentation is not destroyed. Yeast that has been kept for some long time in contact with tolerably strong prussic acid was found, after washing out the acid, to produce perfectly normal fermentation in sugar solution.

It appears, therefore, that prussic acid does not effect any decomposition of the cell contents, nor enter into any permanent combination with any of its constituents, but that its presence suffices to suspend the molecular motion taking place in the cells just in the same way that a weak solution of carbolic acid or of creasote does.

When yeast is brought in contact with solution of peroxide of hydrogen, a copious evolution of oxygen takes place, as pointed out by Schlossberger; but if the yeast be mixed with some prussic acid beforehand, there is no decomposition of the peroxide of hydrogen and no evolution of gas.

This phenomenon calls to mind the remarkable observations of Schönbein as to the action of prussic acid on blood-pigment and materials susceptible of putrefaction. He found that when fresh blood is mixed with a solution of peroxide of hydrogen, the equilibrium of this unstable compound is so much disturbed that its constituents rapidly break up into water and oxygen gas. However, the admixture of a very minute quantity of prussic acid entirely neutralized the decomposing influence of the red pigment on the peroxide, and the mixture then became dark blackish-brown.

It is well known that pure colourless blood serum, of the same degree of concentration as in blood, may be left for weeks in contact with the air, and that it will not putrefy; while defibrinated blood, on the mixture of blood serum with the corpuscles of the blood, rapidly passes into a state of putrid fermentation. In this case the blood-pigment appears to act upon the albumen of the blood just in the same way as yeast acts on sugar. An addition of a thousandth part of prussic acid to blood is sufficient to suppress putrefaction for a long time, just the same as it prevents the fermentation of sugar.

Neither strychnine, quinine, pyrogallic acid, nor oxide of mercury prevents the action of blood-pigment upon peroxide of hydrogen, neither does chloroform nor hydrate of chloral. Blood diluted with water is rendered sensibly paler-coloured by chloroform, while, on the contrary, the colour is darkened by hydrate of chloral, even in a slightly acid solution.

Thénard observed that well-washed white blood fibrine, when mixed with peroxide of hydrogen, produces the same effect as Schönbein observed with blood-pigment; the threads of fibrine immersed in a solution of the peroxide become covered with gas bubbles. However, if the fibrine be moistened beforehand with a few drops of prussic acid, and left for an hour before being immersed in the solution of peroxide, there is then no evolution of gas caused.

In the behaviour of yeast-cells towards chemical agents, such as strychnine, chloroform, quinine, and prussic acid, there seems to be some analogy with the influence exercised by some medicines upon certain parts of the living animal body, and from this point of view it may be of interest.

In regard to yeast as a plant-cell, it is remarkable enough that it has a chemical composition nearly the same as that of animal structures; the chief difference is, that the cell-membrane of the yeast-cell consists of a non-nitrogenous material. The mineral constituents are the same in both cases, and in the large amount of potash and phosphoric acid present analogy with those of muscle; moreover, the products of the putrefaction of yeast-cells are scarcely different from those afforded by animal materials.

It is to be assumed that in the living cell in the animal organism, there is incessant transformation or metamorphosis just as in yeast-cell; also, that the action of many medicines upon the living body, such as quinine, chloroform, prussic acid, etc., depends essentially upon the influence exercised by them upon the normal state of metamorphosis upon their altering the condition and normal functions of the nerves. Some chemical agents, such as sulphuretted hydrogen and pyrogallic acid, act in a purely chemical manner upon the blood; but the action of quinine, of prussic acid, or of strychnine is not so simple, and it does not admit of explanation simply by chemical alterations.

The liver and some glands may be compared to a system of yeast-cells in which, during its construction out of the constituents of the blood, peculiar compounds are formed that constitute the contents of the cells—compounds that have only a temporary existence, that exercise a special action upon the blood and its constituents (inasmuch as their constituents separate or arrange themselves differently)—just as the yeast-cells act upon beer-wort, and while decomposing its sugar, constantly reproduce themselves.

The observation recently made by Schmulewitsch, under the guidance of Ludwig, that the liver of a freshly-killed rabbit continues to secrete bile for several hours when defibrinated dog's blood is passed through it, is, in this respect, of the greatest significance, and so is the formation of sugar in the liver observed by Bernard to take place even when the food consists exclusively of flesh.

The fact that a fresh calf's liver cut into pieces, and kept in water at 30° to 40° C., begins after four or six hours to evolve pure hydrogen gas without giving off the slightest smell, is, I believe, indicative of a powerful process of metamorphosis going on in the liver. Considering the part played in digestion by one of the organic substances contained in the gastric secretion; considering also the peculiarities of the saliva and of the pancreatic secretion, it is scarcely possible to avoid the conclusion that a number of processes in the animal organism are dependent on the same causes that give yeast its remarkable influence.

ON MEDICINAL PEPSIN.*

BY RICHARD V. TUSON, F.C.S.,

Professor of Chemistry at the Royal Veterinary College.

Since the introduction into medicine of Corvisart and Boudault's "poudre nutrimentive" in the year 1854, pepsin obtained from the stomach of the pig,† calf, or sheep, in a state of greater or less impurity, has been extensively prescribed in dyspepsia and certain other affections. According to the testimony of some authorities of high standing, long experience in the use of this agent fully justifies the predictions relative to its therapeutic value, which were put forward by Corvisart as based upon physiological reasoning. However, there are other authorities, equally eminent, who either express doubts as to the efficacy of pepsin, or positively state that it is totally devoid of medicinal power. In all probability this difference of opinion mainly arises from the circumstance that pharmaceutists supply medical men with various preparations; all bearing the same specific name of pepsin, but differing very considerably in their digestive powers and other qualities. In fact, so far as I have at present been able to collect evidence relative to the merits and demerits of pepsin, I find those who speak favourably of its employment in the treatment of disease have prescribed that prepared by the best makers; while those who express a doubtful or adverse opinion respecting its value have been in the habit of prescribing those varieties or makes which the experiments of myself and others have proved to be practically without any digestive activity whatever. The relative digesting capability of several samples of English and Continental pepsin was investigated by Dr. Sieveking‡ in 1857 and a similar inquiry was conducted by Dr. Pavy§ in 1863. The results of the experiments of both gentlemen indicated that there was not merely a difference in the qualities of the pepsin prepared by different makers, but that—as was particularly shown by Dr. Pavy—some of the samples examined were totally incapable of digesting muscular tissue. One would have thought that the publicity given to these facts in the medical journals would have caused the prescription of none but the best makes of pepsin; that it would also have induced those who had hitherto fabricated an inferior article either to have abandoned its manufacture, or to have improved the methods they employed for its preparation. Such, however, was not the case, for pharmaceutists at the present date continue to vend, while

‡ 'Medical Times and Gazette,' 1857, vol. i. p. 336.

§ The 'Lancet,' April 25th, 1863.

medical men continue to prescribe, both the good and the bad qualities of pepsin. Only a few days ago an old-established and well-known wholesale druggist told me that a customer applied to him for two ounces of pepsin. He asked the customer whose make he required. The reply was, "the cheapest." On examining the kind of pepsin supplied on this occasion, it was found to be absolutely worthless as regards its power of digestion. Nevertheless it will be used medicinally and if the patient derives no apparent benefit from its administration, the practitioner who prescribed it may be induced to condemn pepsin *in toto;* or, should the patient soon get better, the improvement will in all likelihood be attributed to a preparation which is perfectly inert. In the first case, injustice would be done to a medicine which is said by many eminent practitioners to possess great therapeutic value when properly prepared; while in the second case, a worthless preparation would receive credit for performing a service it is totally incapable of rendering.

Being about to conduct some investigations on artificial digestion and requiring for my purpose considerable quantities of medicinal pepsin, possessing the highest digestive energy, I purchased, in March last, samples of the principal English makers; also some French samples, and one of a German maker. These were examined in the manner hereafter described. The results arrived at corroborate substantially those obtained by Dr. Pavy seven years ago, although the methods of investigation adopted by that gentleman and myself differ.* The following account of them may induce those who are in doubt as to the value of pepsin as a therapeutic agent to reinvestigate the medicinal action of an agent which, according to theory, ought to render good service in cases where the secretion of gastric juice is either deficient in quantity or defective in quality.

Ten samples of pepsin, obtained from different sources, were examined. The preparations of the several makers are distinguished from one another by letters in the following manner:—

A, A1 } Same make, but purchased at different houses.
B, B1 } Ditto, ditto.
C, C1, C2 } Ditto, ditto.

EXPERIMENTS UPON ALBUMEN.

Fresh eggs were kept in boiling water for an hour and then allowed to get quite cold. After depriving them of their shells, the whites were cut into the thinnest possible slices,† great care being taken to reject any portions of yelk, as well as all slices of white of unequal thickness. A weighed portion of coagulated albumen thus prepared was placed in a two-ounce wide-mouthed bottle, covered with distilled water containing 1 per cent. by volume of concentrated hydrochloric acid.‡ These operations were conducted during the latter part of the day. Next morning the required amount of pepsin was weighed out and added to the mixture of albumen and dilute hydrochloric acid. The bottle and its contents were then placed in a water bath and kept at a temperature of 38° C. (100·4° F.). Digestion was regarded as complete when, at the end of four hours, particles of albumen could no longer be seen, and when the insoluble residue consisted of a very minute quantity of fibrous or membranous matters only. These observations were easily made, except in the experiments upon samples of pepsin containing large quantities of starch. In such cases, when digestion appeared to be finished, the result was not recorded until the contents of the bottle had been carefully elutriated, or strained through fine muslin, so that it might be ascertained with certainty, by the appearance of the residue in the bottle or on the filter (muslin), whether or not the whole of the albumen had been dissolved.

In the first series of experiments upon albumen, 5 grammes of coagulated egg-albumen and 25 cubic centimetres of distilled water, containing 1 per cent. of hydrochloric acid, were employed. The quantities of pepsin used are stated in the subjoined table, which is intended to show the relative amounts of the different makers (A, B, C, D, E, F) required to digest the same quantity of albumen in four hours. Two comparative experiments were in every instance set going at the same time.

Table showing Results of First Series of Experiments on Albumen (*25 cubic centimetres of acidulated water*).

5·000	...	...	...	ditto	ditto	ditto

It having been found impossible to continue the experiments on make C, with more than 1·5 gramme of pepsin, in consequence of the inability of 25 cubic centimetres of acidulated water to keep the mixture in a sufficiently liquid state, a second series of experiments were commenced, in which 50 instead of 25 cubic centimetres of diluted acid was employed. The weight of albumen used was the same as that in the first series, viz. 5 grammes.

Table showing Results of Second Series of Experiments upon Albumen (*50 cubic centimetres of acidulated water*).

* Experiments with this make of pepsin were here discontinued, in consequence of the 25 grammes of acidulated water employed being insufficient to maintain the requisite fluidity of the mixture.

* Dr. Pavy noticed the relative solvent action on frogs' legs of mixtures of pepsin and dilute acid.

† It is easier to observe the progress of the digestion of albumen if it be sliced than if it be minced.

‡ This degree of dilution was adopted from the circumstance that the results of special experiments indicated that it was more favourable to digestion than an acid of greater or less strength. It was also ascertained that water containing five per cent. of hydrochloric acid appeared to prevent completely the digestive process taking place. Is it, therefore, wise to administer acids along with or immediately after pepsin, in cases in where the stomach already contains an excessive quantity of acid?

From the results of the experiments detailed in the foregoing tables, it will be seen—

1st. That, in order to effect the digestion of a given weight of albumen, very different quantities of the pepsin prepared by makers A, B, C are required.

2nd. That, taking the digestive power of C as unity, the digestive ratios of A, B, and C are as follows:—

C = 1 (1·25 gramme dissolves 5 grammes of albumen.)
B = 2·5 (0·50 „ „ „ „)
A = 25 (0·05 „ „ „ „)

In other words, A is ten times as strong as B, and twenty-five times as strong as C.

3rd. That, inasmuch as coagulated albumen mixed with acidulated water and equal weights of D, E, and F did not give the slightest indication of being digested, even at the expiration of twenty-four hours from the commencement of the experiment, it is evident that such samples of pepsin are, to say the least, practically destitute of the power of digestion. A 1, B 1, C 1, and C 2 were tested in precisely the same manner as the other samples; it was found that their digestive powers did not materially differ from the corresponding samples A, B, and C, which, it will be remembered, were prepared by the same makers, but obtained from different sources.

The evidence afforded by the results of the experiments already referred to, will doubtless be considered quite sufficient to prove the existence of a wide difference in the digestive energy of certain samples of pepsin met with in pharmacy, and the utter worthlessness of others. Nevertheless, the following series of experiments upon fibrin was undertaken for the purpose of ascertaining whether or not the results would accord with those obtained in the previous investigations upon albumen.

EXPERIMENTS UPON FIBRIN.

In these experiments 5 grammes of finely-minced fibrin (lean of rumpsteak) was mixed with 50 cubic centimetres of distilled water containing 1 per cent. by volume of concentrated hydrochloric acid, and the quantities of pepsin stated in the following table. Temp. 38° C. (100·4° F.); duration of experiment, four hours. Two comparative experiments were invariably set going at the same time. When, in consequence of the presence of starch, the progress of digestion could not be satisfactorily watched, the mixture was strained through fine muslin for the purpose previously named when describing the mode of experimenting with albumen.

Table showing Results of Experiments upon Fibrin.

Weight of Pepsin employed.	MAKE OF PEPSIN.					
	A.	B.	C.	D.	E.	F.
Grammes.						
0·45	Digested.	Not digested	Not digested	Not digested	Not digested	Not digested
1·00	...	ditto	ditto	ditto	ditto	ditto
1·50	...	ditto	ditto	ditto	ditto	ditto
2·00	...	ditto	ditto	ditto	ditto	ditto
3·00	...	ditto	ditto	ditto	ditto	ditto
4·00	...	ditto	ditto	ditto	ditto	ditto
5·00	...	...	ditto	ditto	ditto	ditto

We are now enabled to see—

1st. That the relative digestive power of A and B on fibrin was very nearly the same as with albumen, the ratios being

10 A to 1 B with albumen;
8·88 (in round numbers 9) A to 1 B with fibrin.

2nd. That inasmuch as 5 grammes of fibrin was undigested by equal weights of pepsins C, D, E, and F, these preparations are practically destitute of medicinal value.*

Having shown, from the results of nearly three hundred experiments upon albumen and fibrin, that the pepsin distinguished by the letter A is far superior in quality to that of any other make, it appears to me simply an act of duty to the medical profession and of justice to the undermentioned firm, to state that it is prepared by Messrs. Bullock and Reynolds, of Hanover Street, Hanover Square.* In conclusion, I beg to thank my very able assistant, Mr. E. Lapper, for the aid he has rendered me during the prosecution of this inquiry.

* The fibrin remained undigested even at the end of twenty-four hours from the commencement of these experiments.

HYDRATE OF CHLORAL.

In one of a series of articles on the "Progress of Therapeutical Science," the 'Medical Times and Gazette' mentions that some years ago the late Sir J. Y. Simpson predicted† that among the organic compounds constantly being discovered by chemists some one would be found "as important as that most useful of all drugs—opium—and yet without either its constipating effects, or indirect tendency to excite subsequent nausea." Such a substance was found before his death in hydrate of chloral. From the same article we take the following particulars:—

Chloral itself was discovered by Liebig, in 1832; subsequently it was further examined by Dumas, but up to last year it remained a substance of merely chemical interest. Though itself a thin, colourless oil, clearer than water, greasy to the touch, possessing a peculiar pungent odour, and exciting a copious flow of tears, it forms with water a solid crystalline compound; and, as shown by Liebreich, of Berlin, this compound possesses great power as a hypnotic and anæsthetic. The hydrate of chloral contains 89·02 per cent. of chloral and 10·88 water. It dissolves freely in water, a saturated solution containing about 50 per cent. When pure, its diluted solution has a rather agreeable taste, a point of no small importance in its favour.

Dr. Richardson has characterized Liebreich's discovery of the medicinal virtues of chloral hydrate as a brilliant illustration of modern advance in therapeutics, inasmuch as it was arrived at by a determination of the action of a substance theoretically from a precise knowledge of its chemical and physical properties. Hydrate of chloral reacts with an alkali in such a manner that they are resolved into chloroform and a formiate. The blood being an alkaline liquid, Liebreich inferred that it ought therefore to produce this change, and that if chloral hydrate were introduced into the animal organism, "every small particle of it would consume the surrounding alkali, the decomposition being completed only after the requisite quantity of alkali had been furnished by the blood within an infinitesimal period; a minimum quantity of chloroform would thus be formed and passed to its first place of action, viz. the ganglia cells of the cerebrum." On account of the slight alkalinity of the blood, formation of chloroform would not take place explosively, as it were, but gradually and slowly, its own peculiar action would therefore also be exercised gradually and slowly on the ganglia of the cord, and lastly on the heart.

Liebreich first experimented with the substance on animals, and finding his anticipations realized, then extended his observations to man. His results were communicated to the Academy of Sciences in Paris during 1869, and he has since published a valuable pamphlet on the properties of chloral hydrate.‡ Last August, during the meeting of the British Association at Exeter, speci-

* Dr. Pavy also showed in 1863 that the pepsin of Messrs. Bullock and Reynolds was much more active than that of any other maker.

† 'Physicians and Physic,' 1856, p. 100; 'Monthly Journal of Medical Science,' vol. xvi. p. 359.

‡ 'Das Chloral Hydrat, ein neues Hypnoticum und Anästhesien,' etc. Von Dr. O. Liebreich. Berlin, 1869.

mens of the medicine, and Liebreich's report having been received in England, Dr. Richardson examined its properties, confirming Liebreich's statements, and considerably enlarging our knowledge of the medicinal action of the substance.* He also inclined towards Liebreich's theory as to its mode of action. Personne also supports this theory, and has advanced evidence in its favour. Dr. D. B. Russell has likewise found that typhus patients are very sensitive to the action of chloral hydrate; and, in explanation of this fact, he points to the opinion, that the alkalinity of the fluids is increased in typhus. Of course, the more alkaline the blood, the more rapidly the decomposition of the hydrate and the production of chloroform might be expected to take place.

But, whatever the value of Liebreich's theory may be, the chief thing is to learn what are the effects of chloral hydrate—what is its real value as a medicine? One of the earliest to try it in England was Mr. Spencer Wells.† Since then it has been employed so extensively, that it may be useful to gather up somewhat the knowledge acquired as to its value. There does seem not a little danger of its being erected into a kind of panacea for all the ills that flesh is heir to, of its true worth and fame suffering from too indiscriminate use. Its value is probably too great and too real for actual eclipse by its abuse; but the repute of this medicine may be dangerously compromised.

Hydrate of chloral ought, when used as a medicine, to be perfectly *pure*. When impure it has, like impure chloroform, highly irritating properties, and in the formation of chloral other chlorinated compounds may be produced. These must be carefully removed. In the great demand that has arisen for chloral hydrate, and the desire to cheapen its production, there is danger of impure specimens being supplied.

Liebreich stated that, in sufficient doses, the hydrate produces, after a short interval, deep sleep, and when carried far enough, complete anæsthesia; that its action is not accompanied with excitement, and that it leaves no bad after-effects. Dr. Richardson concluded from his experiments that "deep and prolonged narcotism can be safely produced by the hydrate; that, during a portion of the period of narcotism, there may be complete anæsthesia with absence of reflex actions; a condition in which every operation fails to call forth consciousness, and that, during the narcotism, there are intervals of apparent exalted sensibility." But he observes the insensibility and the sleep this hydrate produces do not represent or rival the action of the volatile anæsthetics we use for abolition of pain during surgical operations. Moreover Demarquay, of Paris, in his experiments on rabbits, failed to observe any anæsthetic state; but he found that the animals, though thrown into most perfect sleep, were in a state of highly-exalted *hyperæsthesia.*

On the whole it appears experience has shown that the hydrate is not truly anæsthetic; that very large doses will produce heavy and prolonged sleep, but not true anæsthesia,—certainly that anæsthesia cannot safely be induced by it. There is but very slight record of direct evidence on this point. Professor Nussbaum tried it as an anæsthetic in the Munich Hospital; out of twenty cases it caused anæsthesia in only one, that of a woman of weak constitution. All the other subjects experimented on experienced only drunkenness, and they said the pain caused by operations was less severe than under the influence of chloroform, sometimes even being scarcely felt, but only the one experienced no pain at all.‡ This report is so imperfect as to be all but useless; and it may be taken for certain that to produce anæsthesia the hydrate must be given in toxic doses. M. Noira relates,* as a warning, a case of amputation under the influence of chloral hydrate. The patient, a man of sixty-four, took five grains of the hydrate; in two hours amputation of the leg was performed without his making a movement or uttering a cry. But the pulse then became filiform and uncountable, while a state of alarming coma lasted for eleven hours. Then violent delirium came on, with vomiting and pain in the stomach, lasting for eight hours, and leaving the patient in the most extreme prostration, the bad effects of which did not pass off for many hours longer.

From smygmographic observations made by M. Bouchat, Drs. Anstie and Burton Sanderson,† it appears that chloral hydrate contracts the arterioles. Dr. Russell Reynolds has also recorded a case in which a dose of 50 grains produced most alarming toxic effects in a lady of middle age. "The superficial pulses were almost imperceptible, and, when they could be detected, were excessively rapid, weak, irregular, and intermittent. The heart was regular in its beat, although feeble, and intensely rapid in its pulsations." Hence it would seem that the drug produces arterial anæmia of the brain when given in hypnotic doses, and it can hardly be desirable to push that effect by very large doses. M. Bouchat considers it to be contraindicated in cases of organic cerebral and cardiac mischief; certainly its effects may be feared in cases of fatty or otherwise weak heart.

But, as a hypnotic, there is no doubt Liebreich has placed in our hands a most valuable and admirable medicine. As a sleep-compeller it is, in a very large number of cases, unrivalled; for while, in power, opium alone can be compared with it, there is this superiority to opium, that its use entails no unpleasant after-symptoms,—no headache, no nausea, no anorexia, no constipation,—while the sleep it produces is gentle, calm, and continued. At least this is the general rule, though there have been cases where chloral hydrate has excited unpleasant effects, such as nausea and painful dreams. Cases of this kind will occur now and then, so long as human beings differ so greatly in temperament, constitution and sensibility to the action of medicine.

CULTIVATION OF CINCHONA IN MEXICO.

Mr. Hugo Finck, Vice-Consul of the North German Confederation at Cordova, Mexico, writes as follows, under date 10 July, 1870, to Mr. Hanbury, who has favoured us with the extract:—

> * * You remember sending me some seeds of *Cinchona officinalis*: I sowed them and a good many germinated, but the plants were all lost save one. That plant is now 7 feet high and looking very healthy. Afterwards I got from Mr. Nieto about a hundred small plants of *C. Calisaya*, *C. succirubra*, and *C. Condaminea*, which are all growing amazingly well. Some are already 12 feet high, with leaves from 10 to 15 inches long and wide in proportion. One three-year-old plant flowered at the house of Mr. Nieto, but I think this was premature and caused by some impediment in the ground, as a large stone or some other obstruction with which the roots came in contact.
>
> In 1866, the late Emperor Maximilian obtained some cinchona seeds from England which he distributed in this country. Mr. Nieto got the largest share of those seeds, and as he took great pains with them he raised thousands of plants, which he distributed to a number of persons. Of these plants the greater part were lost through injudicious management, so that actually only about 300 are alive, of which number I possess one-third.

REPORT OF EXPERIMENTS ON THE BROMIDE OF POTASSIUM USED IN MEDICINE.

The bromide of potassium now used in medicine is remarkably pure. Out of six samples described below, only one contained iodine; and even in that case the amount of iodine was very minute. The crystals of bromide of potassium, like those of the iodide, are sometimes transparent and sometimes opaque; the latter kind containing a certain amount of water, while the former are almost, if not entirely, anhydrous.

Analyses of these six samples gave the following results:—

No.	Obtained from	Quantity taken.	Silver-salt obtained.	Silver required.
		Grains.		
1	Eye Hospital, Moorfields; transparent kind	5·955	9·32	5·40
2	London Hospital; ditto	5·955	9·32	5·40
3	Douthwaite, 58, Bishopsgate Street; ditto	5·955	9·22	5·40
4	Skin Hospital; ditto	5·955	9·40	5·40
5	Warner and Co., Fore Street; ditto	5·955	9·26	5·40
6	Bell and Co., Oxford Street; opaque kind	5·955	9·05	5·26
	The theoretical numbers for absolutely pure bromide of potassium are	5·955	9·40	5·40

A determination of water was made in the sample of opaque bromide (No. 6). It contained 2·7 per cent. of water.

The sample No. 3, from Douthwaite's, contained a trace of iodide of potassium; all the rest were quite free from iodine.

These results show that chlorides are almost entirely absent from the commercial bromide of potassium in some instances; and that in the worst of the samples examined there was not more than 5·2 per cent. of chloride of potassium.

The method of examination adopted in this case was the same as that described in the Report on iodide of potassium.—*British Medical Journal.*

THE MILK AND WHEY CURES.*

BY DR. HERMANN LIEBERT,

Professor of Clinical Medicine in the University of Breslau.

The time is past when mineral waters were regarded as simple units (without reference to their constituents), where the mysticism of the healing power of the spirits bubbling from the depths of the earth had a particular charm, not for the layman only, but also for many practitioners; when the might of the propitious Naiads within the province of balneology gave rise, not only to large numbers of doggrel verses, but to a still greater quantity of prose writing. Natural philosophy, chemistry and experience sifted by a process of severe criticism, have at last begun to bear sway even in this department. We have become aware that the ghosts rising from the deep are nothing but aerated water impregnated with salts derived from the soil and rocks through which it has flowed, and from this fact we derive a knowledge beneficial to therapeutics, as to the proper relations of solution and chemical combination. Of the gases again, we know that sulphuretted hydrogen for instance, is generated by the decomposition of sulphate of lime or other sulphates; the bubbling carbonic acid from carbonated salts, earths, and particularly from carbonate of lime. From a chemical point of view we are better acquainted with the mineral waters than we are with most of our composite medicines; we know that their temperature depends on a definite law, that of the increase of the heat of the earth by one degree Centigrade for every hundred feet in depth; we know that from the very cold to the hot springs, physical condition as regards temperature exercises a decided influence on their action.

Concerning the bath, it has been ascertained that the salts contained in solution are not at all, or but little, absorbed by the skin. Consequently that a direct influence is exercised by the bath only in diseases of the skin or in affections which have communication with the skin by means of fistulous sores and otherwise. The unquestionable influence exercised on the nerves of the skin is much weakened by the epidermis, but nevertheless the physical action of the bath becomes quite prominent in the majority of diseases which do not directly concern the surface of the body. Here temperature plays a most important part; also in douches the degree of concentration, the force of the jet and the height from which the water falls; in vapour baths minute atomization and high temperature, etc.

The more hygiene becomes a subject of close and profound investigation, the more does climatology attain to its full and important rights. On taking a survey of many and accurate meteorological, physical, geographical, and geological investigations, it is found that they afford to the physician many useful and important data, but at the same time they impress him with a feeling of the responsibility of acting on a strictly critical and scientific basis in respect to such knowledge.

The courses of treatment by milk and whey occupy a prominent position amongst the hygienic courses, which are very often combined with climatic and mineral-water treatment. They are annually ordered for so large a number of patients that it seems very necessary a clear idea should be given of them; since, on the one hand, the milk cure, more particularly with respect to the different species of animals which supply the milk, has not yet been sufficiently appreciated, whilst on the other hand, the course of treatment by whey has been very much over-estimated, having attained to such proportions in the watering-places of Silesia as to render the latter rivals even to those of Switzerland. Most health resorts where the whey cure is practised have an advantageous climatic position; their arrangements and the whole mode of life in them are well arranged; the medical advice is mostly derived from full experience and beneficial results in chronic cases cannot be denied. Nevertheless, we must in many cases confidently conclude that the patients have been benefited or cured, not in consequence of, but in spite of the whey. Concerning this point, a want of knowledge in natural philosophy and chemistry is felt by many physicians, and this again proves that secular traditions must not be mistaken for verified experience.

The author then makes the following remarks on the chemical nature of milk and whey:—"If we compare different kinds of milk with reference to their solid constituents we find that asses' milk is most dilute, containing scarcely 9 per cent. solid matter; next stands human milk with somewhat over 11 per cent.; next, goats' milk with 13½ per cent.; next cows' milk with over 14 per cent.; then sheep's milk containing 16 per cent. (according to an analysis recently made in my laboratory, even 18 per cent.); lastly, mares' milk, containing 17 per cent. From these facts asses' milk would be applicable in cases where dilute milk seems desirable. Goats' and cows' milk represent the average quality; sheep's milk would be suitable when that containing a large amount of nourishment is thought necessary, and it is preferable to the rich mares' milk—which in the

* Abstract of a lecture published in the 'Medical Times and Gazette.'

central parts of Europe is also frequently applied to therapeutic purposes—because it contains a larger quantity of albumen and casein.

"Still more important than the total amount of the solid matter, is the amount of casein and albumen. Excepting mares' milk, which is excessively poor in this respect, human milk is the poorest, containing only 4 per cent. of casein, whilst cows' milk contains nearly 5 per cent., with more than ½ per cent. albumen. In direct opposition to the latter stands asses' milk, with only 2 per cent. casein and albumen; for this reason it is beneficially employed in inflammatory chronic diseases, in which the supply of nitrogenous matter must be confined within moderate limits. Goats' milk, with 5⅗ per cent. of casein and albumen, is particularly characterized by its large amount of albumen, which is 1⅓ per cent., while sheep's milk is in this particular again the richest, since of 5⅓ per cent. of casein and albumen, as much as 1⅗ are albumen.

"Asses' milk contains also the smallest quantity of butter, whilst cows' and human milk contain 4½ per cent., sheep's milk nearly 6 per cent., goats' milk nearly 7 per cent. Goats' and sheep's milk contain, again, the largest amount of hydrocarbons; the sheep exhibiting the enormous value of the nourishing constituents of its milk by its containing 11¼ per cent. of proteine matters and hydrocarbons.

"The milk sugar amounts on the average to 4 per cent. in the milk of the cow, goat, and sheep, while there is more than 5 per cent. in the milk of the ass.

"The salts, chlorides of the alkalies, earths, etc., amount to ½ or ⅗ per cent. on the average in different kinds of milk. The large amount of milk-sugar in mares' milk, viz. 8 per cent., only moderately increases its nutritive value, but renders it prone to alcoholic fermentation, whence arises its manifold application in the 'Koumyss' cure treatment practised amongst Tartar tribes."

POPPY CULTURE IN NORTH AMERICA.

In order to supply the requirements of American pharmacy, the cultivation of the poppy has been commenced in various parts of North America. According to the 'Journal de Pharmacie d'Anvers,' the Californian agriculturists have tried it upon a large scale, and as they have been assisted by the extensive experience of the Chinese, great numbers of whom are now settled in the State, the experiment has succeeded very well.

There is much in this enterprise to tempt the farmer. It is well known that the poppy will grow in almost every kind of soil, and in nearly all climates, and that it needs very little skill for its cultivation. The amount of labour, too, required for collecting the opium is small. No process can be more simple than to split open the poppy-head when it is mature, and to extract from it the milky juice; this is rolled into a ball by means of a spatula with as much ease as a dairymaid forms a roll of butter. Twenty-four hours afterwards, the opium is ready for sale.

The poppy is also cultivated in Louisiana. Last spring a farmer planted seven acres with it there, and he hopes to collect fifty pounds of opium per acre. This would be an excellent return; but much depends, as in the case of cotton, upon the rapidity with which the gathering is done.

The 'Journal of Applied Chemistry,' in a recent number, states that Mr. C. Wilson, of Monkton, Vermont, sowed in the spring of 1868, rather more than six and a quarter acres with opium poppy seed. The yield from the gathered juice of the poppy-heads, or capsules, was 140 pounds, which, when dried, became marketable opium. For this the grower obtained prices ranging from eight to ten dollars per pound, from druggists and physicians in New England. The opium furnished 6·25 per cent. of morphine. It is stated by Professor Proctor, that with greater care in obtaining the pure juice of the capsules, the opium might be made to yield 10 per cent. of morphia. The proportion of this alkaloid which the best Turkey opium is capable of affording, varies from 9 to 14 per cent.

LARGE DOSES OF CHLORAL.

The following account of the effect of an overdose of chloral upon the writer, who was suffering from insomnia, has been furnished to the 'Lancet':—

"With the exception of want of sleep, I am otherwise in good health. I have found out that alcohol, taken in excess, will in my case procure sleep; but in it I have no sort of inclination to indulge, and therefore it is that I am obliged to have recourse to narcotics. I have tried morphia, both bimeconate and muriate, and have experienced from its exhibition anorexia, nausea, and want of energy; cannabis indica almost provoked delirium, and bromide of potassium had no effect whatever. So you may be sure I was delighted when I saw the first account of hydrate of chloral in your Journal. I procured a supply without delay, and for months had the intense delight of refreshing sleep, waking in the morning with a good appetite, and fit for any amount of work. But, alas! its effects were not lasting. In the beginning 20 grains would have the desired effect; but latterly I have often taken as much as a drachm without any effect at all. On the night of the 2nd August I took 1 drachm of the hydrate of chloral at about 11 o'clock, and soon after went to bed. At 1, finding myself hot, restless and weary, I determined to take another dose. I could find no matches in the room, and, as I did not like to alarm the house, I took the bottle of chloral syrup (20 grains to 1 drachm), took a mouthful, and again sought sleep, but with no better result. Being teased, wearied and stupefied, but without any inclination to sleep, I again sought the syrup, and again took another very large mouthful. I was scarcely in bed when I was fast asleep and slept soundly from about 2 till half-past 10 in the morning. A servant, who had occasion to enter my room about 6 in the morning, says that I was then snoring loudly. I was called at 10 o'clock and aroused with some difficulty. When I tried to get out of bed, I found, to my horror, that I had no control whatever over my legs from the knees down. I could not stand; my legs tottered, and I should have fallen had I not clung to the bedpost. I wish your readers to understand that I had the use of every part of my frame, except from the knees down. With the aid of a servant I dressed myself, and proceeded as well as I could to descend the stairs. In doing so I had several stumbles, and should have fallen were it not for my servant's support. I made a hearty breakfast and went about my business as usual, the only inconvenience I felt being the unsteadiness of my gait and a slight diminution of sensation about the lower extremities. On measuring the quantity remaining in the bottle, and knowing exactly how much it contained when I took the first dose on the night of the 2nd of August, I find that between the hours of 11 and 2 I swallowed about 7 drachms of chloral! Had I made a similar blunder with any of the other narcotics I have mentioned, I fear I should now be in that region where 'the wicked cease from troubling, and the weary are at rest.'"

SATURDAY, AUGUST 20, 1870.

HOSPITAL DISPENSING.

A case tried at one of the London police courts this week will serve to show that some of those medical authorities who are most urgent in pressing the adoption of stringent restrictions upon dispensing by pharmaceutists are by no means the most earnest and careful in themselves adopting such precautions. Jane Brant, aged thirty-four, a married woman, was brought before Mr. Cooke by the police. They had been called to the defendant's apartments, and there found her suffering severely from the effects of poison which she had taken. She was an out-patient of the Royal Free Hospital, Gray's Inn Road, and had a lotion and some medicine given her. Both the medicines were in quart bottles; the lotion was labelled poison in large letters, but in the dark she had drunk some of it by mistake. It was rather an odd reversal of the usual current of affairs under such circumstances, to find the prisoner charged with criminal negligence before the magistrate. But the woman, it was stated, was not unknown at the court; they placed her at the bar to have the matter investigated. She was, of course, discharged, but she got the reprimand which would probably have fallen to the share of the institution had that been one of a private character instead of being public.

There is unquestionably a good deal of carelessness about bottles, and labels too, at a great many hospitals. The patients usually find their own bottles and jars, and any poisonous compounds find their way into harmless and familiar vessels, the customary receptacles of various household drinks and domestic dainties. Very strange and potent confections find their way into old jam-pots. Hemlock and the deadly nightshade are passed into vessels long identified with British wine and stronger drinks; and the same bottle may be seen making alternate pilgrimages to the public-house and the dispensary of the best-regulated hospitals.

So much laxity in high places is not without its dangers, both of fact and effect, inherent and by example. If the system of poison-bottles be anywhere openly set at defiance, it is at hospital dispensaries in the out-patient departments; and this, too, in dealing with the least educated and most careless part of the population; those who have the smallest opportunities of precaution in storage of their prescribed medicines, and who are the most liable, by absolute ignorance and by intemperate habits, to omit to study their labels.

HELP FOR THE WOUNDED.

The eloquent appeal made by the 'Times' last Monday in behalf of the sick and wounded in the present war, will doubtless meet with a cordial response throughout the kingdom. A society has been formed for this purpose, under the presidency of the Prince of Wales, and considerable subscriptions have already been given, the Queen heading the list with a contribution of £500. This Society works under the Red Cross, adopted by the Governments of Europe at the Convention of Geneva as the badge of neutrality. Its agents are respected as neutral, and they succour the wounded of both sides alike.

A Committee of Ladies has been formed for collecting, preparing, and issuing materials, while the Central Working Committee, presided over by Lieutenant-Colonel Loyd Lindsay, will provide for surgical and other aid being sent out at once.

Believing that many who are connected with pharmacy would gladly contribute towards this laudable undertaking, we venture to suggest that they should do so in concert, and that a fund should be raised to hand over to Colonel Lindsay's Committee as the contribution of British Pharmacists. This body numbers no less than some 12,000 members, and though some might say that what they could afford to give would be little assistance to such a great undertaking, it must be remembered that even a small subscription individually, would amount to a very considerable sum in the aggregate. We hope therefore that this suggestion will be favourably received by the trade generally, and all connected with it, each helping to the extent of his ability. We do not fear in that case obtaining a result that will be creditable to the whole body. Contributions are requested of money, lint, sticking-plaster, chloroform, chlorodyne, quinine, morphia, carbolic acid, etc. We propose publishing weekly a list of Subscribers to the Fund, and we have much pleasure in stating that Mr. Bremridge has consented to act as Treasurer.

THE REGISTER OF CHEMISTS AND DRUGGISTS.

A recent correspondent, in referring to the fact "that grocers who have sold drugs are now registered chemists," adds, "time, of course, will settle the many sham druggists now afloat," and no doubt he is so far correct in his opinion; but there is no need for the realization of this result being left entirely to the sure though slow agency of time. There is now an official Register of Chemists and Druggists, which contains a list of all members of the trade, with statements of their respective qualifications. This book is supplied by Government, just as the Medical Register is, to all the law courts in the kingdom, and to various public officials, numbering in all 1306, so that it is easy for magistrates or judges to ascertain whether a person coming before them in reference to any case is or is not legally qualified to practise pharmacy.

That this is not sufficiently attended to we have frequent occasion to notice, and we think it desirable for the general credit of the trade, to call especial attention to the matter. As will be seen in another part of the Journal, a person who has no place on the Register has recently been convicted of obtaining goods under false pretences, and he is described as a "chemist." This case affords an illustration of the readiness with which titles, improperly assumed, are recognized without further notice or inquiry, and we can scarcely be considered unreasonable in expressing the hope that in future both public officials and editors will avail themselves of the means afforded by the "Register" for preventing impostors from representing themselves as belonging in any way to the pharmaceutical body.

The Society's Local Secretaries throughout the country would also do good service by looking after these and similar cases. We have just received from a correspondent a circular bearing the name of the proprietor of a Provincial Medical Hall and Drug Establishment, who describes himself as being a "Registered Chemist *of the Pharmaceutical Society, London*," though he is in no way connected with the Society.

ACTIONS AGAINST DRUGGISTS.

Under the head of Legal Intelligence will be found the report of a case that will doubtless interest many provincial pharmaceutists. Mr. Barker, the defendant in that case, writes to ask if there be any fund available in the Society to defend actions of the kind. There is not any such provision; but the fact that pharmacists are liable to suffer from legal proceedings taken against them without due cause, is sufficient to show that the subject is one worth consideration.

Even in the event of a successful defence being made in such cases, costs are incurred in money, time and anxiety, which in fact amount to an unjust punishment. Only a few weeks ago* we had occasion to notice a case in which a defendant was condemned to costs, though there did not appear to be any ground for the verdict, so far as the report of the case went, and it is probable that some organization calculated to deal with such cases would be good for the general interests of the trade.

THE article we republish this week, from the 'Lancet,' on the subject of "Pepsin," will doubtless attract the attention of the makers of this remedy, and we shall be glad to receive from them any remarks on the subject which will lead to its being more generally understood.

* See *ante*, No. 5, p. 93.

Proceedings of Scientific Societies.

LONDON INSTITUTION.

On the 10th inst., J. P. Gassiot, Esq., D.C.L., F.R.S., distributed the prizes awarded, and certificates granted, to students who passed the examinations connected with the courses of educational lectures delivered during the past session by Professors Guthrie, Bloxam, and Bentley. The prizes consisted of standard works on physics, chemistry, and botany, handsomely bound. Dr. Gassiot stated that Prof. Odling would open the coming Session with a course of educational lectures "On Chemical Action," and that, after Christmas, Prof. Huxley would deliver a course "On the First Principles of Biology."

BRITISH MEDICAL ASSOCIATION.

THIRTY-EIGHTH ANNUAL MEETING.

Newcastle-on-Tyne, August 9th, 10th, 11th and 12th.

After the preliminary gathering of members and their friends at the Reception Room on Tuesday, there was a meeting of the Council, at which the chief business was the election of Mr. Ernest Hart as Editor of the Journal. At a general meeting held in the Lecture Room of the Literary and Philosophical Institution in the evening, the retiring President, Dr. Chadwick, in opening the proceedings, spoke of the influence exercised by the Association in reference to the Medical Acts Amendment Bill and dwelt strongly on the power of the Association to promote professional advancement. Then, after a passing mention of the losses the medical profession has sustained by deaths within the past year, he expressed his high sense of the honour that had been conferred upon himself and, with the appropriate words, "The President is dead! Long live the President!" relinquished the presidential chair to his successor, Dr. Charlton, who, in his inaugural address, reviewed at length the subjects of medical politics and sanitary reform, urging their extreme importance in regard to the general prosperity of the country. Referring to the time when the title of the Association was changed from Provincial to British, he said:—

It was then that, for the first time, our interests in the provinces became thoroughly identified with those of the profession in the metropolis. Since then, we have worked in perfect harmony with our London brethren, no longer regarding them as mere visitors, but welcoming them to our provincial meetings as *bonâ fide* members of the Association. Indeed it seems to us that most of the great reforms of our profession have taken place subsequent to this change of name—to this amalgamation of provincial and metropolitan interests. Although the deficiencies of medical education and the condition of the medical practitioner, had long before been discussed in our journals and set forth in language sharp and incisive as that of Junius, still it is only within the last two decades that the whole profession, tired of calling upon Jupiter, has unanimously put shoulder to the wheel and moved, with one accord, to remedy our wrongs. United by its able journal, united still more by the cordiality engendered at these annual meetings, the British Medical Association has pushed forward in the path of medical reform and the general regulation of the profession. Now the struggle for a good standard of medical education is finally before us. Hitherto the paramount obstacle to progress has been the multiplicity of sources from whence licences to practise medicine have been derived. No uniform standard of education could be kept up amid these jarring interests. The well-meant endeavours of the Medical Council, by sending out examiners to visit the different universities and corporations was no guarantee for permanent improvement; these bodies were ever competing for licentiates and were exposed to the deadly temptation of lowering their standards of education to attract more graduates. Against this crying evil there was but one remedy—a single gate by which all should enter the profession; a single but searching examination for the licence to practise."

For attaining this, he insisted upon the necessity for the great mass of practitioners being directly represented in the Medical Council and he regarded the recent action of the Government as acknowledging the existence—outside the Medical Council—of an interest and a power that it was the business of the Association to augment and consolidate.

Passing from the question of educational reform, Dr. Charlton went on to say that, when that shall have been settled, the Association would still have before it the wider field of sanitary reform, the prevention of zymotic disease, the cleansing of our cities and the purification of our rivers. In these matters some of our most time-honoured institutions are pre-eminently defective. With all our liberality of thought, and our boasted tendency to progress, it must be confessed that we in England are, in many respects, wonderfully conservative. We hold pertinaciously to an institution simply because it is an ancient form of procedure peculiar to our own country. We often cannot bring ourselves to acknowledge that what was advantageous in older and ruder times is quite unsuitable to the present state of society.

We have, however, the subject of hospital improvement, so ably advocated at the Leeds Meeting by Captain Douglas Galton. We have, too, the coming struggle as to the extension or the repeal of the Contagious Diseases Acts, where a band of strong-minded women and weak-minded men are striving to reverse the verdicts of the wisest and the best of the medical and legal profession. There will be no lack of objects for the energies of the rising generation and when, in after years, they shall peruse the records of what was done at this Newcastle meeting, they will, we trust, return a kindly verdict that we did our best, according to the lights we were then permitted to enjoy.

After the usual vote of thanks, the Secretary read the Report of Council, showing that there were now 4258 members on the books. The subsequent proceedings were tedious and somewhat disorderly.

On Wednesday, after the members of the Association had breakfasted with the Sheriff of Newcastle, the second general meeting was held and Mr. Whipple, of Plymouth, was elected President for the ensuing year. The address in medicine was then delivered by—

Dr. Sibson, who characterized the present age as being marked by experiment and exact inquiry, directness of aim and skilled power to do the work required, with completeness and economy. The labour of the past was surpassed, but not superseded; while nothing that had been done was lost, invention would still awaken invention, discovery would follow discovery. Each advance was a fresh starting-point for the future labourer. It was, indeed, everywhere taken for granted that, good as this or that work might be, better work—more simple and more to the purpose—still remained before them. The ship, the bridge, the rail, the telegraph and the gun of the present day, as compared with the past, were types and marks of the advance in the skill, precision and energy of the time. Medicine, too, partook of the movement that was going on around them. The knowledge of disease was becoming at the same time more accurate and more large. Each year gave them a better knowledge what medicines could do, what they could not do. If the spirit of scepticism had shaken the belief of a few in the medicinal means at their command, that spirit had aroused inquiry and cemented belief which was rapidly shifting into knowledge that would be secure. Those great old forms of medicine—the tincture of the muriate of iron, the sulphate of quinine, opium, the iodide of potassium, the infusion of digitalis, an occasional shot, but not a battery or running fire, of calomel—all those things, in fact, that had served their fathers well, would serve the present generation better. They knew what these could do when they were wanted, as well as when they were not wanted, so that, with gathered power, they applied them at the proper moment. Then science reached forth its arms, adding recently-discovered remedies to those of the day just gone by, chloroform, bromide of potassium and the still more newly-discovered hydrate of chloral. So knowledge of disease ripened, until the aim in its treatment became more precise and vigorous. Men asked themselves at each step they took, why they did this or that. Reason had taken the place of routine, while rational medicine had become at last the common property of the profession. Side by side with the use of medicine, not second to it, was the so-called hygienic treatment of disease, the study and regulation of the vital forces. The influence that every physician exercised upon the mind and, through the mind, upon the body; the soothing or stimulating of the nervous power; the calming of exaltation or the stirring up of apathy; the quieting of the over-busy brain or the spurring of the flaccid will; the repose of over-used powers or the awaking of suspended vital functions; the subduing of the over-sensitive skin or the stimulating of it when wan, muddy and lifeless; the limiting of supplies to an over-fed frame, or the repair of the body wasting with disease, by the proper kinds of food and stimulants; the bringing into play and, as it were, into fresh existence, muscle that had become wasted and paralysed by disease,—these were all among the aims that the physician sought to accomplish. These were among the means that he sought to employ irrespective of, but by no means without the use of medicine. These were the agencies that they all held in their power; that each of them exercised daily in coping with the various forms of malady, ailment, and constitution. There was a method of treatment, that of rest and ease, belonging to this great class, which he had himself been employing with deep interest in acute rheumatism and acute gout for some years. Therefore, it might be of interest if he narrated the results of his experience in that method of dealing with a disease that did so much to cripple the heart, limit the bodily powers and shorten life. During the last four years he had submitted all his patients in St. Mary's Hospital—affected with acute rheumatism and acute gout—to a rigid system of absolute rest, protection from external injury, gentle pressure, equal warmth and the removal of pain chiefly by treatment from without. Those two diseases, often so apparently identical, differed, as they would know, in this, that, while rheumatism attacked those whose blood and tissues were previously healthy, being produced by over-work and exposure, gout seized upon persons whose blood and tissues were already infected and contained uric acid in excess. In acute gout, therefore, he always gave iodide of potassium and sometimes colchicum, in the hope of getting rid of the special poison; but in acute rhematism he gave no internal medicine during the actual stage of the disease, unless it was called for by some special reason. He gave his patients no coloured or flavoured liquid to make them think they were taking medicine when they were not doing so, because he did not think it quite right and did not find it needful to employ such a system of fiction. If they did so, they complicated their observations, deprived themselves of the help that the patient could give them when he understood the aim of the method of treatment. Whatever might be the line of treatment adopted for disease, the influence of treatment on the disease itself was less than the physician was apt to think. The great majority of diseases tended to get well. They had, so to speak, a lifetime of their own, with its periods of growth, maturity and decline; they were the passing tenants of the body which they occupied, often with great injury, for a limited time. Treatment could not change their nature, could not expel them at once, could not quench them, could not materially shorten or prolong their existence. But treatment could lessen the sufferings of the body occupied by the disease, shield it from outer injury, repair its waste, support and reinforce its powers; while it could ward off those causes which tended to increase or re-awaken the disease by lessening the intensity of its action, inflammatory or otherwise, especially upon the local structures. To watch, then, the treatment of a disease was to watch, so to speak, not the remedy and its immediate effects, but the disease itself and its behaviour during a certain method of treatment. The thoughtful physician, while taking notice of this or that change in the malady, knew that such change was due mainly to the natural growth of the disease; he did not attribute it to the means which he had employed unless he had good grounds for doing so. Dr. Sibson then proceeded to describe in detail the working of his rest and ease system as carried out in St. Mary's Hospital.

Among the papers read at the several sections, the following possess an interest for pharmaceutists:—

Dr. Sansom read a paper "On the Sulpho-carbolates, and the Antiseptic Method in Medicine," in which he alluded to the difference of opinion with regard to what is termed the "germ theory" of disease. He thought much of the diversity depended on the connotation of the word "germ." There is abundant evidence that the "contagia" of transmissible disease are material and organic; they bear a strong analogy to ferments in their mode of operation; whatever the initial cause of each, the existence of organized material possessed of reproductive powers is intimately bound up with both processes. The author alluded to the recent researches of Chauveau on vaccine, glanders, and sheep-pox, as showing that the activity of "contagia" depended on the solid particles proved by Beale to be actively-moving masses of bioplasm. He considered the efficacy of disinfectant and antiseptic measures was due to no obvious chemical influence, but to the poisoning of those septic organisms which are intermediary agents of decomposition between organic and inorganic matter. He thought that the proliferation of contagia (bioplasm) might be checked within the living body. He then discussed Polli's treatment by the sulphites. From the well-known properties of carbolic acid he hoped more from the sulpho-carbolates, of which he gave a succinct description. (1.) The *alkaline sulpho-carbolates*. There was evidence of great success from the administration of the sodium salt in throat ulcerations and in scarlatina. There was promise of success in variola. In enteric fever, Dr. Ligertwood, of Newbury, considered the treatment to be efficacious. (2.) *Sulpho-carbolates of alkaline-earth metals*. Of these the most interesting is the very soluble calcium salt which the author had employed in cases of rickets with remarkable success. (3.) *Sulpho-carbolates of the metals*. The zinc and copper salts had been used by surgeons, especially by Mr. John Wood, as antiseptic dressings for wounds. A very favourable opinion of them had been given. The author had employed the iron salt internally, with varying success; he was doubtful whether it had any advantage over other salts of iron. In conclusion, he hoped that the remedies would be tried upon their merits, as he considered that, all theory apart, they would prove a useful addition to the materia medica.

In the Physiological Section, Dr. Bolton, of Lancaster, drew attention to the Turkish Bath, expressing his conviction that, properly constructed, it would become a valuable addition to the British Pharmacopœia. He showed that it had been used by our forefathers 2000 years ago, and he regarded the part taken by David Urquhart in reviving the use of this bath as constituting him one of the greatest benefactors of the present age.

In the Section of Public Medicine, Dr. Leonard Armstrong read a paper on "Difficulties in applying Sanitary Laws," in which he took a retrospective glance at the efforts which had been made in South Shields to secure an abatement of the smoke nuisance. The water supply was an excellent one, the population increasing and prosperous; yet, on comparing the Registrar-General's return for the last two years, the mortality of South Shields exceeded Sunderland greatly. To what were they to attribute this excessive mortality in South Shields? Lack of pure air. The atmosphere was polluted with smoke and gaseous nuisances. Continuing his remarks, Dr. Armstrong enumerated the various efforts made of late years to abate the nuisances, and expressed his opinion that no abatement could be expected when local and interested authorities would not inflict the pains and penalties of the law. He hoped the President would support some representation that all future sanitary Acts should not be permissive, but unfettered by local interests and feelings.

Dr. Stewart, of London, mentioned that at the works of Mr. Titus Salt, at Saltaire, the smoke was consumed; what had been done by Mr. Salt, in his great establishment, might be done in nine out of ten of the manufactories of the country.

After some discussion, Dr. Armstrong moved the following resolution, which Dr. Robinson seconded, and it was agreed to:—

"That in future sanitary legislation the smoke nuisance and other gaseous pollutions of the atmosphere must be dealt with by compulsory measures to be carried into effect by authorities independent of the district, and instructed by competent local inspectors unfettered by local interests and feelings."

In the evening the members of the Association were entertained at dinner by Sir W. Armstrong at Jesmond.

The President's Soirée in the Town Hall was brilliantly attended. Among the objects of scientific and artistic interest were ornithological specimens, archæological collections, photographs and porcelain. The principal table was devoted to the display, under a series of microscopes, of some of the most remarkable results of modern zoological research in the collection of deep-sea organisms, kindly placed at the service of Dr. Charlton by Dr. Carpenter, V.P.R.S. It may be remembered that in the recent 'Lightning' and 'Porcupine' expeditions, in the course of which these specimens were obtained, the sea-bed was explored even to the enormous depth of three miles and these organisms were obtained, creating a large addition to our knowledge of several divisions of the animal kingdom.

On Thursday the Third General Meeting was held, and, after some business had been disposed of, the address on surgery was delivered by Mr. Heath. This was a most satisfactory and masterly production, philosophical in spirit, comprehensive and practical in its scope, besides being eloquently delivered. In sketching the characteristics of modern surgery, he remarked upon the "boldness and magnitude of its proceedings; its respect for the integrity of the human body, and its reticence of the knife. It stretches out its hand to regions, and takes within its grasp organs, formerly thought beyond its reach, grappling, not unsuccessfully, with diseases hitherto considered incurable by scalpel or drug. Dangers and difficulties do not appal it, nor does it fear to undertake the gravest responsibility, if only its audacity is justified by the well-founded hope of destroying a fatal disease, or removing one which, although not fatal to life, may yet render that life a misery, a burden so wearisome to him who carries it, that death itself is not a greater calamity than life so oppressed.

Paradoxical as it may seem, whilst in one direction it is thus acquiring new dominions and showing itself capable of the most daring enterprises, in other quarters it lays down the knife and employs measures more sure, safer, and attended with less suffering; or it substitutes milder for more severe operations, shrinks from unnecessary mutilation of the human body, in every way seeking to conserve and maintain its integrity as complete as may be compatible with the object to be gained.

I claim for it, moreover, that in its bold, as well as in its milder and more conservative measures, it realizes a larger and more uniform amount of success; is thus a more useful and reliable agent than the art of former days—a success which is the more satisfactory that, though brilliant, it is the result of sound principles, industriously sought after and carefully carried out.

After illustrating these views at length, tracing out the principles that lead to the success of modern surgery, and discussing various new methods of procedure, which would be out of place to describe in this Journal, Mr. Heath went on to speak of improved education, placing at the disposal of the student means of learning the use of his hands, as one of the chief causes of increased operative skill.

The interchange of knowledge, by means of the periodicals of the day, the rapidity with which a new and improved proceeding or a brilliant operation becomes known throughout the profession, tends also to the general level of our success. Moreover, I will venture to say that an association like this, which gives to us obscure provincials the opportunity of seeing and hearing the brighter luminaries of our time, that brings vividly to our minds every advance which from year to year may be made in our art, exerts a more potent influence upon the origination and spread of improvements and in the upraising of the general standard of professional power than has yet been recognized.

I have also made it apparent that our special branch of surgical art is not stationary, but progressive; and that we may fairly challenge comparison with other arts and sciences, both as to the amount and rapidity of our progress.

As the world grows older, as the results gathered by past workers and thinkers accumulate, each succeeding generation stands on more advanced ground than its predecessors; facts already ascertained furnish a basis whereon to build new and truer theories, more efficient instruments are at command to investigate and to construct; thus the arts and sciences which increase our knowledge teach us the properties and conditions of matter, tell us of the true place and value of this little world in the crowded universe, or forge us weapons to fulfil our destiny and subdue the earth, press onwards with more and more rapid strides.

Our fellow-workers, the physiologist, the chemist, and the physician, are not idle; the innermost recesses of living things are made to give up their secrets; the mysteries of life in health and in disease are wrested from the minute molecules of structure; new drugs rise from the alembic; strange plants yield up their juices and their fruits to soothe our pains or cure maladies hitherto incurable; and, with greater knowledge and more effective means, the physician advances to the combat of disease with bolder and more certain steps, with greater assurance of victory.

What have we, the votaries of the knife, to show beside these marvels? If we cannot answer this question, this address has been written in vain. Gibbon asserts that the meanest insect which crawls along the dome of St. Peter's is more worthy of regard, more wonderful than that magnificent structure. Human life is surely more precious than the appliances which are subservient to it; but life itself may be far below its value, or a mere burden, when cumbered by painful disease or by deformity. We have seen with what audacity the modern surgeon encounters the most formidable enemies of life, what slight traces of his work he leaves behind, how limbs are preserved and yet the diseased part taken away; with what facility the cripple is rendered active, the humpback made straight, deformities conjured into symmetry; with what safety the thickened lens is taken away from the eye, the torturing stone extracted from the bladder. We know with how much confidence he can say to yon poor wretch writhing in inextinguishable sickness, Suffer me to put you to sleep for a brief space; I will undo in a few minutes the cause of your complaint; you shall be a sound man in not much longer time than would see you in your grave without such assistance. That haggard creature, too, whose form is rendered misshapen, whose life is being exhausted by a monstrous growth, whilst she is unconscious he will take away the encumbrance that oppresses her, raise her in a few weeks from her bed of suffering, and restore her to the world a fresh and blooming woman.

But we must not boast too much; we must confess that there are still foes whom we cannot yet overcome; still wide domains where the great enemy death remains victorious, but which it is for us and our successors to rescue from his scythe and bring under the dominion of the knife.

Nevertheless what I have been able to relate of the achievements already accomplished, will suffice to show that operative surgery has not stood still whilst other arts have advanced; that, if we do not occupy the foremost place, we are at least well to the front in that glorious race which they win who do the most to diminish human suffering and prolong life; to elevate and improve the condition of man.

In the Medical Section—

Dr. John C. Murray read a paper on "Snuff-taking," in which he stated that according to the experience of himself and others, the habitual snuffer seldom or never dies from consumption. He further declared that six cases of recovery from phthisis had come under his own notice consequent upon free snuff-taking. He concluded that snuff-taking is in some degree preventive of consumption, and its frequent concomitant bronchitis, in virtue, perhaps, of its derivative and *quasi* counter-irritant action. The way to cure a cold, according to Dr. Murray, is to have recourse to snuff-taking at once.

The Public Dinner of the Association took place in the Town Hall in the evening, and the satisfaction of the members was warmly expressed for the facilities afforded so willingly by the corporation for the transaction of the Association business.

On Friday there was an excursion to Durham University, where honorary degrees were conferred on several members. The following papers were read at the sectional meetings:—

Professor Hughes Bennett read an interim report by committee investigating the antagonism of remedies, and illustrated the subject by experiments on some rabbits. Having given one rabbit the 150th part of a grain of strychnia, by which it was killed, he next injected the same dose into a second rabbit, as well as 12 grains of hydrate of chloral. The second rabbit, after having been thrown into a deep sleep, recovered, and appeared none the worse for the experiments made upon it.

Dr. J. Henry Bennett contributed a paper "On the Climate of Algeria," in which he brought forward important facts deduced from an exploration of Algeria made in the spring of 1869. Algeria is a kind of Switzerland, extending above 400 miles from east to west, from Tunis to Morocco, and about 120 from north to south, from the Mediterranean to the desert of Sahara. This region is entirely occupied by the Mount Atlas, which divides into three ranges, running from east to west—the Lesser Atlas, the Middle Atlas, and the Greater Atlas,—with connecting buttresses, intervening valleys and elevated plains. These mountains, not attaining an elevation of above 7000 feet, do not reach the line of eternal snow, so there are no glaciers to form large rivers. But they are high enough to precipitate rain and snow in winter from moist air. The constant rarefaction of the atmosphere over the immense desert of Sahara causes, nearly all the year round, a rush of cooler air from the northern quarters—that is, from the Mediterranean and the Atlantic, the atmosphere being thus all but constantly charged with moisture winter and summer. Rain and snow fall in abundance during the six months of winter;

and heavy dews fall at night both in winter and summer. The climate of the mountain region of Algeria is, therefore, rainy and cold in winter. Algiers, being on the sea-level, is warmer; indeed, warmer than the north Mediterranean shores, but moist and rainy. The average rainfall is thirty-six inches; the average number of rainy days is ninety. The climate of Algiers, being thus mild and moist, is not suited to those cases of phthisis that require a dry bracing air, such as is found on the east coast of Spain and the Genoese Riviera.

The treatment of drunkenness was considered in the Psychological Section, and the business of the Association was then closed by the concluding General Meeting, which measures in reference to the Medical Bill were decided upon.

One of the most attractive features of the present meeting was the Annual Museum held in the Library, the Museum, and the Hall of the Newcastle Infirmary, in where all new objects of interest to the profession were exhibited, under the superintendence of Dr. Page, of Newcastle. Large numbers visited it.

The principal exhibitions of objects interesting to Pharmaceutists were—

H. B. Brady, Newcastle, chemical and pharmaceutical preparations, among which were samples of chloral, the hydrate of chloral, hydrate of bromal, and chloride of ethylidene, the last new anæsthetic introduced by Dr. Liebreich; also a collection of medico-electrical apparatus, and a new mercurial lamp for calomel fumigation.

Messrs. Calvert, Manchester; specimens of carbolic acid.

Messrs. Ellis and Son, Ruthin; aerated and mineral waters.

Messrs. Harvey and Reynolds, Leeds; clinical thermometers.

Messrs. Hopkins and Williams, London; chemicals and pharmaceutical preparations, including Matthiessen's apomorphia, and the crystallized tartrate of ammonia, in which Dr. Bastian found living organisms.

Messrs. Orlando Jones and Co., London; bread and biscuits made of entire wheat flour.

Messrs. Krohne and Suzeman, London; various instruments.

Messrs. Mayer and Mottyer, London; various instruments.

Messrs. Newbery, London; French specialities, etc.

Messrs. Savory and Moore, London; pepsine, pancreatine, and chemical food.

GRANT COLLEGE MEDICAL SOCIETY, BOMBAY.

July, 1870.

A New Indian Remedy.

BY MR. NARAYAN DAJI, GRADUATE OF THE GRANT MEDICAL COLLEGE.

Ailanthus excelsa, Roxb.—Indian *Ailanthus*, Nat. Ord. *Simarubaceæ*.—In the following paper my object is to bring to the notice of the society a new indigenous article of materia medica yielded by the Indian *Ailanthus*, upon which I have experimented for some time past. My investigations into the medicinal properties of this simple, cheap and agreeable vegetable bitter, have led me to form a favourable opinion of its efficacy in certain diseases. Believing that an extended notice of this article, so common in many parts of India, might not be unacceptable to the members of the profession, I submit this communication to you, and trust that others may be induced, as opportunities offer, to determine for themselves its medicinal virtues.

The bark of the *Ailanthus excelsa*, Roxb., which is the article in question, is interesting firstly on account of its being almost unknown to the medical profession; secondly from the likelihood of its proving a useful substitute for one of the officinal drugs of the British Pharmacopœia. The tree is pretty common in many parts of India, and its bark can be obtained in sufficient quantity for general use. If attention be paid to the cultivation of the tree, the bark will, no doubt, be found to be still cheaper, and being an indigenous product, its use will tend to our advantage.

Collection, Preservation, etc.—The only part of the tree which is commonly employed as a remedial agent is the bark, frequently of the trunk, and rarely of the root. The leaves are said to be occasionally used in medicine, but they are free from the characteristic bitterness of the bark. The usual season for collecting the bark is either the cold or the beginning of the hot season; during the rains the process should be stopped on account of the difficulty of drying it, a point requiring particular attention. In order to strip the tree of its bark, it is convenient to fell it with a hatchet. When the tree is down and the useless smaller branches are cut off, the bark is easily removed by first striking it with the back of the hatchet, which causes the liber to loosen from off the sapwood. Before this is done, the useless and thick corky layer (epiphlœum) must be scraped off. The bark is then cut longitudinally so as to admit of its being turned up by the hand, when it comes off in large pieces, which are further cut into small ones so as to expedite its drying. The drying should be done as quickly as possible by exposing the pieces to the sun's rays; at night they should be covered to avoid the effects of dew. The hygroscopic nature of the active principle of the bark must be kept in view. If the precaution of early desiccation is not taken, a fermentive decomposition soon commences, the bark becomes mouldy, of a blackish colour, and begins to stink. A quantity of bark thus decomposed was in my possession, which, on being subjected to the usual process of extracting its active principle, yielded a dark blue compound having the smell of an indigo-vat and apparently resembling indigo itself, and which tinged the comparatively small quantity of the bitter principle obtained.

General Characteristics.—The bark of *Ailanthus excelsa* is in flat pieces, of various sizes and lengths, depending upon the manner in which it is removed and preserved. The largest pieces are sometimes one foot or more in length and about six inches in breadth, but on account of their friable nature, they easily go into small pieces by rough handling. In thickness the bark varies generally from a quarter of an inch to half an inch or more; the age of the tree, as well as the part from which the bark is chopped, much affect its thickness and general qualities. Its external surface is rough and irregular from a coat of corky layer (epiphlœum), which varies in thickness from two to four lines, and is marked with deep irregular furrows and protuberances; its colour varies from dirty-grey to yellowish-green; its substance is rather hard, gritty, and insipid. The *derm* (which in fact is the bark proper, consists of a porous outer portion (mesophlœum), and a compact inner portion (endophlœum). The former is about half an inch thick, of a uniform pale yellowish colour, porous, and fibrous. Its longitudinal section presents a reticulated fibrous structure marked with numerous pores, in which here and there are observed concrete masses of gummy exudation (pectine), which is of a pale brownish colour and insipid.* Its transverse section is rough, granular, porous and somewhat lamellar. The inner portion of the bark (endophlœum or liber) is about a line in thickness, pale yellow, smoother and more compact than the outer portion.

It is tough and fibrous, and, when fresh, sticky. In the fresh state the endophlœum and the mesophlœum, particularly the former, contain a glutinous and bitter substance of a deep orange colour which is the active principle in a state of combination.

The mesophlœum is easily pulverizable, forming a

* This is particularly seen in the bark of very old trees.

greenish-grey powder, which, when examined under the microscope, presents numerous crystals of carbonate of lime. The liber (endophlœum) is tough, and leaves fibrous pieces on being pounded. The dry bark is light and breaks easily across with a fibrous porous fracture. It scarcely possesses any smell, but has a pure strongly bitter taste, especially at its inner surface. The wood, as well as the leaves of this tree, are entirely devoid of bitterness.

Seat of the Active Principle.—On examining a section of the fresh bark with an ordinary magnifying glass, the meshes between the interlacing fibres of the liber are seen filled up here and there with a reddish- or orange-yellow and somewhat glistening amorphous substance, which abounds within the inner part of the liber. Intermixed with it, and covering the whole of the fibrous texture of the mesophlœum, are seen shiny rhombic particles of crystalline carbonate of lime. The yellow amorphous substance is very soluble in water, and extremely bitter, and is the active principle of the bark in a state of combination. It is found in the largest proportion in the thick bark of old trees. The thinner bark of the top and branches is less valuable, for it contains a smaller amount of the active principle.

Composition and Chemical Characteristics.—No complete analysis of the *Ailanthus* bark has as yet been made. My experiments, however, lead me to conclude the presence in it of an uncrystallizable bitter principle in combination with lime, carbonate of lime, salts of magnesia and alumina, uncrystallizable sugar, gum, a trace of volatile oil and lignin. The medicinal virtues of the bark depend entirely upon an azotized bitter principle possessing an acid nature, to which I propose to give the name of 'Ailanthic acid.' It is to this that the bark owes its bitterness.

A cold infusion of the bark, in the proportion of one ounce to twenty-four ounces of cold water, and allowed to macerate for twenty-four hours, was somewhat turbid, lemon-coloured, and very bitter. A strong decoction of it was turbid and highly bitter: when kept for some days, it slowly deposited a sediment, and the liquid became of a clear pale lemon-colour, and retained its bitterness. A tincture of the powdered bark, prepared with rectified spirit, was of a pale yellow colour and much less bitter than the decoction or infusion. The decoction exhibited the following reactions:—Tincture of iodine or tincture of the sesquichloride of iron produced no change; oxalic acid or oxalate of ammonia caused a copious white precipitate (oxalate of lime), insoluble in acetic acid; alcohol produced muddiness (from the precipitation of gum) in a concentrated decoction; protonitrate of mercury solution gave a copious white precipitate of a complex compound of the acid principle with mercury; solution of basic acetate of lead produced abundant white precipitate; alkalies produced no change except removing its bitterness, which reappears on the addition of acids; alkaline carbonates and earths showed no such effect; acids produced no change; litmus-paper showed no signs of acidity (evidently showing that the acid principle was in combination with a base).

Ailanthic Acid.—It was in the beginning of the year 1867 that I first noticed the existence of this principle in the *Ailanthus* bark. Owing to its uncrystallizable nature and its comparative insolubility in other solvents than water, the difficulty of obtaining it in a pure state is such as to make its analysis still unsatisfactory. I leave to abler chemists its further examination. The following method gives the process of manufacturing this substance:—

Exhaust the powdered *Ailanthus* bark by repeatedly boiling it with water, collect and concentrate the decoctions. When cold, filter and add a sufficient quantity of a strong solution of oxalic acid to precipitate the lime. Add a sufficient quantity of strong solution of basic acetate of lead, which precipitates gum, extractive matter, colouring-matter, and excess of oxalic acid; filter. Concentrate the clear liquor on a slow fire, remove it when cold into a proper vessel, and pass through it sulphuretted hydrogen gas so as to precipitate all the lead; boil, filter, and evaporate the clear liquid on a water-bath.*

The proportion of ailanthic acid contained in the bark varies a good deal according to the age of the tree, as well as the thickness, collection, and preservation of the bark. The average quantity of acid I obtained from two pounds of good thick bark was nearly one ounce.

Properties, etc.—When solid, ailanthic acid is of a waxy consistence, reddish-brown, becoming dark coloured when liquefied, almost inodorous, deliquescent, very soluble in water, much less so in alcohol or ether, insoluble in chloroform or benzole. It is uncrystallizable and is extremely prone to become glutinous, even when kept in a stoppered phial; on account of its hygroscopic properties, it swells so much as to be preserved with great difficulty in an ordinary bottle. Its aqueous solution absorbs oxygen. When heated, it swells, burns, and leaves ash, consisting chiefly of carbonate of lime and salts of alumina. Its taste is purely and strongly bitter, it reddens litmus, is neutralized by alkalies and strong earths, forming combinations which are devoid of bitterness. Its compound with ammonia is readily decomposed by heat, leaving the acid free. It decomposes the carbonates of alkalies, of earths, and of several metals, especially when aided by heat, and takes the place of carbonic acid, which escapes with effervescence; the compounds thus formed are all more or less soluble in water and are bitter. When heated along with a strong solution of caustic potash, ammoniacal fumes are given off, indicating the presence of nitrogen in its composition. When heated along with strong sulphuric acid, it becomes blackened and a penetrating odour is evolved. Hydrochloric acid produces no change when cold, but, on boiling, it changes its colour to a deep dark red. Nitric acid oxidizes it immediately with the production of effervescence (from the escape of nitrogen), especially when boiled, it makes the liquid clearer and paler. Chromic acid produces no change. Tincture of galls gives no precipitate. Protonitrate of mercury solution gives a copious white precipitate, which is blackened by the addition of ammonia; this forms one of its characteristic tests. Persalts of mercury give no precipitate. Chloride of gold gives a dirty purple precipitate, which slowly exhibits greenish and purplish tints by reflected light. Chloride of platinum gives no precipitate. Nitrate of silver gives a whitish precipitate, which soon turns dark coloured. Diacetate of lead gives a white precipitate, but does not throw down the whole of the ailanthic acid. Acetate of lead produces no change. No evident changes were produced under the following tests:—Chlorine water and ammonia; oxalate of ammonia; red and yellow prussiates of potash; sulphocyanide of potassium; protochloride of tin; potassio-tartrate of antimony; proto- and per-salts of iron; and sulphate of copper.

Ailanthic acid does not possess the power of setting free iodine from a solution of iodide of potassium. A concentrated solution of it dissolves oxalate of lime.

Ailanthate of Lime.—In this form ailanthic acid exists in nature. It is soluble in water, forming a pale orange-coloured solution, which is very bitter. Oxalic acid and oxalate of ammonia separate the lime from combination. It can be dried into a hard, solid, reddish-brown mass, which, when exposed to air, attracts moisture, but less quickly than the pure acid, and is less sticky to the feel. When drying, it swells much more than the pure acid. Its taste is not so bitter as that of the pure acid; it dissolves freely in water, and is uncrystallizable.

Ailanthate of Lead.—This compound is formed during the preparation of ailanthic acid. It is of an ochre-yellow colour when fresh, but changing to a darker red when kept. When hot and dry, it is hard and brittle like

* In this process ailanthic acid still retains a small percentage of uncrystallizable sugar, which is difficult of removal.

resin; but when cool and kept for some time, even in an air-tight bottle, it gets sticky and soft. While hot and soft it can be moulded into any shape like wax or gutta-percha, and can be drawn into silk-like fibres, which, on cooling, become soft and glutinous. The freshly-dried salt can be easily powdered, a property not observed in other compounds of this acid. The powder, if inhaled through the nose, excites sneezing; it readily attracts moisture when cool: sulphuric acid or sulphuretted hydrogen removes the lead, and leaves the acid free. Its taste is as bitter as that of the free acid. It is freely soluble in water, and is uncrystallizable.

(*To be continued.*)

Parliamentary and Law Proceedings.

ALLEGED POISONING OF SHEEP BY DIPPING COMPOSITION—ACTION AGAINST A CHEMIST.

SUFFOLK SUMMER ASSIZES, BURY ST. EDMUNDS.

NISI PRIUS COURT, 12*th August*, 1870.

Smith *v.* Barker.

Mr. O'Malley, Q.C., and Mr. Mayd, appeared for the plaintiff; Mr. Bulwer, with whom was Mr. Naylor, for the defendant.

It appeared from the evidence given in this case that the arsenical solution was sold with printed instructions, in which it was stated to be "poison;" that every gallon of the composition was to be mixed with forty gallons of water, and that this quantity was sufficient for two scores of sheep. Further directions were also given to squeeze out the liquor from the wool of the sheep after they had been dipped. The plaintiff's men appear, however, to have used four gallons and five quarts of the composition for five score sheep, and to have hurried the operation of dipping, so that the liquor was not sufficiently squeezed out of the sheep's wool. Consequently arsenic was absorbed and several of the sheep died. Several witnesses gave evidence that the composition could be used without danger if properly diluted and if the instructions were carried out; while others testified to having used it for hundreds of sheep without any injury to them.

The declaration alleged that the defendant did not use due care and skill as a chemist in preparing a certain composition to destroy lice in sheep, which composition was to be used according to certain directions, that the plaintiff used this composition with due care; nevertheless the solution was so badly compounded that a number of his sheep were killed and others injured.

The judge, in summing up the case, said the plaintiff complained that the defendant had not used due and proper care and skill as a chemist, in preparing the composition which was to be used according to certain directions delivered by the defendant to the plaintiff at the time of selling. This was the real question which the jury had to try. The counsel for the plaintiff was in error in supposing it was the business of the defendant to satisfy them that the plaintiff was negligent. The onus or burden of proof was the other way, because the plaintiff complained defendant did not use due and proper skill, and that his mixture could not be used with reasonable safety according to the directions. Certainly in these instructions there was the most distinct notice that could possibly be given in writing and print as to the poisonous nature of this solution, because there were the words "Poison" "Poison." Then again nothing could be more precise than the directions given as to the use of this dangerous mixture, and he presumed the jury would be of opinion that it behoved every one who used it to be careful about it. On the present occasion there was no doubt that the death of Mr. Smith's sheep was caused by the absorption of the liquid into the system of the sheep. They might take it as a fact that the plaintiff had proved the death of his sheep was occasioned by absorption into the system of this chemical solution. How was that caused? Was it caused by the solution itself being defectively prepared? If it was then the defendant was liable, if it was not the defendant could not be liable. That the solution as prepared by Mr. Barker, if the directions were followed, was a harmless one, there seemed to be no doubt. The defendant said that for nineteen years he had been in the habit of preparing the solution, and that it had been very extensively used on thousands and thousands of sheep. Was the negligence or want of care on the part of the defendant, or on the part of the plaintiff? One question was important, namely, how did the $4\frac{1}{2}$ gallon bottle, together with the quart added to it from the first bottle become so nearly exhausted with the dipping of 100 sheep? If they were satisfied that the defendant did not use proper care in making the preparation, and that the death of the sheep was occasioned thereby, the plaintiff would be entitled to their verdict; if on the other hand they were of opinion that the death of the sheep was not caused by the want of proper care and skill on the part of the defendant, then the defendant would be entitled to a verdict in his favour.

The jury then consulted for about twenty minutes, and without leaving the box returned a verdict for the defendant.

CENTRAL CRIMINAL COURT.

August 15.

George Gorfenkle, chemist, pleaded "Guilty" to obtaining, by false pretences, goods of considerable value from Messrs. Maw and Son, instrument makers, Aldersgate Street, and Messrs. Huxley and Co., cigar merchants, Whitechapel Road. He was sentenced to twelve months' imprisonment.

[*** This report is taken from the 'Times' of the 16th inst. There is no such name on the Register of Chemists and Druggists as that of George Gorfenkle.—ED. PH. J.]

A NEW ANTIPERIODIC.

Dr. Lorinser, of Vienna, gives the results of a number of observations made regarding the effect of a new remedy for intermittent fever. The remedy is the tincture of the leaves of the *Eucalyptus globulus*, a plant of the natural order *Myrtaceæ*. In 1869, Dr. Lorinser made some experiments, the results of which he published; but he was brought to a standstill by the want of a supply of the medicine. The plant has since been cultivated by Herr Lamatsch, an apothecary; and a sufficient quantity of tincture has been made from the leaves to supply a number of medical men in the districts of the Theiss and Danube, and in the Banat. The records of fifty-three cases of intermittent fever in which the eucalyptus was administered have been communicated to Dr. Lorinser; and he gives very brief outlines of each, with the following summary of the results obtained. Of the fifty-three patients, forty-three were completely cured; in five, there was relapse in consequence of a failure of the supply of the tincture of eucalyptus, and quinine had to be employed; two of the cases were not true ague; in one case, neither the eucalyptus nor quinine cured; in one, the medicine (as well as other remedies) was vomited; and in one, the patient would not allow the treatment to be continued. In eleven of the cases, quinine had been used without effect; and nine of these were cured by the eucalyptus. There was return of the fever in ten cases, at intervals varying from one to four weeks; in five of these quinine had to be used, in consequence of there being no tincture of eucalyptus, and in the other five the eucalyptus was successfully employed. The tincture is said to be easily made, and to have a pleasant aromatic taste; it acts favourably on the digestive organs. Dr.

Lorinser believes that in it we have a valuable remedy for intermittent fever. It may be so; but, considering the comparative failure of the substances which have hitherto been recommended as substitutes for cinchona and quinine, still more extended and careful observation will be necessary before recognizing the claims of the *Eucalyptus globulus* to rank as an antiperiodic on which dependence can be placed. The districts which Dr. Lorinser has chosen for testing the effect of the remedy are, we believe, well fitted for the purpose—intermittent fever being very prevalent in them.—*Philadelphia Medical and Surgical Reporter.*

CHINESE THERAPEUTICS.

The Chinese divide medicinal substances into heating, cooling, refreshing, and temperate. Their materia medica is contained in the work called the *Pen-taoscang-mou*, in fifty-two large volumes, with an atlas of plates. Most of our medicines are known to them and prescribed, also mineral waters, with which the country abounds. They also have animal magnetizers, called *cong-mou.*

They divide their prescriptions into seven categories, viz.:—1st. The great prescription. 2nd. The little prescription. 3rd. The slow prescription. 4th. Prompt or through-by-daylight prescription. 5th. The old prescription, for fools, madmen, hypochondriacs, and the hysterical. 6th. The even prescription, for the wise and good. 7th. The double prescription, for those in the family way.

Each of these recipes is applied to particular cases, and the ingredients that compose them are weighed out with the most scrupulous accuracy.

The physician never pays a second visit unless sent for, and sometimes his services are no longer needed.—*Philadelphia Medical and Surgical Reporter.*

Chapters for Students.

CHEMICAL NOTES TO THE PHARMACOPŒIA.

BY WILLIAM A. TILDEN, B.SC. LOND.

DEMONSTRATOR OF PRACTICAL CHEMISTRY TO THE PHARMACEUTICAL SOCIETY.

Acidum Nitro-hydrochloricum Dilutum.—[§. Take of—

Nitric acid	3 fluid ounces
Hydrochloric acid . .	4 fluid ounces:

Mix the acids, and allow them to remain for twenty-four hours in a bottle, the mouth of which is partially closed, then add the water in successive portions, shaking the bottle after each addition, and preserve the mixture in a stoppered bottle.]

The reaction which the two acids enter into gives rise to the production of a good deal of gas.

$$2HNO_3 + 6HCl = \underset{\text{Chloronitric gas.}}{N_2O_2Cl_4} + 4H_2O + Cl_2.$$

And also simultaneously,

$$2HNO_3 + 6HCl = \underset{\text{Chloronitrous gas.}}{N_2O_2Cl_2} + 4H_2O + 2Cl_2.$$

Such a mixture is called aqua regia; it has the property of dissolving gold, from the presence of free chlorine. In the preparation of the dilute acid for pharmaceutical use the best apparatus consists of two Winchester quarts, connected by a piece of flexible tubing. One contains the two acids, the other the water; gases evolved from the acids are thus collected in the same water with which they are afterwards to be mixed.

There is no advantage in the official process over the plan of mixing the acids with the water immediately; for after dilution, the elements rearrange themselves so as to reproduce nitric and hydrochloric acids. This occurs more perfectly the larger the proportion of water added: the less water, the larger will be the amount of nitrous acid and chlorine remaining.*

Acidum Phosphoricum Dilutum.—Phosphorus is digested with diluted nitric acid till dissolved: the solution is then evaporated to expel the excess of nitric acid and complete the oxidation to phosphor-*ic* acid, and it is then diluted to the proper strength. The reaction which occurs will be understood after studying "nitric acid."

$$20HNO_3 + 3P_4 + 8H_2O = 12H_3PO_4 + 20NO.$$

With ammonio-nitrate of silver, phosphoric acid gives a yellow precip. of Ag_3PO_4. Evaporated to complete dryness, it leaves a residue (glacial phosphoric acid) consisting chiefly of metaphosphoric acid.

$$H_3PO_4 = HPO_3 + H_2O.$$

Phosphoric acid is a most important example of a tribasic acid. With each metal it forms three distinct salts, in which one, two, or three atoms of the metal replace an equivalent quantity of the hydrogen of the acid. It is also capable of forming other double or triple salts. The following are some examples:—

Phosphates of Sodium.

Monosodic	NaH_2PO_4
Disodic	Na_2HPO_4 (B.P.)
Trisodic	Na_3PO_4.

Phosphates of Calcium.

Monocalcic .	$Ca''H_4 2PO_4$ ("superphosphate")
Dicalcic . .	$Ca''_2H_2 2PO_4$, or $CaHPO_4$
Tricalcic . .	$Ca''_3 2PO_4$ (bone-ash).

Ammoniæ Phosphas, B.P., or diammonic phosphate.

$$(NH_4)_2HPO_4.$$

If the first phosphate of soda is heated to redness, the residue is metaphosphate of sodium.

$$NaH_2PO_4 = NaPO_3 + H_2O.$$

The second one by heat gives the sodium salt of pyrophosphoric acid.

$$2(Na_2HPO_4) = Na_4P_2O_7 + H_2O.$$

These three acids of phosphorus are thus distinguished from each other.

a. Common, tribasic, or orthophosphoric acid, when neutralized, and its soluble salts give a yellow precipitate with nitrate of silver.

b. Pyrophosphoric acid does not coagulate albumen, and with nitrate of silver gives a chalky-white precipitate only after being neutralized by an alkali.

c. Metaphosphoric acid coagulates albumen, and gives, with nitrate of silver, a transparent white precipitate without neutralization.

The impurities indicated by the tests of the Pharmacopœia are as follows:—Metals, such as *copper*, *arsenic*, or *lead*, by sulphuretted hydrogen; *sulphuric acid* by chloride of barium; *hydrochloric* acid by acidified nitrate of silver; *metaphosphoric* acid by solution of albumen; *nitric* acid by darkening a

* See Pharm. Journ., N.S., Vol. X. p. 580.

solution of sulphate of iron; *phosphorous* acid (the result of imperfect oxidation) by heating with perchloride of mercury. In the last test, calomel or metallic mercury may be precipitated.

$$H_3PO_3 + OH_2 + 2\,Cl_2Hg = H_3PO_4 + 2HCl + Hg_2Cl_2.$$

Or,—

$$H_3PO_3 + OH_2 + Cl_2Hg = H_3PO_4 + 2HCl + Hg.$$

355 grains of the B.P. acid evaporated to dryness with 180 grains of oxide of lead, and heated to dull redness, increase the weight of the residue to 215·5 grains.

Oxide of lead.		P_2O_5.		Oxide + phosphate of lead.
180	+	35·5	=	215·5

Six fluid drachms (354·375 grains) therefore contain 35·5 grains of P_2O_5 (10 per cent.), or 49 grains of H_3PO_4.

Medical Arrangements in the French Army.—The Paris correspondent of the 'Lancet' writes, "A cause of complaint has been the curious medical *cantine* given to the regimental surgeons. It consists of a box, which, when opened, contains only one solitary phial, filled with calomel; it holds no sulphate of soda, no subacetate of lead—in fact, none of the most ordinary medicaments required for the sick or wounded soldier. Besides this, it consists of an extraordinary number of small drawers, which, on any dampness supervening, would render the *cantine* unfit for use. The presence of a large number of pharmaciens on the field, in comparison with the limited number of medical men, has also given rise to much criticism, and it is asked of what earthly use will be so large a number of pharmaciens, unless to 'help to make the soldier's soup.'

"The fact is, that the number of medical men attached to the ambulances is absurdly limited. It has been related to me by French army surgeons that after Magenta their arms had become deadened from operating, and their instruments useless, while there were yet a large number of the French wounded unprovided for, not to mention at least 1500 Austrians. And yet the number remains as limited in this campaign. How this can be is a mystery.

"Each division of the army includes one ambulance; and as there are four divisions to a *corps d'armée* the total number is four ambulances, to which, however, must be added a fifth attached to the head quarters of the *special corps*. Now each ambulance consists only of five surgeons, making a total of twenty-five surgeons to a division. Obviously this number must be altogether below the requirements of the service, especially during the present campaign, when such energetic and rapid movements are necessary, and when the wounds that are inflicted are so numerous, and of a special character on account of the arms in use. Therefore, the help afforded by the volunteer ambulances must prove invaluable under existing circumstances."

Liverpool and its Health Officer.—The Town Council have rejected, by 18 votes to 16 on a division, the Report of the Health Committee, which proposed to put a check upon the medical officer of health in regard to the conversion of cesspools into waterclosets. This has led to the resignation, by Mr. Alderman Dover, of the chairmanship of the Health Committee, that gentleman having apparently been led by strong economic tendencies to oppose the principle on which Dr. Trench has acted, as leading to unnecessary expenditure. It is, of course, matter for regret that the Council should lose the valuable services of so able and energetic a man as the worthy alderman; but we are quite sure that they have done wisely in supporting their medical officer of health, who cannot possibly desire to put his fellow-townsmen to needless expense. Whoever has studied the proceedings of Dr. Trench since he has been health officer for Liverpool must have been led to the conclusion that his policy throughout has been based on the soundest principles of economy.—*Lancet.*

How to Drive away Mosquitoes.—One of the greatest plagues of hot countries is the mosquito, and various have been the means recommended for getting rid of this pest. Jagor, a celebrated German traveller, who spent a number of years in the jungles of the Malayan Archipelago, recommended, if we remember rightly, the roots of *Pyrethrum roseum.* In a paper recently published by Dr. Birdwood on olibanum, the author says that in Bombay nothing so quickly clears one's bed of mosquitoes as the burning of a little olibanum or myrrh in it. The Protestant churches there are infested by mosquitoes, as by a plague. He was often asked how to get rid of them, and always answered that while the ugly and irreverent punkahs were of no use, the only remedy was the immemorial and most beautiful rite of burning frankincense.

Convention of Colleges of Pharmacy.—At a stated meeting of the Maryland College of Pharmacy, the following resolution was unanimously adopted:—

"*Resolved*, That a Committee of five be appointed to request the several Pharmaceutical Associations of the United States to send Delegates to a Convention, proposed to be held in the City of Baltimore in September next, at the time of the meeting of the American Pharmaceutical Association."

The purpose being to consult and determine upon the best uniform course of study for those learning the profession of pharmacy, and to recommend the same for adoption in the schools of the several associations they represent, to the end that there may be a uniform standard of qualification for all graduating in pharmacy.—*The Chicago Pharmacist.*

Substitute for Lint.—Mr. H. Pownall, late chairman of the Middlesex Sessions, submitted to Lord Lindsay's committee a sample of very fine picked oakum, which has been used in some of the London hospitals as a substitute for lint in dressing wounds. Should this substitute prove as useful as represented, the inmates of unions and prisons might be advantageously employed in its preparation. It would be not only remunerative, but a means of turning the labour of the pauper to a highly beneficial purpose.—*Standard.*

Inefficacy of Immature Cantharides.—Recent investigation shows that young cantharides do not possess the epispastic property, and it would seem that in medium-sized insects it is equally wanting. It is only the full-grown insects that will raise blisters. Cantharidine appears not to be developed until the complete maturity of the insect. In purchasing cantharides, therefore, those only should be chosen which have attained their full growth.—*Zeitschrift für Chemie.*

Poisoning by a Salt of Copper.—A serious case of poisoning has occurred at Geneva. Six workmen, two hours after dining at their usual place of resort, were seized with violent pains in the stomach, followed by vomiting. A doctor having been called in, he recognized immediately the symptoms of violent poisoning. The men were carried to the hospital, where, in spite of every attention, three of them died after some hours of severe suffering.

Upon the police officer going to the house where they had dined, he found the proprietor, his wife and child, and a domestic dangerously ill; the man and his wife dying the same evening. At the inquest it was found that the mishap was due to the negligence of a servant, who had prepared the soup in a copper utensil, at the bottom of which was a large quantity of verdigris.—*Journal de Chimie Médicale.*

Health of the Armies on the Rhine.—Besides the dreadful death-roll of slain and wounded, we may soon expect to hear of disease causing ravages in the ranks of the hostile legions. Dysentery is commonly prevalent in the Rhine provinces of France and Prussia, as well as in Belgium, during July and August. The favourite treatment just now among French surgeons is bismuth in full doses. Ipecacuanha seems to have failed with the medical men on the borders of the Rhine. If the war be not suddenly concluded, intermittent fever will probably in about a month from this time be epidemic. It is almost sure to be of a very low type. Then these fevers will assume a remittent form, and true camp fever will become established. It is not improbable that cases of typhus will also occur in numbers to cause anxiety, though other forms of fever will probably be most prevalent. We are, of course, presupposing that every hygienic precaution will be adopted, for neglect of any would be sure to give rise to proportionate loss. We speak only of what is to be expected under most favourable circumstances. As autumn advances the weather will become a more potent element,—rheumatic affections and diseases of the lungs then taking the lead. At present the one question is whether the camp will be exposed to heavy rains.—*Medical Press and Circular.*

BOOK RECEIVED.

An Elementary Course of Botany, Structural, Physiological, and Systematic. By the late Professor Henfrey. Second Edition; revised and in part rewritten by Dr. Maxwell T. Masters. London: Van Voorst, Paternoster Row, 1870.

Obituary.

Mr. J. T. Porter, whose death we reported last week, was one of the most promising of recent students of the Pharmaceutical Society. About five years ago he entered the School of Pharmacy under somewhat interesting circumstances. The gentleman with whom he was apprenticed, Mr. Sutterby, of Long Sutton, Lincolnshire, was in the habit of giving his pupils a fortnight's holiday every summer. Mr. Porter, with the consent of his employer, denied himself the pleasure of the holiday on one occasion, in order that the next year he might devote a whole month to continuous study. Having, meanwhile, saved enough money to pay expenses, he travelled up to London, and spent that month in the Laboratory at Bloomsbury Square. This energy in seeking culture under great difficulties was sure to meet with success. It obtained for Mr. Porter friends, who enabled him, on completing his apprenticeship, again to work in the Society's Laboratory, this time for three months. He subsequently became private assistant to the Professor of Practical Chemistry, afterwards filled the position of under-manager in the laboratory of Messrs. Bell and Co., and ultimately was appointed chemist to the Hastings Sewage Works, where, in the full career of successful labour, and while actually attempting to save the lives of others, he suddenly met with his death.

Mr. Porter was a steady worker in the cause of natural and revealed truth. He published several original researches on matters connected with pharmacy, and was Secretary of the London Chemists' Association.

We are indebted to correspondents for the following periodicals, containing news' reports, and other matters of pharmaceutical interest:—The 'Newcastle Daily Chronicle,' Aug. 11, 12, 13, and 15, from Mr. H. B. Brady; the 'Essex and Suffolk News,' Aug. 13, from Mr. Barker; 'Allen's Indian Mail,' Aug. 9, from Dr. Cleghorn; the 'British Medical Journal,' from the publishers; the 'English Mechanic,' from the publishers; the 'Philadelphia Medical and Surgical Reporter,' May 21, June 11, 18 and 25, from the publishers.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the Editor, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

State Aid for Pharmaceutical Education.

Sir,—I think the result of the following correspondence is of sufficient importance to justify my requesting you to give it a place in the text of your next number.

I am, Sir, your obedient servant,

Clifton, August 14, 1870. G. F. Schacht.

"*To the Secretary, Science and Art Department.*

"Sir,—As Hon. Secretary of the Bristol Pharmaceutical Association, I beg leave to ask you for information on a point of some importance to this and similar organizations.

"Our Association has for its principal object the education of our apprentices and assistants in the sciences applied to their profession, a fair knowledge of which a recent Act of Parliament has made obligatory upon every one who now enters the practice of pharmacy.

"In Bristol we have calculated upon the aid of your department, but in other localities it has been thought that the regulations do not warrant this course, inasmuch as the fathers of some apprentices pay income-tax.

"An apprentice to a pharmaceutist is boarded, lodged, and taught his profession in return for his services, to which is generally added a premium. He may, therefore, be looked upon as having taken leave of home.

"The apprentice, in due time, becomes an assistant, and it would be difficult to find an assistant whose salary reaches the minimum amount assessed.

"Under these circumstances, we have thought that the department might be disposed to aid the spread of this movement to other cities, by the official announcement—that they will consider pharmaceutists' apprentices and assistants as coming within the scope of paragraph xxxvi, clause (C), page 13 of the 'Directory,' which awards premiums upon 'Persons in the receipt of salaries not large enough to render them liable to the income-tax, as some descriptions of clerks, shopmen, etc.'

"I have the honour to be, Sir,
"Your obedient servant,
"G. F. Schacht,
"*Hon. Sec. Bristol Pharmaceutical Association.*
"*Clifton, July* 30, 1870."

"*Science and Art Department, London, W.*
"*August 3rd*, 1870.

"Sir,—I am directed to acknowledge the receipt of your letter of the 30th ultimo, respecting the payment on the results of the examination of pharmaceutical apprentices and assistants, and to inform you that the subject will be considered.

"I am, Sir,
"Your obedient servant,
"Norman M'Leod,
"*G. F. Schacht, Esq.*" "*Assistant Secretary.*

"*Science and Art Department, London, W.*
"*August 11th*, 1870.

"Sir,—In reply to your letter of the 30th ultimo, I am directed by the Lords of the Committee of Council on Education to inform you that, under the circumstances set forth by you, their Lordships have been pleased to allow payments to be made on the result of the examination of pharmaceutical apprentices and assistants in science.

"I am, Sir,
"Your obedient servant,
"G. F. Duncombe, *Chief Clerk.*
"*G. F. Schacht, Esq.*"

Safeguards against Poisoning.

Sir,—A respected correspondent suggests the use of elastic gum capsules as a safeguard against poisoning.

I beg to suggest that, however well the secondary object (namely, to prevent evaporation of ethereal and spirituous liquids) might thus be attained, it would be impossible to obviate the accidental displacement of a capsule, thus causing uncertainty and confusion.

Many years since, I had the honour of suggesting a very simple expedient, which, during a long experience, has been found truly effective. It is merely to place the labels of dangerous poisons perpendicularly on the bottle instead of in the usual manner, which, in some instances, prevents half the inscription being read. Having adopted this plan in my shop for very many years, without the occurrence of a single accident, I venture to recommend it to my brother pharmacists. The appearance of certain bottles thus distinguished from their fellows frequently calls forth the notice of intelligent persons, both medical and otherwise, thus tr. opii and mist. sennæ co., tr. aconiti and tr. myrrhæ, acid. arseniosum and p. antim. co., stand side by side, in perfect safety. Like the red light upon the railway, everybody knows the signal of danger and respects it accordingly.

I remain, yours faithfully,

P. Goodwin Mumbray.

14 A, *Hill Rise, Richmond, S.W.*

August 10, 1870.

Our Responsibilities.

Sir,—No further information appears in the last number of the Journal respecting the case of "Damages against a Druggist," at Liverpool, reported and commented on in previous number. If we are to be exposed to actions and convicted on such flimsy evidence as appears to have been relied on in that case, then ours is a most unenviable position. If the defendant does not appeal against what appears to be a miscarriage of justice, do not the common interests of the trade require that the case should be further investigated? One such case successfully prosecuted will lead to others, and we shall soon be having every old lady who may take a dose of castor oil, and "feel sick after it," wishing to try the effect of the very comforting antidotes they administer so freely at the "Court of Passage," in Liverpool.

By the way, the case goes to show that sal volatile and liq. potassæ must find their place in the poison-cupboard,—that *very comprehensive* receptacle "set apart for dangerous articles."

I am, etc.,

London, August 9, 1870. George Pattison.

[*** We are informed by the Local Secretary for Liverpool, that the bottles in Mr. Trilfield's shop are well-labelled, the bottle for the Aq. Cinnam. has a good gold label, and that for the Liq. Potassæ is one of a series with labels engraved in the glass.—Ed. Ph. J.]

"Rule of Thumb."

Sir,—May I again trespass on your space with a few words in reply to "J. Houlton"?

He asserts that there is more "cry than wool" in the letters published on the above subject. I think not. I cannot see why a grain of calomel is not to be weighed equally with ʒij of magnesia. Measurement being an accurate mode of dispensing, while guessing is inaccurate, the public will certainly have little confidence in any hap-hazard method of preparing medicines. I still contend that it is the imperative duty of the pharmacist in all cases to rely upon his scales rather than his eye.

As to "Trade Grievances," there seems really to be "much ado about nothing." The plain fact is that pharmacy, pure and simple, will not afford a living to the country pharmacist, and consequently he must of dire necessity become a general dealer in perfumery, oils and colours, articles of grocery, etc., so as, by hook or by crook, to earn enough to keep body and soul together. At present pharmacy is a profession that does not afford professional remuneration to many of those engaged in it, who thus resemble poor noblemen, who, with all the distinction afforded by titles, lack the fortune to support them.

Yours, etc.,

August 16*th*, 1870. Minor Associate.

"Pharmaceutical Titles."

Sir,—It has for some time been matter of surprise to me that so little attention has been drawn to the subject of "Pharmaceutical Titles."

I allude to the different degrees of honour contained in the names of "Pharmaceutical Chemist," "Chemist and Druggist," etc., adopted by those to whom these names belong either by examination or by registration.

My surprise is excited by the little notice taken of encroachments on the advantages attaching to the *higher distinction* made by those who, having never passed the "*Major*" Examination of the Society, cannot claim the privilege of calling themselves "Pharmaceutical Chemists," but nevertheless resort to means by which they may mystify the public (who are, in this matter, only half taught), and so prevent their recognizing a difference between the man who passes a *high scientific* Examination (as the Major) and one who merely "*goes in*" for the "Modified."

I do not say that those who thus make the most of their attainments do anything which is not strictly legitimate, for they surely have a perfect right to take advantage of their position as far as it will go.

But the grievance lies in the fact that *their privileges* are too nearly identical with those of their more distinguished brethren.

Who (that is not connected with the business) could understand the difference between "Pharmaceutical Chemist" and "Chemist by Examination of the Pharmaceutical Society"? and I find the latter term, to *which they have a perfect right*, is coming into use amongst those who have passed the "Minor" or "Modified" Examinations.

Now, Sir, is it fair to him who works hard to succeed in the three Examinations of the Society, paying a considerable sum as fees, besides numerous other expenses, to let another who "gets through" what is generally acknowledged to be a VERY "*modified*" form of questioning, reap equal advantage, so far as public opinion goes?

I am glad to see that the matter has already been started in the Journal by others, who think, as myself, that this subject should no longer be neglected. I would strongly counsel the adoption of the title "Fellow of the Pharmaceutical Society," for indicating the great distinction between "Major" and "Minor" Associates, and think this would—to a great extent, at least—meet the wants and desires of the great body of the former, and also of those who aspire to attaining eventually "the top of the tree."

I would wish to add "one word" to those who are desirous, with me, of this amendment in the laws of the Society, and that is "agitate," and so try to induce those in whom the power of alteration lies to consider the best means of conferring upon such a large portion of the members of the body this great desideratum.

Hoping this subject will not now be allowed to drop and pass into oblivion,

I am, Sir, yours obediently,

An Aspirant to the Major.

Evaporation in vacuo *without an Air-pump.*—A correspondent has reminded us that the method recommended by Mr. A. B. Prescott, as quoted in the Pharm. Journ. for August 6, is identical in principle, and the arrangement of the apparatus essentially similar, to that described by the late Mr. J. T. Barry in the *Medico-Chirurgical Transactions*, vol. x. (1819) part 1.—See also Pharm. Journ. Vol. VI. (1865), 30.

"*A Minor Associate.*"—Questions are sometimes put to test the candidate's powers of "guessing."

"*Quæsitor.*"—See Vol. V. N. S. pp. 408 and 462. The Editor of the last edition seems to think the presence of a little free carbonic acid gas an advantage. As a *domestic* remedy, we think the public prefer the flavour of that made with the carbonate.

"*Inquirer*" (Farnham).—We should use the B. P. fluid extract unless "*Battley's*" name were mentioned. Many London prescribers of the present day prefer the term "liquor" for bark, taraxacum, sarsaparilla, etc., as being shorter to write, and less liable to the possibility of confusion with the old extracts.

Arthur Bolas (Birmingham).—Yes, if the excess of nitric acid used in preparing the "liquor" be not driven off. See Squire's 'Companion to the Pharmacopœia,' p. 121.

S. L., M.P.S. (Horton) will find that the formula he requires has been already given in the 'Pharmaceutical Journal,' O. S. Vol. XVIII. p. 579.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

GOLD THREAD.

Coptis teeta, Wall., and *Coptis trifolia*, Salisb.

BY M. C. COOKE.

Two species of *Coptis* are collected and employed in Asia and North America respectively, for similar purposes and with like results. The Asiatic species is the Mishmi Tita of Assam, included as a primary article in the Pharmacopœia of India; the *Coptis teeta* of Wallich, a native of the Mishmee mountains, east of Assam. The officinal part is the dried root imported into Bengal from Assam in small rattan baskets, each containing from one to two ounces of the drug. This consists of pieces of a woody rhizome, of the thickness of a small goose-quill, and from one to two inches in length, often contracted at one extremity into a short woody stem; the surface is usually rough, irregular, more or less annulated, and marked with the remains of rootlets in the shape of short spiny points. Externally it is of a yellowish-brown colour, internally much brighter, frequently of a golden-yellow colour, exhibiting on fracture a radiated structure. Taste persistently bitter, and when chewed tinges the saliva yellow. It contains neither tannic nor gallic acid, but abounds with a yellow bitter principle, soluble in water and alcohol.[*]

This drug was first brought into notice by Dr. Wallich in 1836,[†] and was reported upon by Mr. Twining. The late Dr. J. E. Stocks, in his collection of drugs from Scinde, described in the 'PHARMACEUTICAL JOURNAL' (Vol. XIV. p. 456), sent a root called 'Mahmira,' and Dr. Pereira published an elaborate paper on it,[‡] in which he endeavoured to show that this was the root termed 'Mahmira' in the writings of Avicenna, Paulus Ægineta, and other old authors. Dr. Waring at one time doubted whether this might not be more correctly referred to *Thalictrum foliolosum*, DC., which has also a bitter yellow root, but he has since accepted Dr. Pereira's views.

According to the same authority, the *Coptis* root has long been known in Europe under other names. In Guibourt's Hist. Nat. des Drogues it occurs under the name of 'Racine de Chynlen ou de Mangouate.' It is also described by Murray under the name of 'Chynlen;' and it is mentioned by Ainslie with the name of 'Sou-line' or 'Chyn-len,' and he says it is a bitter root which is brought from China to India.

It was used extensively at the Calcutta General Hospital by Mr. Twining, who reported that its influence in restoring appetite and increasing the digestive powers was very remarkable, and that it might be said to possess all the properties of our best bitter tonics. It did not seem to exercise any febrifuge virtue, but, under its influence, several patients, recovering from acute diseases, manifestly and very rapidly improved in strength. The dose was five to ten grains of the powder, or an ounce of the infusion, thrice daily. The Bengal Pharmacopœia contains the following formula for the tincture:—Mishmee teeta root, powdered, ℥iij, proof spirit lb. ij; dose ʒi to ʒij. O'Shaughnessy states that in its chemical properties it corresponds exactly with the American species. Both contain *Berberina*. For an account of its virtues as a tonic, the following authorities may be consulted:—Wallich and Twining,[*] O'Shaughnessy,[†] Macpherson,[‡] and Captain Lowther.[§]

The American Gold thread is *Coptis trifolia*, Salisb. It inhabits the northern regions of America and Asia, and is found in Greenland and Iceland. It delights in the dark shady swamps and cold morasses of northern latitudes and alpine regions, and abounds in Canada and the hilly districts of New England. All parts of the plant are more or less bitter, but this property is most intense in the root, which is the officinal part. It is a primary article of the United States Pharmacopœia.

"Dried Gold thread, as brought into the market, is in loosely matted masses, consisting of the long thread-like orange-yellow roots, frequently interlaced and mingled with the leaves and stems of the plant. It is without smell and has a purely bitter taste, unattended with aroma or astringency. It imparts a bitterness and yellow colour to water and alcohol, but most perfectly to the latter, with which it forms a bright yellow tincture. The infusion is precipitated by nitrate of silver and acetate of lead. It affords no evidence of containing ether, resin, gum, or tannin." [||]

According to Professor F. F. Mayer, this drug contains *Berberina*, as well as *Hydrastis canadensis*, associated with a colourless alkaloid, which is not precipitated by muriatic or nitric acid, but the precise nature of which does not yet appear to have been demonstrated.[**]

The properties and uses of this article are thus described by Dr. G. B. Wood. Gold thread is a simple tonic bitter, bearing a close resemblance to Quassia in its mode of action and applicable to all cases in which that medicine is prescribed, though, from its higher price, not likely to come into general use as a substitute. In New England it is employed as a local application in aphthous ulcerations of the mouth, but it probably has no other virtues in this complaint than such as are common to the simple bitters. It may be given in substance, infusion or tincture. The dose of the powder is from ten to thirty grains; of a tincture made with an ounce of the root to a pint of diluted alcohol, one fluid drachm.

Although differing considerably in external appearance, it will be seen that these two species of Gold thread have very much in common; but if the reports are to be fully relied upon, the Asiatic plant, *Coptis teeta*, certainly has the advantage in quality and recommendation. Does it not deserve a fair trial in this country?

THE SOURCE OF MUSCULAR POWER.

BY BARON LIEBIG.

As the result of general experience, I have formerly expressed the opinion that the source of the mechanical actions of the animal body must be sought in material metamorphosis, and especially in the transformation of the nitrogenous constituents of muscle. Accordingly, the work done by any two individuals should be proportionate to the respective mass of their muscles, while the duration of the work should be proportionate to the supply of material suitable for restoration of the transformed parts of the muscular mass.

The comprehensive and carefully conducted investigations of Playfair in reference to the requirements of various classes for albuminates in their daily food, appear to leave no doubt as to the correctness of this view. He demonstrated that everywhere and under all conditions, the labourer required, for the maintenance of working power and health, a larger amount of albuminates than was needed by an individual that no work. This is the case in prisons, in penitentiaries, and with soldiers both in war and in peace.

Moreover, the results of Playfair's investigations have not encountered any earnest opposition resulting from observations of equal value. Isolated observations have been urged against his conclusions; but I consider that these should be regarded with as much caution as the opinion popularly held in Bavaria, that beer is a good article of nutrition and that hard-working men owe their strength chiefly to the consumption of beer. Exact observation of the diet of the brewery labourers in Munich, who consume the largest amount of beer, shows, on the contrary, that these people are also the largest meat-eaters.*

The question as to the source of muscular power has been rendered confused by an inference that has proved to be erroneous, and for which I am myself accountable. If the muscular substance in undergoing metamorphosis be the source of muscular power and, if the ultimate nitrogenous product formed in this metamorphosis with the aid of oxygen be urea, then it would follow (it was erroneously inferred) that the work done might be deduced from the quantity of urea. It was assumed that the metamorphosis would be proportionate to the work done and that the urea secreted would be also proportionate to it.

The first facts ascertained in opposition to this view that urea was a measure of muscular work, were established by Dr. Bischoff in his investigation on urea as a measure of metamorphosis. Then followed the still more comprehensive investigation, undertaken by Bischoff and Voit in Munich, which may be regarded as a continuation of the experiments made at Giessen. It is probably unnecessary to mention here that I have always taken the liveliest interest in these investigations; indeed, the method devised by me for estimating urea owes its origin to them.

In these experiments a dog was fed with known quantities of meat and fat, with meat alone, with meat, carbohydrates and gelatin. At the same time the daily quantity of urea secreted was determined.

The quantity of nitrogen in the meat and the urine being known, it might be assumed in calculation that when the nitrogen in the urine was found to equal that in the meat consumed, the whole of the meat had been metamorphosed; if the quantity of urea was less, a portion of the meat consumed must have remained in the body or, in other words, must have been assimilated, while if the quantity of nitrogen was greater, the excess must have been furnished by parts of the body.

The following are among the most important results of these experiments:—

With a certain proportion of meat and fat, the animal experimented upon could be maintained at a constant weight. In this case all the nitrogen appeared as urea in the urine, and since there was no increase of weight, the fat must have been consumed in respiration.

It then became apparent that by increasing the supply of meat without increasing that of fat, the quantity of urea secreted became greater in the same proportion as the meat supply had been increased, while at the same time the weight of the animal increased.

In opposition to the opinion, then prevailing, that fat lessened the metamorphosis in the body—inasmuch as it appeared to be far more susceptible of oxidation than flesh—it followed from this experiment, on the contrary, that an excess of meat took the place of fat in the process of respiration. While, in the former case, the fat was entirely used up, it appeared that with more meat a part of this fat remained unaltered in the body.

This fact acquires high significance in a particular direction, inasmuch as it proves that there is in the animal body an arrangement by which increase of the blood or of constituents of blood beyond a certain limit is prevented. When albuminates are supplied in quantities greater than the body is in need of, they are removed in the most speedy way.

The particular causes that destroy this excess cannot, under normal conditions of nutrition, exercise any action upon the constituents of the blood; for, otherwise, in the case of deficient supply of food, or during abstinence, those constituents would be as much subject to the destructive influence of such causes, as if the excess of those constituents in the food had been acted upon.

It was further shown by Bischoff and Voit that the animal experimented upon could be sustained upon meat entirely destitute of fat and maintained at its full weight with very slight variations. In this case the secreted urea corresponded in quantity to the nitrogen of the meat consumed.

The constancy of the animal's weight indicated that fat may be entirely replaced by meat in the process of respiration; one part of the meat had undoubtedly served for generating heat, while another part served for the restoration of metamorphosed parts of the body.

But in both cases the nitrogenous product of the meat was the same, viz. urea.

However, if urea were a product not only of metamorphosis, but simultaneously also of respiration, then the quantity of urea secreted could not afford any indication as to the extent of the metamorphosis. If, moreover, the muscular work were determined by the metamorphosis, the amount of work could not be measured by the urea secreted. The view previously held could only be maintained if it could be shown that the work done by the animal was augmented in proportion as the supply of meat was increased.

In this case it must have been assumed that the meat was converted into muscle, that this muscle was metamorphosed, and that the products of this metamorphosis had served as material for generating heat.

* In the brewery of Sedlmayer, at Munich, 95 workmen, six women, and nine children, in all 112 persons, consumed 11,189 kilog. bread, 17,870 kilog. meat, and 159,120 litres of beer from the 1st October to the 30th April. Reckoning the 6 women and 9 children as equal to 9 men, the daily quantity of meat consumed per head would be 810 grm. The work of the brewery labourers is the most severe of any, and only very strong men are fit for it.

However, in certain cases the animal produced ten times as much urea as in normal feeding, without there being any recognizable outward sign of increased internal work.

From the view that the metamorphosis of nitrogenous constituents of the body gives rise to the working power, while the urea secreted is a measure of the metamorphosis, it would necessarily follow that the metamorphosis must be augmented by increased outward work and that this must also increase the quantity of urea secreted within a given time.

These considerations led Voit to institute the experiments by which he showed that, with a given diet, the quantity of urea secreted was the same during both rest and work.

This investigation consequently demonstrated that though urea was indeed a measure of the nitrogenous constituents supplied in the food and of those metamorphosed in the body, still it could not be taken as a measure of the work done by the body. An increase of the work did not appear to have any influence in augmenting the quantity of urea secreted.

However, in reflecting on these facts, one perceives at once that this could not be otherwise, for if the metamorphosis of muscular substance were increased by work, a man would be able to use up his entire store of muscle, since the performance of work is subject to the will. But the work done by the muscles must have a limit; beyond a certain point exhaustion is produced. The cases in which animals are killed by excessive work requires a special explanation.

Muscular force arises from a process that takes place in the muscles; so much of them may be consumed for producing work as is available for that purpose, but no more. The application of the available force may perhaps, for a time, accelerate those processes in the muscle by which it is generated; but the work done is not the cause of the metamorphosis.

There is no doubt as to the origin of muscular force, or that its seat is in the muscles themselves; neither is it doubted that it arises from some material alteration or metamorphosis of the muscular substance; but opinions still differ as to the process and as to the substances that undergo the change.

According to one view the force is generated by transformation of the nitrogenous constituents of muscle, in which oxygen takes part, though without directly causing it.

According to the other view, on the contrary, the force is generated by combustion, either of the non-nitrogenous constituents of the muscles themselves or of the non-nitrogenous constituents of the blood flowing through the muscles.

The capability of muscular material to produce muscular work cannot be doubted.

A carnivorous animal can be sustained in good health with meat alone and without any non-nitrogenous material. In this case the internal work and heat must be produced by the transformation of flesh.

No fact of equal significance can be brought forward to indicate the capability of fat or the so-called carbo-hydrates to generate the working force by their combustion.

An animal cannot be sustained by feeding with fat and carbo-hydrates alone; a certain quantity of albuminates of muscular material is always necessary. Moreover the work done does not bear any relation to the non-nitrogenous materials of the food consumed; it cannot be increased by a larger supply of them; it is not lessened by reducing the supply of them, when the quantity requisite for generating heat is made up by an equivalent quantity of nitrogenous material.

On the contrary the most every-day experience seems to show that the power of an individual to do work is, under otherwise normal conditions of diet, in a certain ratio to the quantity of muscular material consumed in his daily food, or to the quantity of material adapted for the production of muscle; that the supply of such constituents of the food must be increased as the work to be done is increased, so that a working individual requires more of them in his food than one who is at rest. Moreover this is the case not only from one day to another or during a few days; but during a month or a year.

(*To be continued.*)

FRANKINCENSE, OR OLIBANUM.*

The following is an abstract of the paper on this subject by Dr. Birdwood, which was referred to in our number for July 30:—

The burning of incense for purposes of worship is of very old date, it being represented in painting and sculpture on the monuments of Egypt and Assyria. The first mention of it and of the use of frankincense occurs in the Bible. In Exodus xxx. 34–36, we read that "Stacte and onycha and galbanum, with pure frankincense," were the "sweet spices" from which the "pure and holy perfume" or "confection" of divine prescription which was offered on the "Altar of Incense," was to be made "after the art of the apothecary." In other parts of the sacred writings it is often mentioned, Sheba being indicated as its source.

Herodotus (born B.C. 484) mentions frankincense frequently and affirms that Arabia was the only country producing "frankincense, myrrh, cassia, cinnamon and ladanum," and that the frankincense trees were guarded by winged serpents, "small in size, and of varied colours, whereof vast numbers hang about every tree . . . and there is nothing but the smoke of the storax which will drive them from the trees." The Greeks obtained their storax from the Phœnicians.

Theophrastus (B.C. 394–287) gives the fullest and most accurate account of frankincense of all ancient writers. Dr. Birdwood has supplied the following translation:—

> "Concerning frankincense and myrrh and balsam, and whatsoever is like these, it has [already] been said that they are produced by incision and spontaneously. And we must [now] endeavour to tell what is the nature of the trees, and if they have anything peculiar as to their origin or collection, or other matters; and, in like manner, concerning the other sweet-smelling trees; for almost the whole of them grow in places towards the south and east. The frankincense-tree and myrrh and cassia and cinnamon grow in the Chersonese of the Arabians, about Saba and Adramyta, and Citibæna and Mali. But the trees of frankincense and myrrh grow, some of them on the mountain and others in private plantations at the foot of the mountain, on which account some of them are cultivated and others are not; and they say that the mountain is lofty and thickly wooded and covered with snow, and that rivers also flow down from it into the plains, and that the frankincense-tree is not large, being five cubits high and covered with boughs, and that it has a leaf like that of the pear-tree, only much smaller, and is of a glassy colour, very like rue, and has altogether a smooth bark like the laurel; but that the myrrh-tree is still smaller in size and more shrub-like, and that it has a hard trunk, and is twisted towards the

* Transactions of the Linnean Society, vol. xxvii. pp. 111–148. On the Genus *Boswellia*, with Descriptions of Figures of Three New Species. By George Birdwood, M.D. Edin. Communicated by Daniel Hanbury, Esq., F.R.S. & L.S.

ground, and is thicker than a man's leg, and has a smooth bark like purslane. But others, who say they have seen them, nearly all agree concerning their size, namely, that neither of the trees is large, the myrrh-tree being the smaller and lower [of the two]. And they state that the frankincense bears a resemblance to a laurel and that it has a smooth bark, but that the myrrh is prickly and not smooth, and that it has a leaf like the elm, only crisp and prickly at the top, like the ilex tree. And they say that in a voyage they were making from the Bay of Heroes, they disembarked to search for water on the mountain, and thus saw the trees and the mode of collecting [the frankincense]. And that the trunks and boughs of both were incised; but that the former appeared to have been cut, as it were, by an axe and the latter to have had more gentle incisions; and that the drops partly fell down and partly remained on the tree. And that in in some places mats woven of palm-leaves were placed underneath, while in others the ground underneath was hardened and kept clean; and that the frankincense on the mats was pure and transparent, but that on the ground less so; and that they scraped off what adhered to the trees with knives, so that the bark stuck to some of them. And they said that the whole mountain was divided amongst the Sabæans; for that they were the lords [of the place], and that they were just towards one another, on which account no one kept any guard [over his own property]; and that having themselves taken thence an abundance of frankincense and myrrh, which they placed in their ships, none of the inhabitants being present, they had sailed away. And these both told this and said that they heard that the myrrh and frankincense is gathered together on every side to the temple of the Sun; and that this belongs to the Sabæans, being by far the most sacred thing in the country, and that certain armed Arabs have the custody of it; and that when they bring it, each, heaping up his own frankincense and the myrrh in a similar way, leaves them with the keepers, and placing upon the heap a little tablet, stating the number of measures and the price at which each measure is to be sold; and that when the merchants come they inspect these tablets, and having measured any heap that pleases them, they put the price of it in the place from which it is taken; and that the priest then coming takes a third part of the price for the god and there leaves the remainder, which is kept safe for the owners until they come and take it. But certain others say that the frankincense-tree is like the lentisck, and its fruit to the berries of the same, and that the leaf of it is reddish; and that the frankincense from the young tree is whiter and less fragrant, while that from the older trees is yellowish and more fragrant; and that the myrrh-tree is like the terebinth, but rougher and more thorny and the leaf a little rounder, and, if chewed, resembling the terebinth in taste; and that of these, also, the older are the more fragrant. And that both grow in the same place, and that the ground [there] is argillaceous and flaky, and that springs of water are rare. These things, however, are contradictory [to the statement] that it snows and is wet [in that locality] and that rivers issue from it. And others also say that it is like the terebinth, and others that it is the terebinth itself; for that specimens of the wood were brought to Antigonus by the Arabs who conveyed the frankincense, and that they differed in nothing from the terebinth. These, however, showed still greater ignorance, for they thought both the frankincense and the myrrh grew on the same tree. On which account, the report brought by those that sailed from the City of Heroes is more credible; since the frankincense-tree that grew above Sardis, in a certain temple, has a leaf like the laurel, if from this we can form a conclusion, and the frankincense produced from it, whether from the trunks or branches, is like the other frankincense in appearance and smell when it is burnt. And this tree alone grew without [any culture]. And some say that the frankincense grows more abundantly in Arabia, but more beautifully in the neighbouring islands, over which the Arabs have sway; for there they make figures upon the trees of whatever they like; which is not incredible, as they admit of any incisions that persons may wish to make in them. Some of the grains also are very large, in bulk as much as a handful, and in weight more than the third part of a mina. All frankincense is brought to the market in a rough state, similar in appearance to the bark of a tree; but of myrrh there are two kinds, the one in drops and the other in moulds. The quality is judged by the taste; and from this they choose what is of uniform colour. Concerning frankincense and myrrh, this is nearly as much as we have heard up to the present time."

Diodorus (about B.C. 50) gives a long account of this substance, in which he gives a very glowing description of Arabia the Happy, where the air is so highly perfumed with frankincense and other odoriferous trees "that it even ravishes the senses with delight, as a thing divine and unutterable," and the perfume is wafted out to sea, so that those sailing near the coast are entertained "with its pleasures and delights." He also gives credence to the myth of the trees being surrounded by fearful serpents. Speaking of an island off the coast of Arabia called Holy Island, on which no one was allowed to bury their dead, he says,—

> "The sacred isle produces frankincense, and in that abundance as suffices for the service and worship of the gods all the world over; it has likewise plenty of myrrh, with other odoriferous spices of several sorts, which breathe out a most fragrant smell. The nature of frankincense, and the manner of getting it, is thus: the tree is very small, like to the white Egyptian thorn, and bears a leaf like to the willow; it puts forth a flower of a golden colour; from the bark of this tree, by incision made, distils the frankincense in drops like tears."

Strabo (B.C. 54–A.D. 24) says,—

> "Frankincense is produced in Catabania, and in the parts of Arabia opposite. Here the frankincense-tree grows along the banks of the Isis and Nilus. The country of the Sabæi produces not only frankincense but balsam, sweet-smelling palms, calamus, and larimnum, a most fragrant perfume. By the trade in these aromatics the Sabæans and the Gerrhæi have become the richest of all the tribes."

Pliny (A.D. 23–79), too, gives a long account, agreeing in most particulars with Theophrastus. He says that the gum was at first only collected once a year, but when a greater demand sprang up, the inhabitants "feeling the sweetnesse of the gaine," made a double vintage, —the first and best in summer, about the dog-days, and the second in the spring; the first being called Carpheotum, and the second or spring crop, much inferior to the first, Dathiatum.

Ptolemy (about A.D. 150), in his Geography, places the Libanotophoros, or thuriferous region, between Makalla and Muscat.

The casual notices of frankincense by the Latin poets and historians are, as Dr. Birdwood observes, very valuable in the present argument and are very numerous. The most pertinent of them are quoted by Celsus in his 'Hierobotanicon,' who "makes a very determined effort to exhaust all the learning on the subject," and "very well proves how impossible it is to be universally learned on even so infinitesimal a subject as frankincense."

The high honour in which frankincense was held by the ancients is shown by its being one of the three gifts brought by the Magi to the infant Saviour.

The Arabian writers all agree that frankincense is produced in the Hadramaut, though Scrapion and Avicenna copy Dioscorides' mistake in saying it was also produced in India. Ibn Batuta says:—

> "Leaving Zofar (Dofar, Lee; Sephar of the Bible? G.B.), I proceeded to sea towards Amman, and on the second day put into the port of Hasik, where many Arab fishermen reside. We have here the incense-tree. This tree has a thin leaf, which, when scarified, produces a fluid like milk, this turns into gum, and is then called *loban*, or frankincense."

Marco Polo, a European writer, says of the city of Escier, or Escher:—

> "This district produces a large quantity of white frankincense of the best quality, which distils, drob by drop,

from a certain small tree that resembles the *fir*. The people occasionally tap the tree or pare away the bark, and from the incision the frankincense gradually exudes, which afterwards becomes hard. Even when an incision is not made, an exudation is perceived to take place, in consequence of the excessive heat of the climate.

"The frankincense is so cheap in the country as to be purchased by the governor at a rate of ten bezants the quintal, who sells it again to the merchants at 40 bezants. This is done under the direction of the Soldan of Aden, who monopolizes all that is produced in the district, and derives a large profit from the resale."

Thevet says that frankincense is produced, with myrrh, in the country about Pecher (Sheher?) and Fartack, cities of the kingdom of Aden; that there are two kinds, the best being whitish, pure, clean-cut and solid, collected in summer; the second, a reddish kind, collected in spring; also that the tree resembles the resinous *firs*. He gives a figure, which Dr. Birdwood takes to be an undoubted *Boswellia*, with a background of *firs*.

Garcia ab Horto, from whom Gerard copies, says that no frankincense is produced in India and he wonders that such a mistake should have been made; that there are two kinds, the best produced on mountains, and the dark and inferior produced in the plains; that the darker kinds of frankincense are called Indian by the Arabs. His figure is a copy of Thevet's without the background of *firs*.

The word olibanum, as a synonym for frankincense, was used by Pope Benedict IX. in 1033, and by Gerard in his translation of Avicenna in 1490.

Purchas, in 'His Pilgrimes' (London, 1627) notes olibanum amongst other articles brought by the Arabs for sale on the Arabian coast.

Celsus, in his 'Hierobotanicon,' has the following information regarding the native country of Olibanum:—

"It is most true that frankincense does not grow in any part of India, since whatever frankincense is consumed in India, and whatever is conveyed thence to Portugal, is brought out of Arabia, where alone it grows, and is called Lovan. On which account, I believe that writers are mistaken who consider that it is Libanum in Greek, and Olibanum in commerce, from the fact of its growing in Mount Lebanon."

Linnæus referred frankincense to a *Juniperus*, *J. Lycia*. Dr. Birdwood says he takes the statement at second-hand. This is, however, true. Linnæus in his 'Materia Medica' (Schreber's ed. Alt. 1772) says,—

506. JUNIPERUS LYCIA foliis ternis undique imbricatis ovatis obtusis. *Roy. Mgdb.* 90. Sp. Pl. 1471.

Cedrus, folio cupressi, major, fructu flavescente. *Bauh. Pin.* 487.

Loc.: Africa, Æthiopia, Arabia, *Arbor*, *peregrina*.

PHARM. OLIBANI (THURIS) Resina, granulata, oleum stillatitium, etc., and in a foot-note "OLIBANUM *ex hac arbore desumtum esse alii statuunt, alii negant, &* Sandaracam *non prioris sed hujus esse resinam volunt alii; lis pendet.*"

Bruce, whose narrative of travels met with so much undeserved opposition and incredulity, actually figures in his atlas a plant, afterwards named by Richard, *Boswellia papyrifera*, remarking that it was called *Angouah* by the people about Tacazza, and believed by the Abyssinians to be the true frankincense; he adds, "in reality it produces a gum much resembling it."

In 1807, Colebrooke proved that a frankincense-like gum was yielded by *Boswellia serrata*, of Roxburgh (=*B. thurifera*, Colebr.). From this it was concluded that this plant yielded the olibanum of commerce, and it was even denied that Arabia yielded any.

Bruce's plant was afterwards described by two botanists under different names; in 1820 by Delile, under the name of *Amyris papyrifera*, and by Endlicher in 1838, under the name of *Plösslea floribunda*.

Wellstead in 1838 found that large quantities of olibanum were exported from the Soumali coast. He says, "two kinds of frankincense are brought here for exportation to Hindustan, one called *Luban*, from Hadramaut, which is a powerful aromatic, used in the temples and houses for fumigation; the other, *Luban mati*, less fragrant, but preferred for chewing."

Cruttenden in 1837 saw the frankincense-tree on his journey from Merbat to Dyrcez, the principal town of Dejar, and in 1843 the frankincense-tree of the Soumali country. He is reporting on the Mijjertheyn tribe of Soumalis, and says,—

"During the hot season the men and boys are daily employed in collecting gums, which process is carried on as follows:—About the end of February or beginning of March the Bedouins visit all the trees in succession, and make a deep incision in each, peeling off a narrow strip of bark for about five inches below the wound. This is left for a month, when a fresh incision is made in the same place, but deeper. A third month elapses, and the operation is again effected, after which the gum is supposed to have attained a proper degree of consistency. The mountain sides are immediately covered with parties of men and boys, who scrape off the large, clear globules into a basket, whilst the inferior quality that has run down the tree is packed separately. The gum, when first taken from the tree, is very soft, but hardens quickly. The flame is clear and brilliant, and the traveller is frequently amused by seeing a miserable Bedoui family, cowering under a wretched hovel, eating their scanty meal by the light of half-a-dozen frankincense torches. Every fortnight the mountains are visited in this manner, the trees producing larger quantities as the season advances until the middle of September, when the first shower of rain puts a close to the gathering o that year."

The export, he goes on to say, is in the hands of "those never-failing speculators, the Banians of Porebunder (Kattiawar) and Bombay." At the close of the north-east monsoon they arrive at the coast, and settle at Feluk (Mount Elephant of the ancients, Cape Felix of the Portuguese, and Jibbel Feel of Captain Saris), Bunder Marayah, Bunder Khor, and other Bunders. "The Bedowins from the interior immediately visit them, and, as there is no one to compete with them, they manage to engross the greater part of the trade." He estimates that the quantity annually exported is,—

To Bombay	377 tons.
To Red Sea	235 "
To Arabia	120 "
	732

"The trees that produce *Luban*, or frankincense, are of two kinds, *Luban Meyti* and *Luban Bedowi*. Of these the *Meyti*, which grows out of the native rock, is the most valuable, and, when clean-packed and of good quality, it is sold by the merchants on the coast for one and a quarter dollars per frasila of twenty pounds. The *Luban Bedowi*, of the best quality, is sold for one dollar per frasila: of both kinds the palest colour is preferred. The trees vary greatly in height, but I never saw one above twenty feet with a stem of nine inches in diameter. Their form is very graceful, and, when springing from a mass of marble on the brink of a precipice, their appearance is especially picturesque."

In 1843 Kempthorne and Vaughan visited the Soumali country. Kempthorne's specimen was identified by Mr. Bennett, of the British Museum, with Endlicher's *Plösslea floribunda*, but on the agreement of the peculiar papery character of the barks only. Dr. Vaughan, in 'Notes upon the Drugs observed at Aden,' mentions the following kinds:—*Luban maitee*, *Luban nankur* or *aungure*, *Luban makur*, *Luban berbera* or *muslika*, and *Luban Marbat* or *Saharee Luban*, the finest kind. Vaughan's original specimens are in the Pharmaceutical Society's museum.

In 1847 Carter published a figure of the frankincense-tree of Arabia, accurately defining the thuriferous region. He says,—

"Coming from the north-east, we first meet with the frankincense-tree on the Sabhan mountains in latitude 17°. 30′ N. and longitude 55° 23′ E., where the desert ends, and the wooded mountainous region commences; and, following the coast, which runs south-west, we find the frankincense exported from the different towns gradually diminishes after the Bay of Al Kammar until we arrive at Makalla, from whence none is exported from the interior of Arabia, and but little used, except what is brought from the African coast opposite that town. By the same inquiry we learn that the produce of the Arabian trees is exported in large quantities from places on that part of the coast which intervenes between the latitude and longitude mentioned (viz. 17° 30′ N. and 55° 23′ E.) and the town of Damkote in the Bay of Al Kammar, 52° 47′ E. longitude. Between these two points the trees are congregated in two distinct localities —on the summits and sides of the highest range of mountains near the coast, and on the plain between them and the sea; the former is called *Nedjee*, or highland, and the latter *Sahil*, or plains on the coast. The *Nedjee* is about two days' journey from the shore; it is the most elevated portion of the great limestone formation of this coast, which, from a height of 5000 feet here, descends in sudden and lofty steps upon the Arabian Sea. To get to it you first cross the *Sahil* already mentioned, and then ascend a minor range, which is covered with long grass and trees, and, after passing a less fertile region, called the *Găthăn*, at last arrive at the *Nedjee*, where there is no grass and but few trees beside those which produce the frankincense. The soil is red and subargillaceous, and, in consequence of its scarcity, the trees are generally found growing out of the crevices of the limestone rock. It is from this part that the frankincense is chiefly brought, and, as I have before said, the largest quantities of it are exported from the different towns on the coast between the longitudes 50° 47′ and 55° 23′ E.

"The libanophorous region, therefore, lies behind the towns on this part of the coast where Theophrastus places it, and not, as Ptolemy places it, in Oman."

Mr. Carter also procured dried and living specimens of the tree, and made careful drawings of them. In 1859, when Dr. Birdwood took charge of the Agri-Horticultural Society's "Old Gardens" at Bombay, he found Carter's plant still living. Through the kind exertions of Colonel Playfair, then at Aden, he obtained a fine collection of several varieties of dried specimens and cuttings of the African frankincense-tree, together with the frankincense yielded by them. Both Carter's and Playfair's plants have since flowered, and thus allowed of their being named.

Dr. Birdwood, in his "conclusions," says:—

"It will, I believe, be now agreed that Arabia produces frankincense, and in the very region indicated by common opinion of the ancient world, and so accurately limited by Theophrastus. Now that it has been demonstrated by Carter that the libanotophorous region lies along the coast of Hadramaut, the agreement between the statements of the Bible, Herodotus, Theophrastus, Diodorus Siculus, Strabo, Pliny, Arrian, Ptolemy, the Arabs, Marco Polo, Bochart and Celsus is very striking. It will, I believe, be agreed also, as implied in the more ancient references to Arabia, and expressly asserted by Diodorus, Strabo, Arrian, and others of the ancients, and demonstrated with such fulness by Cruttenden, Kempthorne and Vaughan, and the overwhelming evidence of modern travellers (beginning with Bruce) generally, that the Soumali country also produces frankincense and probably the bulk of the olibanum of commerce. The agreement as to the region about Mount Elephant (Ras Fieluk, Cape Felix, Jibbel Feel) between Arrian, Captain Doventon and Captain Saris, in Purchas, Milburn, Cruttenden, Kempthorne and Vaughan is indeed quite startling.

"It will be admitted also, I believe, that *Boswellia Carterii* (*Mohr Madow*), which—with *B. Bhau-Dajiana* (*Mohr Add*), the source of the bulk of the olibanum of commerce exported from the Soumali country—is the same species as the plant (*Maghrayt d'sheehaz*) which Carter found produced the frankincense of the Hadramaut, and also that *Boswellia thurifera* (including *B. glabra*) of India and *B. papyrifera* of Abyssinia, although thuriferous species, are not known to yield any of the olibanum of commerce.

"It is very surprising that so great weight of evidence in favour of frankincense being produced in Arabia Felix and the Soumali country should ever have been set aside for the idle fancy that India was the source of the olibanum of commerce."

Dr. Birdwood rightly attributes at least a portion of this mistake to a most prolific source of error, namely, the alteration which has taken place in the trade-routes.

In the Paris Universal Exhibition of 1867, Dr. Birdwood noticed several bottles of frankincense labelled "Olibanum, so called because it comes from Mount Lebanon;" also aconite labelled "*Aconitum Nepaullus*, so named because its root is the famous poison of Nepaul"!

Dr. Birdwood then gives descriptions of the genus *Boswellia* and the species belonging to it, as enumerated below, with the synonyms of each species.

Genus Boswellia.

Roxburgh, Pl. Corom. iii. p. 4. t. 207; Benth. and Hook. Gen. Plant. i. p. 322.

Libanus, Colebrooke in Asiat. Res. ix. p. 377. t. 5. f. 1.

Plösslea, Endlicher, Nov. Stirp. Dec. 47; Iconog. t. 119, 120.

Species 5. natives of Nubia, Abyssinia, Berbera, Arabia, and India.

1. Boswellia Carterii, Birdwood, n. sp. (with figures).
   B. thurifera, Colebrooke? Carter in Journ. Bombay Br. Roy. As. Soc. ii. 1847.
   "Mohr Madow," Playfair.
   "Maghrayt d'sheehaz," Carter.
   Habitat. Soumali mountains, Africa; Hadramaut Mountains, Arabia.

   The "mohr madow" and "maghrayt d'sheehaz" are two varieties, figures of both are given.
2. B. Bhau-Dajiana, Birdwood, n. sp. (with figure).
   "Mohr Add," Playfair (Soumali mountains).
   Habitat. Soumali mountains.

   These two species yield the bulk of the olibanum exported from the Soumali country under the name of "Laban-Sheheri."
3. B. papyrifera, Richard, Tent. Flor. Abyss. etc. iv. p. 140. t. 33.
   Amyris papyrifera, Delile, Cent. Pl. d'Afrique; Caillaud, Voyage à Méroé, ii. p. 293.
   Plösslea floribunda, Endl. Nov. Stirp. etc., n. 47. t. 119, 120.
   "Angouah," Bruce's Travels, vii. p. 334. tab. 48.
   Habitat. Senaar, Soudan, Gondar, and the valley between the Taccaze and Mareb.
4. B. thurifera, Colebrooke, Asiat. Res. ix. p. 377. t. 5.
   B. serrata and *B. glabra*, Roxb. Flor. Ind. ii. pp. 383, 384.
   B. glabra, Roxb. Cor. Pl. ii. t. 207.
   "*Salai*," India (Birdwood).
   Habitat. In the mountains of Tropical India; Oude and Rohilkund, *Royle*; Behar, *Hooker*; Concan, *Stocks*; Kattyawar, Khandeish, *H. M. Birdwood.*

   There are two varieties of this plant and its gum-resins recognized by the natives of India, of which Roxburgh made two species.
5. B. Frereana, Birdwood, n. sp. (with figure).
   "Yegaar," Playfair.
   "Louban maitee" of the Soumalis.
   "Louban meyti," Cruttenden.
   Habitat. In the white limestone mountains about Bundah Murayha.

We are highly grateful to Dr. Birdwood for this very interesting and valuable paper, which must have cost him immense labour and painstaking research. It is, without doubt, one of the best monographs on any materia medica substance we have had for some time, and will undoubtedly receive the recognition it is so well entitled to. Dr. Birdwood tells us that this is the "first of a series of monographs on such of the vegetable products of the East, the history and botany of which need further elucidation." We look with interest, and with some degree of impatience, for further contributions from his pen, especially when we find he has not overlooked one of the most fundamental desiderata of economic botany, that of procuring really well-authenticated specimens of the products collected from the plants themselves. He tells us that nearly all the gums and resins in the Bombay Museum were collected by his own hands.

OUR SALAD HERBS.

BY C. J. ROBINSON.

There is, perhaps, no country in the world so rich as England in native materials for salad-making, and none in which ignorance and prejudice have more restricted their employment. At every season of the year the peasant may cull from the field and hedgerow wholesome herbs which would impart a pleasant variety to his monotonous meal, and save his store of potatoes from premature exhaustion. Besides there can be no question that in hot seasons a judicious admixture of fresh green food is as salutary as it is agreeable. Much has been said lately about the advantage which the labouring man would derive from an accurate acquaintance with the various sorts of fungus; he has been gravely told that the *Fistulina hepatica* is an admirable substitute for beef-steak; the *Agaricus gambosus* for the equally unknown veal cutlet. But deep-rooted suspicion is not easily eradicated, and there will always be a certain amount of hazard in dealing with a class of products in which the distinctions between noxious and innocuous are not very clearly marked. There is not this difficulty with regard to salad herbs, and we conceive that the diffusion of a little knowledge as to their properties and value would be an unmixed benefit to our rural population.

The first place must be assigned, on the score of antiquity, to the sorrel plant (*Rumex Acetosa*), which in some districts still preserves the name of "green sauce" assigned to it in early times when it formed almost the only dinner vegetable. Its acid is pleasant and wholesome, more delicate in flavour than that of the wood-sorrel (*Oxalis Acetosella*), which, however, is used for table purposes in France and Germany. Chervil (*Anthriscus Cerefolium*) is often found in a wild state and is an admirable addition to the salad bowl; and it is unnecessary to enlarge upon the virtues of celery (*Apium graveolens*) when improved by cultivation. John Ray, writing in 1663, says that "the Italians use several herbs for sallets which are not yet, or have not been used lately, but in England, viz. *selleri*, which is nothing else but the sweet smallage; the young shoots whereof, with a little of the head of the root cut off, they eat raw with oil and pepper;" and to this we may add that the alisander (*Smyrnium Olusatrum*) is no bad substitute for its better known congener. The dandelion, which in France is blanched for the purpose, affords that *amari aliquid* which the professed salad-maker finds in the leaves of the endive, and the same essential ingredient may be supplied by the avens (*Geum urbanum*), the bladder campion (*Silene inflata*), and the tender shoots of the wild hop. Most people are familiar with the properties of the watercress (*Nasturtium officinale*), and the garlic hedge-mustard (*Erysimum Alliaria*); but it may not be generally known that the common shepherd's-purse (*Capsella Bursa-pastoris*) and lady's-smock (*Cardamine pratensis*) are pleasant additions, whose merits have long been recognized by our foreign neighbours. In fact, there is scarcely a herb that grows which has not some culinary virtue in a French peasant's eyes. Out of the blanched shoots of the wild chicory (*Cichorium Intybus*) he forms the well-known *barbe des capucins*, and dignifies with the title of *salade de chanoine* our own neglected corn-salad (*Fedia olitoria*). It would be very easy to extend the dimensions of our list of native salad herbs, for there are, perhaps, some palates to which the strong flavours of the chive (*Allium schœnoprasum*) and stone-crop (*Sedum reflexum*) may commend themselves; but enough has been said to show that Nature has not dealt niggardly with us, and that only knowledge is needful to make the riches she offers available. If the British peasant can be taught to discover hidden virtues in these plants, with whose outward forms he has had lifelong familiarity, we do not despair of his acquiring the one secret of salad-making, viz. the judicious employment of oil so as to correct the acrid juices of the plants and yet preserve their several flavours unimpaired.—*Nature.*

NITROUS OXIDE GAS.

In a letter to the 'Times' of August 17, Dr. Thudichum recommends the use of this gas in surgical operations upon wounded soldiers. He remarks:—

"All possible efforts ought to be made to reduce the sum of pain to which, by surgical operations and dressings, they are necessarily subjected. Chloroform is largely used for this purpose, but its application meets with difficulties in many cases. Thus, the mere excitement of the wounded soldier is frequently so great that, for fear of choking, it cannot be applied at all; in other cases it produces sickness which continues often for hours after its application and compromises the welfare of the patient. Its action is of such a kind that, practically, it is only applied for long and severe operations, rarely for slight ones; but never in that most painful and oft-repeated process, the dressing of wounds.

"All the advantages of chloroform, to the exclusion of the disadvantages just mentioned, are possessed by nitrous oxide gas. It has no smell, produces quickly, in four or five full inspirations, a perfect anæsthesia, in which all operations can be performed without causing pain, and hardly a minute after the cessation of its inhalation its influence on the patient has entirely disappeared. It never produces choking or sickness, and there has never been a case of death under its influence.

"The marvellous effect of this gas was originally discovered by Sir Humphry Davy, but was not appreciated by the scientific world, owing to the wanton ridicule cast upon it by the short-sightedness of Gay-Lussac, and of several chemists following in his wake. It is the indubitable and great merit of British dentists to have again discovered the pain-killing effect of nitrous oxide, and to have made its use for the relief of suffering a matter of daily and easy practice.

"A bulky gas could not be transported with the necessary facility, and therefore its use remained limited to institutions. But industry seized the processes, and the gas was brought into a compressed form. This compression is now carried to fluidification. Nitrous oxide is sold as a fluid in little iron flasks, of which each, hardly bigger than a wine bottle without the neck, evolves 100 gallons of gas. The production of this fluid nitrous oxide is now a branch of industry carried on by the aid of steam power erected specially and exclusively for this purpose and yet the supply is hardly equal to the demand.

"Now, from my experience in war-surgery and in the application of anæsthetics; from the inquiries which I have instituted and the experiments which I have made relating to this nitrous oxide, I have come to the conviction that this agent would be most useful in the military hospitals of the Continent, not only in primary operations, but also in the frequent painful dressings. There is less difficulty in its administration than in that of chloroform, and all surgeons would easily and quickly be able to appreciate and use it.

"I, therefore, propose that a portion of the funds which I have, no doubt, your generous appeal will cause to come forth abundantly should be applied to the purchase of, say, 1000 bottles of this pain-destroying fluid, and of fifty inhaling mouthpieces, and that these should be forwarded to the hospitals abroad as quickly as they can be obtained. The experience should be made on this scale to begin with. The discoveries of the gas, of its properties, and of its application in surgery, are exclusively English, and the processes for its fluidification, or 'coercion,' are worthy examples of English mechanics. The gift would, therefore, be doubly graceful, as being both invaluable and the product of national genius and ingenuity, and would be applied with joy by the surgeons and received with blessings by the stricken warriors."

In reference to the above letter the 'Lancet' has the following remarks:—

"We should be extremely sorry to offer any opposition to any proposal which presented a hopeful prospect of mitigating the pain of the wounded, but we think that the generosity of the public should not be taxed for visionary and doubtful schemes, such as that proposed by Dr. Thudichum for supplying nitrous oxide gas. There are, doubtless, some advantages in using this anæsthetic for short operations, such as toothdrawing and the making of incisions of a simple character. But there is no experience in favour of its use either for dressing wounds, or for more important operations; and, from the fleeting character of the anæsthesia, there is no hope whatever of its being really effective in such cases.

"We would venture to suggest in preference the formation of a special staff for the purpose of directly relieving pain by the use of the many means which are now at our disposal. First and foremost, they would be armed with a full supply of chloroform; secondly, with Dr. Richardson's apparatus for the production of local anæsthesia; and we would, of course, make no objection to nitrous oxide having also a place in the armamentarium. Nor should these be all. The subcutaneous injection of sedatives would be of great use, particularly in allaying the spasms which so painfully follow fractures and amputations; whilst, in the last place, hydrate of chloral would probably be found to relieve insomnolence to a very great extent. One or two physicians armed with these remedies would not only relieve an immense amount of physical and mental suffering, but would afford the profession an experience of the very highest value."

HARD AND SOFT WATER.

At the recent visit of the town council to the waterworks, Mr. Bateman drew attention to the reports which have been industriously circulated of late years to the prejudice of soft water, attributing to its use the great mortality which unhappily exists in some of the large towns and cities in the kingdom. He stated most unhesitatingly that there was in truth no foundation for such reports; that they were entirely fallacious; and that the presumed facts which were relied upon would not bear the test of scrutiny. He referred to a table appended to the evidence taken before the Committee of the House of Commons on the East London Water Bill in 1867, when the whole question of the metropolitan water supply had been inquired into. This table purports to give the mortality of various towns and places, distinguishing between those supplied with water above and below ten degrees of hardness. This division is perfectly arbitrary, and it does not correctly represent the point of distinction between hard water and soft water. The term "hard" is applied to water which breaks or curdles soap,* while the term "soft" is applied to water in which soap may be used without its curdling. Each degree of hardness represents one grain of carbonate of lime, or an equivalent quantity of some other soap-destroying ingredient, in each gallon of water. Water containing only four grains of lime per gallon, or having what is called 4° of hardness, does not break soap; while water having 5° or upwards does. Water of 10°, therefore, is hard water, and its evil consequences, as regards economy, will be shown by the fact that in Glasgow the substitution of Loch Katrine water of 1° of hardness for Clyde water, which varied from 7° to 9°, according to the season, saved one half of all the soap which had previously been used.

The table referred to contains the names of sixteen towns or places supplied with water of 10° or upwards, and of eleven towns in which the water supply does not amount to 10°. Among the latter is Liverpool, where the water is stated to be 9·6°.

The general conclusion is, that in towns with water over 10°, the average being 14·9°, the mortality is only 22·2 per 1000 of the population; while in those having water under 10°, the average being 4·9°, the mortality is 26·1. In London, the water being 13° of hardness, the mortality per 1000 is 23·1.

From these data it has been inferred that the excessive mortality of towns using soft water is due to the use of such water.

However, to say nothing of the unfairness of comparing such towns as Leamington, Southport, Croydon and Cheltenham with Liverpool, Sheffield, Glasgow and Manchester, the table itself is full of inaccuracies. Guildford, the county town of Surrey, is represented to contain 29,330 persons and the mortality to be 19·4 per 1000. Guildford is, in reality, a small town, with less than 10,000 inhabitants. It is situated in a remarkably healthy position, and a large number of the inhabitants which it really does contain reside in what may be considered a purely rural district.

Newcastle and Gateshead are put down as containing 14,646 persons, and the mortality is stated to be 19 per 1000. The real population of those places at the date spoken of was 163,807, and the mortality 27·37 per 1000.

It is evident that no dependence can be placed on tables so carelessly prepared, and it may be shown in a variety of ways that no fair deduction can be drawn from them at all.

The gross population of the sixteen towns or places having water of 10° or upwards is, according to the table, 1,135,514, and that of the eleven towns with softer water 1,532,784. The density of population (which, however, is not shown in the table) is, in the former group, 10·17 persons to the acre, and in the latter group 214·74; so that in the towns of higher mortality the people are living more than twice as thick upon the ground as in those places with which they are compared.

To most persons this density of population would have been supposed to exercise an important bearing on the mortality of a district, and to all those who have paid any attention to the question it is well known to exercise a very important influence, especially on the health of infants under five years of age. Infantile mortality is always greatest in manufacturing towns, and in places of dense population, whatever the character of the water which may be supplied. If these deaths be deducted, then, the mortality per 1000 of those above five years is 13·56 in the towns supplied with water of 10° or upwards, and 13·47 per 1000 in those having softer water, or slightly in favour of the latter, though practically the same.

But the strongest proof that excessive mortality must be sought for in other causes than the hard or soft character of the water supplied to the inhabitants will be seen by an examination of the mortality which obtains in different places supplied with the same water. For instance, in the table alluded to, the population assigned to Birmingham (a town supplied with water of 15½° of

* This effect of hard water is, in fact, a precipitation of the fatty acid of the soap consequent on the formation of an insoluble compound of the fatty acid with the earthy base in the water.—Ed. Ph. J.

hardness) is made up of those living in Birmingham, King's Norton and Aston, the density of population being respectively 100·, 1·37, and 2·7 persons to the acre, the mortality being also respectively 26·5 per 1000, 17·1, and 21 per 1000. This varying mortality cannot surely be owing to the water, which is the same in all the three cases.

Again, Liverpool having water of 9·6° of hardness is composed of Liverpool and West Derby, the mortality being in the former place 33·29, and in the latter 22·73 per 1000. Here, again, the water is exactly the same, but the density of population is respectively 100 and 3·7 per acre.

Sheffield, a soft-water town, is composed of Sheffield and Eccleshall, the mortality in the two places being 28·45 and 22·75.

Manchester, Salford and Charlton-on-Medlock, all places supplied with the soft water of the Manchester Waterworks, exhibited a mortality at the time the table was prepared of 31·48, 26·00 and 23·94 per 1000 persons respectively. If the high death-rate in Manchester were due to the soft water, why did it not poison as many persons in the 1000 at Chorlton-on-Medlock and at Salford?

Instances from all quarters of the kingdom could be crowded upon each other showing a like result, and the fallacy of the deductions which have been drawn from such unfair statistics as have been thus only slightly exposed.

The fact is that neither hard water nor soft water appears to exercise any perceptible influence on the tables of mortality. Both, so far as those characters are concerned, appear to be equally wholesome; and though many painful diseases which are not fatal are, with reason, believed to be aggravated by the use of hard water, there is no reason for assuming that any influence is exercised upon the death-rate by the mere hardness or softness of water.

While it is thus most conclusively shown that, as compared with hard water, soft water is not injurious to health, the economic benefits which attend the use of soft water are so striking and so great, that those people may consider themselves happy indeed who have the advantage of such deliciously pure and soft water as the waterworks of Glasgow and Manchester afford.

In Glasgow, the saving to the consumer of water for domestic purposes only consequent on the introduction of Loch Katrine water in the place of Clyde water was £40,000 per annum, equal to the interest on the entire cost of the new works. This great advantage, too, has been obtained without levying a higher rate on the rental of houses than had previously existed, so that the people of Glasgow have paid no more per head for their water than they had done before, while at the same time they put £40,000 a year into their pockets.

Similar advantages have attended the supply to Manchester, but they have not been so obvious, because the change in the water-supply was introduced gradually, instead of being made at once from hard water to soft.

INVERTED SUGAR.

BY JAMES DEWAR, F.R.S.E.

Lecturer on Chemistry, Veterinary College, Edinburgh.

For some time past an animated discussion has been going on in the columns of the 'Comptes Rendus de l'Académie des Sciences' between MM. Dubranfaut and Maumené regarding the nature of inverted sugar. M. Dubranfaut, many years ago, made many valuable additions to our knowledge concerning the composition and reactions of various sugars, especially in explaining the result of the action of dilute acids on cane sugar. He explained the levo-rotatory action of inverted sugar, and its rapidly varying power with the temperature, as the result of a molecule of water, in reacting with a molecule of cane sugar, generating one molecule of glucose and one of lævulose. Dubranfaut believed that inverted sugar consisted of a mixture of glucose and lævulose in equal weights; and although he did not make a direct analysis of the product, yet he was justly entitled to assume that it was so constituted, seeing that, generally, it agreed with a mean of the properties of inulin sugar and dextrose.

In order to support the above view, he separated levo-glucose from the inverted sugar, through the insolubility of the lime compound, and compared its properties with pure lævulose. The decomposition would, according to Dubranfaut, be as follows:—

$$\underset{+\,73{\cdot}8}{C_{12}H_{22}O_{11}} + H_2O = \underset{+\,56}{\overset{+}{C_6H_{12}O_6}} + \underset{-106}{\overset{-}{C_6H_{12}O_6}}$$
$$(-25)$$

So thoroughly had his facts and explanations been accepted by chemists generally, that up to a recent date, no one had discovered any flaw in his researches, and therefore no doubt was thrown on the validity of this theory. Recently, Maumené has reinvestigated the composition of inverted sugar by analysis. He has attempted to separate the two sugars through the action of chloride of sodium. The dextro-glucose forms a well-defined crystalline compound with chloride of sodium, whereas the lævulose does not form any compound. The results obtained by this method differ greatly from theory. Instead of finding 50 per cent. of lævulose, he found 88 per cent. In repeating the experiments of Dubranfaut on the separation of levo-glucose by hydrate of lime, he has not met with any better results; in fact, his results are quite opposed to those of Dubranfaut.

Apart altogether from expressing an opinion on the merits of the views entertained by the different parties to this discussion, the author has thought some observations of the same subject might not be unworthy of notice at the present time.

Linneman, many years ago, applied the process of hydrogenation to the sugars that he had found so successful in treating the simple organic substances. In the way named he obtained mannite from inverted sugar, the following reaction taking place:—

$$C_6H_{12}O_6 + H_2 = C_6H_{14}O_6.$$

Mannite had long been known to be the product of certain kinds of fermentation, and occurring as a secondary product in the vinous fermentation; but it was this elegant synthesis of Linneman that first clearly showed the connection. But although inverted sugar can be changed into mannite, the next point that demands a solution is the proving the inverted sugar to be composed of equal quantities of dextrose and lævulose. Are they both transformed by hydrogenation into mannite? or is only one of them, and which? Linneman seems to have directed his attention to the solution of this question. He states that it is only the lævulose that is so affected. The reasons why he entertains the above views are not given. In all likelihood he thought that, just as Berthelot had changed mannite by a peculiar fermentation into levo-glucose, so would the levo-glucose in inverted sugar be hydrogenized into mannite.

In repeating the action of sodium amalgam on inverted sugar, I have not seen any reason why the one sugar any more than the other should be supposed to generate the mannite. The following is a description of the mode by which the sugar was inverted and hydrogenized:—20 grammes of cane sugar were dissolved in 150 grms. of water, and inverted through the action of 2 grms. of sulphuric acid, keeping the solution at the temperature of 70° C., afterwards adding pure carbonate of barium, filtering, and then adding one gramme of sodium in the form of a weak amalgam. The action took place without any evolution of hydrogen. If the amalgam was impure from the presence of other metals, it evolved hydrogen at once, and the solution became brown; otherwise it remained perfectly clear. After one month the solution gave no trace of sugar with the alkaline copper solution. It was then carefully neutralized with dilute sulphuric acid, evaporated on the water bath, the greater part of the sulphate of sodium separated by crystallization, and the residue treated with boiling 70 per cent. alcohol, the solution filtered and allowed to crystallize. Sometimes the mannite did not crystallize until all the alcohol had evaporated, leaving a syrup that slowly assumed the crystalline form. The product had no rotatory power. In no case was the sugar entirely changed into mannite—a gummy substance was invariably left, that would not crystallize after exposure to the air for months. Mannitan, or some similar body, may be one of the products.

Dextro-glucose made from honey gave mannite when treated in the same way, having exactly the same melting-point as ordinary mannite. In treating milk sugar with dilute sulphuric acid, changing into gallactose and hydrogenizing, dulcite was not isolated; but I have not specially studied the reaction.—*Proceedings of the Royal Society of Edinburgh.*

Introduction of the Ipecacuanha Plant into India.—The Duke of Argyll addressed the Governor-General on the 20th April as follows:—"I have considered the dispatch from your Excellency in Council, dated 25th January, urging upon me the importance of introducing the ipecacuanha plant into India, and suggesting that Dr. Anderson, Superintendent of the Botanical Gardens at Calcutta, now in this country, should be asked to submit proposals as to the best means for obtaining the object in view. On the application of the Government of Bombay last year, I had already recognized the importance of introducing this valuable medicine; and the two plants received at Bombay having died, I had already taken steps for procuring others for transmission in July next. I transmit to you the correspondence which has been held with Dr. Anderson on this subject; and I trust that, even should the other attempts fail, Dr. Anderson will still have a sufficient number of strong plants to take back with him to India to secure the introduction and establishment of the plant. It seemed to me that an application through the diplomatic agents of her Majesty was not likely to be so successful as an application through commercial or scientific gentlemen. You will see from the accompanying memorandum by Mr. C. R. Markham that he has written to Messrs. Miers and Co., of Rio, to Mr. Bramah and to Dr. Otho Wucherer to obtain roots of the plant. The accompanying correspondence with Dr. Cleghorn and Dr. Balfour will show you that I have also enlisted the kind assistance of the Royal Botanical Gardens at Edinburgh besides the aid promised at Kew. I forward also copies of the memorandum on the propagation of the ipecacuanha plant prepared by Mr. M'Nab, of the Royal Botanical Gardens at Edinburgh. Dr. Christison and Dr. Balfour have likewise applied to Dr. Gunning, a medical practitioner at Rio, to assist them in obtaining plants and seeds. I add to these documents the letters which have passed between Dr. Hooker and this office on the supply of plants for Bombay. You will learn from my dispatch to that Government that the plants destined for them will be retained at Kew, and two healthy plants will be sent to them from the Botanical Gardens at Calcutta."—*Allen's Indian Mail.*

Singular Case of Substitution.—A sample which professed to consist of pure chloride of aluminium in crystals was recently supplied by a leading operative chemist in London. On subjecting it to chemical analysis, however, it proved to be common potash alum.

The Invention of Soda-Water is ascribed to Dr. Hawkins, of Philadelphia, a blind chemist, who, in 1812, made the first soda fountain in America,.—*Philadelphia Medical and Surgical Reporter.*

HELP FOR THE WOUNDED.

We have received through Dr. Sieveking the following letter in reference to the suggestion put forward in last week's Journal:—

2, *St. Martin's Place, Trafalgar Square,*
August 24th, 1870.

TO THE EDITOR OF THE PHARMACEUTICAL JOURNAL.

Sir,—On behalf of the Central Committee of the Association for the Sick and Wounded, I beg to thank you for the appeal you have made in your last issue to the pharmaceutists of Great Britain to promote the objects of the Association. I beg to offer you and the pharmaceutists who may respond to your call our warmest thanks for any aid you may afford us.

With the view of rendering this aid as efficacious and practical as possible, I take the liberty of submitting to you the following list of articles which (with the most available forms for immediate use) have been agreed upon by Doctors Sieveking and Pollock, medical members of our Committee, as being more immediately required from the stores at your disposal.

Opium in all forms.

Opium in pills containing 1 grain each, put up in small bottles, 4 dozen pills to each bottle.

Morphia, in pills containing $\frac{1}{4}$-grain each.

Laudanum, in 2 oz. bottles.

Liq. Ammoniæ, in 2 oz. bottles.

Sal volatile, in 8 oz. bottles.

Chloroform, 1 lb. to each bottle.

Quinia, in bulk, and in 2-grain pills, 4 dozen to each bottle.

Hydrate of chloral, in 2 oz. bottles.

Carbolic acid.

Condy's fluid.

Chlorinated lime and soda.

Effervescing salines.

Lint.

Bandages of cotton, linen, or flannel, with the lengths marked on each.

Cotton-wool—sponges—waterproof sheeting—icebags—oil-silk.

It is thought desirable that all medicines should be distinctly labelled, in English and Latin, with the doses, and that each parcel or box should be accompanied by a list of its contents.

Fuller lists of articles required for the wounded soldiers are published by the Society, but I have confined myself in the above enumeration to the articles that would appear to come more immediately under the cognizance of your readers.

Thanking you again for your advocacy of a cause which demands our liveliest sympathies, I have the honour to be, Sir,

Your obedient servant,
ROBERT LOYD LINDSAY,
Lieut.-Col. and Chairman of Committee.

Supply of Sulphate of Quinine to the French Army.—The *intendance militaire* has advertised for estimates for 500 kilogrammes of sulphate of quinine, to be supplied at the rate of 125 kilogrammes a month. This advertisement has suggested various surmises regarding the health of the army, but they are not of sufficient value to repeat. The fact, nevertheless, is worth noticing.—*British Medical Journal.*

Morfit's Hair Dye.—Scald black tea, two ounces, in one gallon of boiling water; strain, and add three ounces of glycerine, tincture of Spanish flies, half an ounce, and bay rum, one quart; digest the mixture for two or three days, and perfume with essence of rose or bergamot, or any other favourite essence to suit the taste.—*Philadelphia Medical and Surgical Reporter.*

The Pharmaceutical Journal.

SATURDAY, AUGUST 27, 1870.

MAJORS AND MEMBERS.

A glance at the Calendar and at the monthly report of the Council's proceedings, shows that whilst the number of candidates for the Major examination is happily increasing, only a few of those who pass take up their membership before commencing business on their own account. At the present time there are, we believe, no fewer than 200 examined Pharmaceutical Chemists, who are not on the list,—nearly one-tenth of the total number of members.

We desire to call attention to this subject, because it still seems not to be generally known that every one who has passed the Major examination is eligible to be elected a member of the Pharmaceutical Society, whether he be in business or not: that it is only necessary to apply to the Secretary, who will in due course present to the Council the names of applicants for election.

Though it is an obvious truism, it cannot be too often reiterated, that the Society's future strength and usefulness are in a great degree dependent upon the young examined men. Their number is now considerable, and the Society cannot afford to wait for the prestige it would derive from the accession of such valuable alumni.

They may be regarded as the highly trained soldiers of Pharmacy who are destined to replace that noble band of volunteers who have manfully held the ground for nearly thirty years, in the confident hope that every successful student would, at the earliest moment, rush eagerly to the front to relieve them.

We constantly need the daily practical experience of educated assistants as well as of employers; they can render material assistance in the endeavour to deal with the difficult subject of storing poisons. Their views would be of special service for determining the most efficient method of spreading professional knowledge throughout the provinces, so that the poorest apprentice might himself pave the way towards passing a creditable examination. Their solicitude in maintaining the high standard of the examinations and the qualifications of examiners, would also be of real service, while at no distant time, some of the more distinguished of them will be required to fill up vacancies in the Board of Examiners; for, independently of technical qualification, the Examiners must be members of the Society. Nor can we omit to mention the privilege of voting, seeing how much our internal welfare and material prosperity depend upon a thoughtful and judicious exercise of the power which it confers. In order not to be misunderstood, let us disclaim the idea that we are pleading for an extra half-guinea subscription. The last balance-sheet proves that the Society is not only free from pecuniary wants, but that it is investing money largely. We desire, and we hope to secure, the *personal* support far more than the money of those who constitute the truly professional element in pharmacy and to whom we now address ourselves.

We do not hesitate to assert that in regard to influence with the public, in regard to the means for developing a system of liberal education for the rising generation of chemists and, in regard to facilities for generally diffusing sound practical science, the capabilities of our Alma Mater are vastly increased by each single educated pharmacist who becomes in every sense a member of the Society.

MR. SIMON ON THE PHARMACY ACT.

The reports of the medical officer of the Privy Council will henceforth be documents which will have an official interest and authoritative value for the members of the pharmaceutical profession. As the Privy Council is the controlling authority in respect to the working of the Pharmacy Act, while the medical officer of the Privy Council is the official adviser of that body in all concerning the interpretation and administration of the Act, we shall have to look to his reports for the indication of the views of the Government, so far as it concerns itself with our body. Perhaps, on the whole, the less it does concern itself with us, at present, the better for the public, for ourselves and for every one. But since the pharmaceutical profession has received considerable privileges as well as a responsible and important monopoly, it will of course, in the future, have to reckon with official supervisors, while hitherto it has been entirely free and unfettered. We may state that it will be found that the twelfth report, which is about to issue, gives an account of the work done by the department up to the beginning of the present year, in respect to the Pharmacy Act. This is described as consisting in the approval of a code of consolidated and amended bye-laws, under which admission is granted to the practice of pharmacy, additions to the schedule of poisons annexed to the Act, and the appointment of a visitor to the examinations of the Pharmaceutical Society on the part of their Lordships.

"It had long," says Mr. Simon, "been a desideratum in Great Britain, as regards the practice of pharmacy, that this skilled commerce—where unskilfulness means very serious danger to the public health—should only be open to persons whose qualifications for practising it safely had been tested by proper examination; and the appended reports appear to me to give ground for much public satisfaction, as showing that the system which the Pharmacy Act of 1868 brought into operation, provides adequate security to that very important effect."

We will next week give further details from this report, the publication of which marks the commencement of an important era in the history of the practice of pharmacy in this country: the era of universal and improved pharmaceutical education, of State recognition, and of the consolidation, as one united body, of the pharmacists of Great Britain.

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

We are glad to find that the suggestion put forward last week, has met with very cordial approval and recognition, not only from Pharmaceutists, but also from the Committee, as will be seen from the letter of the Chairman, inserted in another column. Contributions are already coming in, and our contemporary the *British Medical Journal* in speaking of the appeal as timely and well-placed, expresses the belief that, on this occasion, the numerous members of the trade will respond to it as liberally as they did, on a former occasion, to a private appeal in favour of the Garibaldian volunteers. In the letter already referred to will be found a list of the articles which the medical members of the Committee, Dr. Sieveking and Dr. Pollock, have agreed upon as being more immediately requisite. The mode of labelling and packing to be adopted is also pointed out there. The following is a list of the contributions received or promised up to the time of going to press:—

	£.	s.	d.
"Bestia"	0	5	0
Binge, Thomas, 23, Stockbridge Terrace	0	5	0
Bishop, Alfred, Mile End, N.E.	1	1	0

				3	11	6

John Bell and Co., 338, Oxford Street:—
Two boxes of medicine, to the amount of 25 0 0
containing:—
I. Opium pills, 1 grain each, in bottles containing 4 dozen each.
Morphia pills, ¼ grain each, in bottles.
Quinine pills, 2 grains each, in boxes.
Chloroform, ½ lb. bottles.
Laudanum, in 4 oz. bottles.
Sal volatile, in 4 oz. bottles.
Citro-tartrate of soda, in 4 oz. bottles.
Lint.
II. 50 lb. prepared oakum for surgical purposes.

J. Robbins and Co., 372, Oxford Street, W.:—
7 lb. lint.
12 yards adhesive plaster.
1 dozen bottles styptic colloid.

J. Robinson, Orford Hill, Norwich:—
A quantity of old linen.
1-oz. bottle of citrate of iron and quinia.
1-oz. bottle of sulphate of quinine.

A. P. Towle, Manchester:—
100 1-oz. bottles of chlorodyne.

The *Lancet*, in stating that the Council of the Royal College of Surgeons has determined to remove from the list of its members the name of Edwin Lowe, lately convicted for administering a drug with criminal intent, says,—"We cannot but admire this vigilance on the part of the Council and applaud the result to which it has led. But we would most respectfully inquire whether it might not be possible to carry similar vigilance a step further, and to remove one or two notorious persons from the list before they have graduated in honours at the Old Bailey. When a man is actually undergoing a criminal sentence, it matters little to any one whether he is a Member of the Royal College of Surgeons or not; but a career tending to the former distinction might sometimes be nipped in the bud if the higher officials of the profession were empowered to warn and to punish before A 22 could legitimately interfere."

The idea expressed in this note applies no less to the practice of pharmacy than it does to that of medicine; in both cases a judicious regard to the axiom that "prevention is better than cure" might do much to remove professional abuses, and to do away with trade grievances.

It appears from evidence given before the Commons' Select Committee on the Abyssinian Expedition that at the sale of surplus stores the loss on medicines alone amounted to £35,829.

Provincial Transactions.

BRISTOL PHARMACEUTICAL ASSOCIATION.

A General Meeting of the Association was held on August 12th, 1870, at the Philosophical Institution; Mr. Stoddart, President, in the chair.

After some routine business, the President called the attention of the meeting to the special business of the evening, namely, the presentation of the prizes to their young friends who had been successful in the recent examinations. The Committee, as the meeting was probably aware, had offered a series of prizes, two in each subject upon which they had been able to arrange a course of lectures. These subjects had been inorganic chemistry, organic chemistry, structural botany and systematic botany. Each course had been complete in itself, consisting of about thirty lectures. They were the courses delivered by Mr. Coomber and Mr. Leipner in connection with the Science and Art Department of the Government, and the examinations were those conducted by Dr. Frankland and Dr. Thomson on behalf of the Department. The officials had supplied this Association, at the request of its Honorary Secretary, with a list of its Associates who had been examined, arranged in the order of the merit of their papers. The result, on the whole, had been highly satisfactory. A large amount of industry and steady application had been manifested by some of the students, one particular illustration of which he could not refrain from mentioning. His young friend Mr. Milton lived at a distance of over five miles from Bristol, and he had walked in and out for each lecture, and had missed none. He had thus walked 600 miles for his chemistry alone. He was very glad to find Mr. Milton's name among the prize-winners. He then called upon Mr. Coomber, Professor of Chemistry, to read his report, which was as follows:—

"Gentlemen,—Your students received two courses of lectures from me during the past session, one on inorganic chemistry and a second on organic chemistry. The first course embraced the chemistry of the non-metallic elements, the second the more important classes of organic compounds. Twenty-six students commenced the study of inorganic chemistry, and twelve presented themselves for examination; nine commenced the study of organic chemistry, and eight presented themselves for examination. Of the twelve who offered themselves in inorganic chemistry, four appeared in the first class, seven in the second class, and one failed; of the eight who offered themselves in organic chemistry, four appeared in the first class, three in the second class, and one failed. The attention and persevering industry of those young men who offered themselves for examination cannot be too highly spoken of. There were others equally diligent, whom circumstances, much to their own annoyance, prevented from attending the examination. Still, in most cases, attendance at the examinations may be taken to be a fair test of the assiduity of a student. The attendance in many cases has been very regular; some students have not been absent on a single occasion, and amongst these Mr. Milton deserves to be mentioned, as he walked in to the lectures from a country village five miles distant from Bristol."

The following are the questions that were put at the Examination. The value attached to each question was the same, and three hours were allowed for each paper:—

INORGANIC CHEMISTRY.

Examiner—Professor Frankland, Ph.D., F.R.S.

First or Elementary Stage Examination.

You are only permitted to attempt *eight* questions. You may select these from any part of the paper.

You are requested, whenever possible, to express the reactions in equations.

You are to give such numerical details as will show the mode of calculation.

1. Explain how you would demonstrate experimentally that water is formed by the combustion of hydrogen in air.
2. What is meant by the atomicity or equivalence of an element? Give the atomicity of all the non-tallic elements.
3. What do you understand by the terms "element," "oxide," "metal," and "non-metal"?
4. One litre of nitrogen gas, measured at 0° C., and 760 mm. mercurial pressure, weighs 14 criths; what is the weight in grains of one cubic metre of the same gas measured at the same temperature and pressure?
5. Mention the composition of Ozone, state its properties, and describe how you would prepare it.
6. How would you demonstrate experimentally the composition of water and of air?
7. Classify the following substances into elements and compounds:—

Epsom salts.	Calomel.	Iodine.
Copper.	Nitre.	Lead.
Bronze.	Tin.	Brass.
Chalk.	Graphite.	Diamond.

8. Give the names of the substances denoted by the following chemical formulæ:—

OH_2	HCl	Cl_2
N_2O_5	B_2O_3	HO_3Cl
O_3	SO_2	NH_3

9. Give the symbolic formulæ of the following substances:—

Water.	Ozone.	Sal-ammoniac.
Perchloric acid.	Hydroxyl.	Boric anhydride.
Sulphuric acid.	Carbonic anhydride.	Hypochlorous acid.

10. What is the specific gravity of ammonia, that of hydrogen being taken as unity?
11. How would you show experimentally that hydrochloric acid consists of hydrogen and chlorine?
12. I add two volumes of oxygen to one volume of each of the following gases; what takes place, and what effect will be produced, if an electric spark be afterwards passed through each of the mixtures?—

Chlorine.	Nitric oxide.
Hydrogen.	Carbonic oxide.
Sulphuretted hydrogen.	Carbonic anhydride.
Nitrous oxide.	

ORGANIC CHEMISTRY.

First or Elementary Stage Examination.

You are only permitted to attempt *eight* questions. You may select these from any part of the paper.

Whenever possible, you are to express the reactions in equations.

You are to give such numerical details as will show the mode of calculation.

Atomic weights to be used:—H = 1; O = 16; C = 12.

1. Give the formulæ and percentage composition of formic acid and oxalic acid.
2. Give two distinct and different processes for the preparation of ethylene, showing all chemical changes by equations.
3. What is the empirical formula of a substance which yields the following results on analysis?—

Carbon	20·00
Hydrogen	6·66
Oxygen	26·67
Nitrogen	46·67
	100·00

4. Give the graphic and symbolic formulæ of the following substances:—Prussic acid, acetic acid, alcohol, methyl, and marsh gas.
5. What member of the alcohol family is found amongst

the products of the destructive distillation of wood; how can you extract it in a state of purity from wood naphtha, and what is its graphic formula?
6. How can you detect the presence of nitrogen in an organic substance?
7. You are required to make 1 oz. of lactic acid from milk; how will you do it?
8. Give the name and graphic formula of a member of each of the following families of organic compounds:—Alcohols, aldehydes, ethereal salts, ethers, and haloid ethers.
9. If a mixture of acetate of potash, caustic soda, and quicklime be heated to a temperature somewhat below redness, what gaseous product is obtained? Give its name and formula, and state where it is met with in nature.
10. You have given to you the following materials, and are required to make acetic acid; state exactly what operations you will perform, and explain all chemical changes by equations:—

Ethylic iodide.	Water.
Sodic carbonate.	Potassic chromate.
Quicklime.	Sulphuric acid.

11. If an alkaline solution of potassic cyanide be boiled, what decomposition takes place?
12. If bitter almonds be macerated in warm water, what member of the aldehyde family is produced, and why is this aldehyde not formed when sweet are substituted for bitter almonds?

Mr. Schacht then asked permission, in the absence of their Professor of Botany, who was unfortunately abroad, to say a few words about the botanical classes, which he had himself attended and watched with some care. He said it was certainly to be regretted that the results of the Examinations in this part of their scheme had not been so favourable as in chemistry; and it was clear the interest felt in it had not been so great. The attendance, which, at the commencement of the course, had averaged about twenty at each lecture, dwindled, after a short time to ten or twelve. In the "Structural and Physiological" course, eight only had entered for the Examination, and two only had passed; and in the "Systematic and Economic" course, five only had entered, and two only had passed. In seeking for an explanation of these somewhat unfavourable facts, he was bound to say he could not attribute them in any way to their very excellent teacher, Mr. Leipner, who, on the contrary, had been most assiduous in his work and most anxious to advance his pupils; but he thought they might be, in part at least, due to the difficulties under which both professors and students of botany lay in the winter season, when so few illustrations of the subject can be obtained—a difficulty he would venture to compare to an attempt to lecture upon chemistry without the display of experiments. He might add that the Committee had already discussed the desirability, in their next Session, of making botany a summer course. Truth, however, compelled him to say they all felt some disappointment at the result of this part of their experiment, which, it must not be forgotten, was of quite as much importance in the practice of their profession as chemistry. He hoped next year to witness greater botanical zeal amongst their young friends.

VEGETABLE ANATOMY AND PHYSIOLOGY.

Examiner—T. Thomson, M.D., F.R.S.

First or Elementary Stage Examination.

You are only permitted to answer *six* questions.

1. How does the root differ from the stem in structure and function?
2. What are the appearances presented by a transverse and longitudinal section of the trunk of an oak? Explain the terms sapwood and heartwood. Which of the two is the more durable, and why?
3. What are spiral vessels and ducts? In what part of the plant are they chiefly found? In what plants are they absent?
4. Define the terms anatropous, campylotropous and orthotropous, and name one or two examples of the occurrence of each.
5. Explain the terms hilum, chalaza, raphe, arillus, and give the relative position of these parts (when present) to each other in the three cases named in the preceding question.
6. Describe the process of respiration in plants.
7. Point out the principal differences between exogens and endogens.

SYSTEMATIC AND ECONOMIC BOTANY.

Examiner—T. Thomson, M.D., F.R.S.

First or Elementary Stage Examination.

You are only permitted to answer *seven* questions, two of which must be 8 and 9.

1. In what Natural Orders of British plants is the placentation parietal?
2. Give the characters of the Natural Order *Rosaceæ*, and point out how it differs from *Leguminosæ*.
3. To what Natural Order does the genus *Clematis* belong? What are its characters? State in which of them it agrees with, and in which of them it differs from, the other British genera of the Order.
4. Define the terms raceme, spike, catkin, umbel, capitulum, panicle, corymb, and give an example of each taken from a British plant.
5. What is estivation? Enumerate the different kinds, and give one or more examples of each, taken from British plants.
6. To what Natural Order do the plants yielding tea, coffee, and chocolate belong? What part of the plant is used in each case? Give a sketch of the mode of preparation of each.
7. To what Natural Order do the following useful products belong? What is their use, and what part of the plant yields them? Marsh-mallow, taraxacum, cucumber, hops, tobacco, colchicum.

8, 9. Describe the two plants laid before you, taking their organs (when present) in the following order:—

Stem.	Sepals.	Ovary.
Leaves.	Petals.	Fruit.
Bracts.	Stamens.	Seeds.

The lists furnished by the officers of the Science and Art Department, South Kensington, were then read, and arranged in the order of merit in which the candidates passed their examinations, from which it appeared that the following gentlemen became entitled to the prizes:—

Chemistry.	Botany.
Inorganic.	*Structural and Physiological.*
1. Mr. A. W. Little.	1. Mr. A. W. Little.
2. Mr. W. D. Tamplin.	2. Mr. T. Milton.
Organic.	*Systematic and Economic.*
1. Mr. T. Milton.	1. Mr. A. W. Little.
2. Mr. W. D. Tamplin.	2. Mr. T. Milton.

The Prizes were then presented by the President,—Mr. A. W. Little receiving a microscope, value £3. 3*s.*; Mr. T. Milton a prize of books, value £2. 2*s.*; and Mr. W. D. Tamplin a prize of books, value £1. 1*s.*

LEICESTER CHEMISTS' ASSISTANTS AND APPRENTICES' ASSOCIATION.

The Half-yearly Meeting of the above Association was held at St. George's Rooms, Rutland Street, on Friday, August 5th, 1870; the President, Mr. J. Young, in the chair.

The Treasurer (Mr. E. H. Butler) read his financial report, and explained that the smallness of the balance in hand was accounted for by the fact that several subscriptions due from honorary members had not been collected, in order that their acknowledgment might appear in the balance-sheet of the next half-year, in which session the subscriptions of the majority of the honorary members would become due.

Treasurer's Balance Sheet for the Half Year ending August 5, 1870.

Dr.	£.	s.	d.
To Balance brought forward, February, 1870	1	6	7
„ Annual Subscriptions of 2 Honorary Members at 10*s*. 6*d*.	1	1	0
„ 14 Assistants' Half-yearly Subscriptions at 3*s*.	2	2	0
„ 11 Apprentices' Half-yearly Subscriptions at 2*s*.	1	2	0
„ Allowance off Printing	0	1	3
„ Cash from Library Fund for Hire of Books	0	5	4
„ Ditto for Fines	0	4	3
	£6	2	5

Cr.	£.	s.	d.
Printing Reports and Rules	0	15	0
Printing Lecture Cards, etc.	0	10	0
'British Pharmacopœia'	0	4	6
Chemicals and Apparatus	0	8	2
Incidentals	0	3	0
Rent of St. George's Rooms from January 1 to June 30, 1870	3	15	0
Cash in hand	0	6	9
	£6	2	5

H. Cooper, W. B. Blunt, } *Auditors.*

The President then called upon Mr. W. B. Clark (Honorary Secretary) to read his report, from which it appeared that during the session nine members of the Association (forming more than 35 per cent.) had passed eleven examinations of the Pharmaceutical Society, as follows,—three Minor, two Modified and six Classical or Preliminary examinations. This highly satisfactory result, the Committee think, has not its equal in any similar Association.

Classes have been conducted by the more efficient members of the Association during the session upon chemistry, materia medica, botany, Latin, and arithmetic. Scientific papers have also been read by several gentlemen upon interesting subjects, to whom the best thanks of the Association are due. Forty-eight meetings have been held during the half-year, which have afforded great facilities for the improvement of the members, and have been well attended.

In acknowledgment of the services rendered to the Association by Mr. Edward Atkins, B.Sc., and Mr. R. Weaver, C.E., those gentlemen were elected honorary members.

The following gentlemen were elected as the Committee for the ensuing half-year:—

*Mr. Jos. Young, *President;* *Mr. W. E. Hill, *Vice-President*; Mr. S. H. Cadoux, *Honorary Secretary;* *Mr. E. H. Butler, *Treasurer;* *Mr. W. B. Clark, *Mr. W. B. Blunt, and Mr. E. Green.

The Committee desire to express their thanks to Professor Attfield, Ph.D., and to the Rev. R. Harley, F.R.S., for their kind services in forwarding the respective examination papers for the chemistry and arithmetic classes.

A programme of the arrangements for lectures, classes, etc., from the present time up to February, 1871, has been issued.

* Associates of the Pharmaceutical Society.

Proceedings of Scientific Societies.

GRANT COLLEGE MEDICAL SOCIETY, BOMBAY.

July, 1870.

A New Indian Remedy.

BY MR. NARAYAN DAJI, *Graduate of the Grant Medical College.*

(*Continued from page* 156.)

Medicinal Properties and Uses.—From the Natural Order to which this tree belongs, it may be inferred *à priori* that it would possess the characteristic properties of that Order, and this is found from experiment to be true. The medicinal and physiological properties of this tree resemble so closely those of the officinal *Picræna excelsa*, or Jamaica Quassia-tree, that our Indian plant may safely be considered a substitute for it. As *Ailanthus* bark owes its efficacy to the ailanthic acid contained in it, there is scarcely any difference of action between the two except in the dose.

Physiological Effects of Ailanthic Acid. (a.) *On Vegetables.*—In a strong aqueous solution of the acid the leaves of *Hydrocotyle Asiatica* were immersed, and kept there for about eighteen hours without any appearance of contraction, or other perceptible change in the leaves.

(b.) *On Animals.*—Monads (*infusoria*) developed during the decomposition of hay in water, were placed in a dilute watery solution of the acid and examined under a microscope, when their motion became less active, and they were observed to perform a kind of rotatory motion round themselves. When a stronger solution was added to a drop on the plate, the animalcules became motionless, contracted and died, showing the poisonous influence of the acid.

Common flies avoid touching the acid, even if it is mixed with sugar; but how far it proves poisonous to them is a matter of question. No poisonous effects were perceptible by its internal administration to a hen: nineteen grains of the acid were given in a single dose.

(c.) *On Man.*—In doses of from one to three grains ailanthic acid, when given internally, acts as a tonic and stomachic, exciting the appetite and promoting digestion. When given continually in larger doses (from grs. iii to grs. v two or three times a day) its digestive and alterative action is distinctly marked, especially in cases of torpid states of the digestive function attended with muscular and nervous relaxation and constipation. It increases secretions, especially that of the liver, as indicated by the stools changing their colour to yellow, improves the tone of the muscular and nervous system, and produces a corresponding healthy change in the general system. Although it much resembles the pure bitters, such as gentian or chiretta, yet its action is specially marked by a peculiar stimulation of the digestive and secretory processes. In larger doses (from grs. xv to grs. xxx) it is apt to occasion uneasiness about the stomach, nausea, vertigo, vomiting and purging, but without any distressing symptoms. It does not produce narcotism, its powers being chiefly directed towards the sympathetic system. It does not exhibit antiseptic properties when placed in contact with dead animal or vegetable matter. It does not prevent coagulation of blood.

The dry ailanthate of lead acts as a sternutatory, causing an irritant effect on the mucous lining of the nose.

Therapeutic Uses.—In dyspepsia, anorexia and torpid states of the digestive organs, accompanied with habitual constipation, ailanthic acid has been found very serviceable. It is particularly useful in cases where the indigestion results from a want of tone in the general system, such as occasionally occurs in the convalescence from fevers, and from the frequent use of purgatives. Its beneficial effects in these cases have been more marked than those from the use of other ordinary bitter tonics.

In hæmorrhoids and *prolapsus recti*, it can be advantageously administered in combination with other remedies which are employed with the view of freeing the portal circulation.

In watery diarrhœa, brought on either from errors of diet or changes of temperature, or sedentary habits, and which is characterized by a catarrhal state of the mucous lining of the stomach and bowels, this remedy proves very useful; it arrests the exhalations from the mucous surface, and restores the secreting functions. In the catarrhal diarrhœa of children I have seen remarkably good effects from the use of it. In diarrhœa attendant on inflammatory causes it is found comparatively inefficient.

In cholera, it has been found of considerable benefit, especially when given in the first stage, when it appeared to have considerable power in preventing the disease from passing to its second stage. It has been also observed that it checked vomiting and purging sooner than the ordinary remedies, and to have changed the colour of the stools to yellow without the use of mercurials. It did not, however, prove effectual in severe epidemics.

In intermittent and remittent fevers, it was found to have considerable febrifuge powers; its beneficial action in these cases depended more on its property of restoring and augmenting the checked secretions, than from any sedative effects on the vascular or nervous systems. Its antiperiodic properties are not trustworthy, but are much more marked than those of several other bitters. It proves very useful as an alterative in reducing the congestion of the liver and other organs often met with in these disorders. In fevers complicated with brain symptoms and accompanied with derangement of the stomach and liver, I have often found it very beneficial.

In general debility from various causes, complicated with an atonic state of the digestive organs, it proves a very valuable tonic and alterative, and may be advantageously combined with preparations of iron.

In rheumatism and gout its use was found of considerable benefit by improving the state of the digestive function, a point of great importance in the treatment of these diseases.

In "elephantoid fever," attended with recurring inflammation of the scrotum (varix lymphaticus), and chylous condition of the urine, the continued administration of this remedy has a marked effect in checking the progress of the disease. Its use in this disease is deserving of further trial.

I have not observed any decided anthelmintic properties from the use of it.

Administration, Preparations, and Doses.—*Ailanthus* bark* can be best prescribed in the form of decoction, infusion, extract, or tincture. The following formulæ were used for the different preparations:—

Decoction of Ailanthus Bark.—Take of *Ailanthus* bark bruised, four drachms; distilled water, one pint; boil for ten minutes in a covered vessel, then strain and pour as much distilled water over the contents of the strainer as will make the strained product measure a pint.

Dose.—From one to two fluid ounces twice or thrice daily. It contains ailanthate of lime.

Infusion of Ailanthus Bark.—Take of *Ailanthus* bark, bruised, two drachms; cold water, ten fluid ounces. Infuse in a covered vessel for half an hour and strain.

Dose.—From one to two fluid ounces twice or thrice daily. It is a cleaner preparation than the decoction; often prescribed in dyspepsia.

Tincture of Ailanthus Bark.—Take of *Ailanthus* bark, bruised, one ounce and a half; proof spirit one pint; macerate for seven days in a closed vessel with occasional agitation; then strain, press, filter, and add sufficient spirit to make one pint.

* The bark should always be deprived of its thick epiphlœum before use.

Dose.—From half a drachm to two fluid drachms.

Extract of Ailanthus Bark.—Take of *Ailanthus* bark, bruised, one pound; distilled water a sufficiency. Macerate the bark with eight fluid ounces of the water for twelve hours; then pack in a percolator and adding more of the water, allow the liquor slowly to pass until the bark is exhausted. Evaporate the liquor; filter before it becomes too thick; and again evaporate by water-bath until the extract is of a suitable consistence for forming pills.

Dose.—From three to five grains, either alone or combined with other tonics or alteratives.

History.—The bark of this tree appears to have been in use as a bitter tonic and alterative amongst the natives of India from the earliest periods. The juice of the fresh bark has been regarded by them as a valuable remedy against indigestion and diarrhœa. The juice of the leaves also is occasionally administered by them in bronchitic affections as an emetic. The tree, however, is not known to the generality of natives, nor is its account and identification accurately given in Hindu works on materia medica.*

The native vaidyas (physicians) on this side of India are ignorant of the medicinal virtues of the tree. In Southern India it appears to be more extensively known, for Dr. Ainslie says, "This bark has a pleasant and somewhat aromatic taste, and is prescribed by the native practitioners in infusion, in dyspeptic complaints to the extent of three ounces twice daily." †

In allusion to this Dr. Wight says, "In confirmation of that statement I may add that some time ago specimens of this plant were sent me, as those of a tree, the bark of which is prescribed in the Circars as a powerful febrifuge and tonic in diseases of debility." ‡

Royle, O'Shaughnessy, Piddington, Roxburgh, Drury, and other writers on Indian plants that I know of do not allude to the medicinal virtues of this plant; and Waring reiterates, in the Pharmacopœia of India, the statements already made by Ainslie and Wight.

SOCIETY OF ARTS.§

On Fermentation.

BY PROFESSOR A. W. WILLIAMSON, F.R.S.

Lecture I.

I have sometimes wished, when building castles in the air, that I could, after a few hundred years, come back and see the state of science at that time. I am convinced that those who will look back, from such a period as a few hundred years hence, at the present state of our knowledge of nature, in any one department, will be surprised at its smallness; in fact, even now, when we work at all earnestly at any one part of the field of nature, we cannot refrain from feeling how little is our knowledge compared with our ignorance. But, if that is generally the case, I think it is peculiarly the case in those studies in which life is concerned; and the phenomena of fermentation have that peculiarity that they consist of processes in which vital organisms

* *Aralu* is the Sanskrit name of this tree according to Ainslie (*vide* 'Materia Indica,' vol. ii. p. 302); but on this side of India that name is a synonym of "*Tetú*," or *Calosanthes Indica* (Bignoniaceæ), as appears from several Sanskrit compendiums of medicinal plants and drugs, viz.:—Chúdámani, Dravyaratnákara, Bhávaprakás'a, etc. The properties and uses of *Aralu* there mentioned are applicable more to *Calosanthes Indica* ("Tetú") than to the tree under consideration.

[*Aralu* is also the vernacular name for *Terminalia chebula.* (*Vide* Moon's Cat.)—Ed. Ph. J.]

† Ainslie's 'Materia Indica,' vol. ii. p. 302.

‡ Wight's Ill. Ind. Bot., p. 170.

§ Cantor Lectures.

are concerned, and in which there is every reason to believe that vital organisms, or living beings, take an active and leading part. I need not say that, for that reason, the explanations which we have, even of the simplest and best known of the phenomena of fermentation, are, as yet, mere sketches of the reality. It is, however, not the less useful or the less important to know them for that reason.

When we chemists are classifying substances, we adopt a principle of classification which I think is almost inevitable, but it may be as well that I should mention what it is. We put the simple things together, and the complex or difficult things together, and then we try to put between them, in as regular an order as possible, the intermediate links of the chain by which they can be connected; and I believe that our best—I might almost say our only—explanations consist in thus arranging, in a natural order, the facts which we have to consider, and then viewing them, and stating what we see, in the clearest and least ambiguous terms. Now, the term "organic," as applied to a certain class of chemical substances might be replaced—and I think, for some purposes, ought to be replaced—by the term "complex." The substances which we are in the habit of including under the term organic are peculiarly complex; in fact, they are the most complex with which we have to do. The phenomena of fermentation relate mainly to them, and consist principally of a process of change,—the breaking-up of those organic bodies into rather less complex substances than themselves,—a process of partial analysis. Of course, when I say that, I give what I conceive to be a characteristic idea of the general method, and I must not be supposed to assert that all processes of fermentation are analytical.

Amongst the characteristics which, I think, are particularly useful and interesting, as serving to distinguish organic from inorganic, complex from simple substances, is their different behaviour under heat. I have found it exceedingly interesting and instructive to bear in mind the fact that while simple and inorganic compounds, as we generally call them, are sometimes destroyed and resolved into other compounds by the action of a high temperature, yet many of them are not. Amongst inorganic substances we find some which are broken up or changed by exposure to a high temperature, but there are others which can stand even the highest temperature without undergoing any permanent change, that is to say, they return, on cooling, to the same state in which they were before the heat was applied. With organic substances that is not the case. All organic bodies are broken up into minute particles, and assume new arrangements, when they are heated to a sufficiently high temperature; and that is, I think, a distinction which is of considerable theoretical as well as perhaps of some practical importance.

The processes of breaking up which are effected by heat upon organic bodies are, in the very great majority of cases, different from those which are effected by the action of these wonderful little organisms, the ferments; and it is a peculiarity of the action of the ferments that they effect the breaking up—the analysis—of complex organic substances, and form products which, for the most part, we have obtained from those materials by no other process.

Amongst the processes of fermentation, there is one which, from its pre-eminent importance, and from the fact that we have had occasion to study it more fully than any other, ought to be first mentioned. I allude to the process of fermentation by which alcohol is formed artificially. I may say, indeed, it is the only process by which alcohol is ever made. It is a process which consists in breaking up some kind of sugar, for sugar is a word which, although popularly restricted to one particular substance, which is extracted sometimes from the sugar-cane and sometimes from beet-root, is used by chemists in a more general sense, serving to characterize a family of bodies which have much in common with one another, being for the most part all of them sweet, and containing the same elements, but in slightly different proportions. They all possess many properties which are of some importance. These different kinds of sugar are broken up by the action of ferment into alcohol, and also into another product, carbonic acid gas, which has been long known, and for a long time the process of alcoholic fermentation was supposed to consist simply in a separation of sugar into these two products, alcohol on the one hand and carbonic acid on the other. A more careful examination of the products has shown, however, that these two never appear alone. I believe I may safely say, from the researches of Pasteur and others, that no case of the formation of alcohol by fermentation has been known to occur in which several other products have not been formed simultaneously with these two. With regard to the difference of properties of these two bodies, there are one or two points of some little interest, especially this one, that whereas alcohol is an eminently combustible substance, and is well known to have properties of that kind, being frequently used as fuel, on the other hand, carbonic acid, the other chief product, is completely burnt; it is a substance incapable of undergoing any chemical change whatever analogous to combustion. Alcohol is a substance which I need not show you, although in its pure state it is not very common; but I will, in order to remind those of you who may be less familiar with its leading properties, make a little carbonic acid by a short process. I will put a little muriatic acid upon some white marble, and the apparent ebullition which you see takes place is known to you all as due to the liberation of carbonic acid. You might imagine the thing to be fermenting, only that the process in that case would be less rapid. Now, if I plunge this little burning paper gradually into the jar containing the carbonic acid, it will burn more and more faintly, and get extinguished when it enters the gas; it is totally impossible to set fire to the gas. And there is one other fact that we may notice at the same time—the great specific gravity which characterizes this gas. I will show you that, in this way. I will go through the motion of pouring from this jar containing it into another smaller jar, and no doubt the heavy carbonic acid will pass from the jar in which I first collected it into the lower one, where we shall find it by means of the taper as before. You see that, on lowering the lighted taper into this small jar it is extinguished as it was before. I will show you the test by which we usually discover the presence of carbonic acid. I have here some water containing lime in solution,—some lime-water,—and I will pour it into the large beaker glass, in which there is probably still some carbonic acid left. You see the solution immediately becomes turbid, or, as we express it, a precipitate is formed by the combination of the carbonic acid with the lime-water. A compound is formed, which is nearly insoluble in the water, called carbonate, which goes down as a precipitate.

In addition to alcohol and carbonic acid, I ought to mention another kind of alcohol, which occurs to a considerable extent in some distilleries where raw grain or potato-starch is used. This substance imparts to the product a very unpleasant odour, and some unwholesome qualities. It is known by the name of fousel oil. It does not mix with water, and if I were to pour some of it on water it would float, without dissolving to any considerable extent. There are some other products which are even more interesting and important; two especially I ought to mention. One is the clear substance which you see in this bottle, and which you might imagine to be oil; it is a fluid largely made now, and known by the name of glycerine, but in chemical language I should say that this was an alcohol. It is a substance which, by tasting, you might mistake for sugar, for it possesses a sweet taste, resembling sugar, but, to chemists, it is a kind of alcohol, and its appearance during fermentation together with ordinary alcohol is no doubt due to a process of the normal kind.

Another product which I might compare to the carbonic acid which I just now showed you, is this beautiful crystalline acid substance, which has been long known by the name of succinic acid. It got that name from the fact that it was originally prepared from amber. By subjecting the amber to dry distillation, succinic acid, among other products, is formed. Glycerine and succinic acid, as well as common alcohol and carbonic acid, are always formed when any kind of sugar is made to decompose by the process which is termed alcoholic fermentation; and it is seldom that there are not other —and probably, in smaller quantities, several other— products formed besides those four. In fact, the different kinds of spirit which are obtained by the process of fermentation and subsequent distillation,—I mean those kinds of spirit to which no artificial flavouring material is added (gin is a general name given to certain spirits which are flavoured by artificial means), such as brandy, rum, and others,—owe their distinctive peculiarities to the presence of small quantities of volatile substances which are formed during the process of fermentation, regarding which a good deal has been observed, and several important facts have been collected.

There is another process of fermentation which I must mention, for it is important from its frequent occurrence, and that is a process by which another kind of sugar usually, but sometimes common sugar, is transformed. The substance which most naturally undergoes this fermentation is milk-sugar. These hard lumps in this bottle, which if you were to take out and taste, you would not imagine to be sugar, are made by the crystallization of the solid substance in whey. The whey is evaporated carefully to a small bulk, and this substance which results is known by the name of milk-sugar. When a solution of this is mixed with cheese, which is the best ferment for the purpose, it gradually turns acid. I dare say it is known to all of you that milk itself, which contains this body, and cheese, or rather caseine, dissolved with it, together with the fatty globules of milk, when exposed to the air, turns acid. That acidity is due to a change which takes place in the sugar. The sugar disappears gradually, and is transformed into an acid substance of which I have a little bottle here. It is a strong acid, and here in another bottle are a few of its salts,—a lime salt and a zinc salt, which is a very beautiful and characteristic compound. I shall have occasion hereafter to show you a large bottle which is now at work, in which I dissolved, not this particular kind of sugar, but the ordinary sugar. I put with it a quantity of calcic carbonate, and some old, lean cheese, with a considerable quantity of water. The mixture was kept at a temperature above blood heat for some considerable time, and a compound of lactic acid is being formed. That is a process analogous in its general features to the fermentation which forms alcohol, but it is a change of sugar in which no alcohol is formed. Sometimes there is a trace of alcohol, but there is not necessarily any, and no carbonic acid is formed; but instead of these products, the elements of the sugar break up into different groups, and arrange themselves in another manner. That is really the nature of the process, as far as our most careful experiments have gone, and the acid which we make in that way, which is lactic acid, or acid of milk, is really sugar, of which the elements are arranged in a different way, so as to acquire acid properties.

The third process, which I must mention from its remarkable products, is one which, perhaps, in some respects ought rather to be compared with putrefaction, for it is a process which has many of the most important characteristics of putrefaction. In order to deal with the question of fermentation generally, it is necessary to allude to some varieties of such chemical changes which are usually classed under the term putrefaction. As a general rule, I think the characteristic of processes of putrefaction is mainly the unpleasant nature of the products which are formed. It is not long since a distinguished chemist, in speaking of alcoholic fermentation, said that it is really a putrefactive process; and in its intimate nature it is, as far as we know, a process much like the truly putrefactive processes, and different from the processes of eremocausis or oxidation. This other process to which I allude consists in forming the acid substance which I have here, and which I will not open, because it is not a very pleasant body. It is a substance which is known, although I believe not very commonly, in butter. The peculiar rancid odour which butter acquires when it is kept too long, especially in warm weather, is due to a transformation of some of its materials into this particular acid, which Chevreul, a very distinguished French chemist, separated from butter, and he named it from that circumstance butyric acid. If we leave some of this product of the last fermentation—some of this lactate of lime, the lime salt of lactic acid—under the same conditions in which it was formed, that is, if we leave it in the same vessel in which it had been formed from the milk or sugar, and leave cheese with it, and keep the mixture warm, the lactate will gradually decompose, and carbonic acid will be given off together with hydrogen gas, and at the same time we find that the lactic acid will be decomposed. and in place of it we get this butyric acid, and generally some valerianic acid and a little acetic acid.

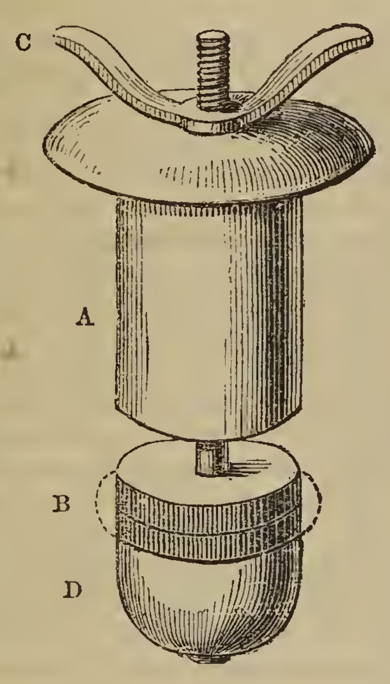
Amongst the processes which really are analogous to fermentation in their nature, but which differ in one particular, I must mention one other, the process of forming vinegar, or acetic acid. This large bottle contains vinegar in a form which most of you, I dare say, have not seen. These fine white crystals are the pure substance which, mixed with water in an impure state, are generally known by the trivial name of vinegar. We call that acetic acid, or hydric acetate. The formation of this body from alcohol represents a variety of fermentation which is of considerable importance and of frequent occurrence. Everybody who has noticed the process which takes place when animal or vegetable matter is left to itself in contact with air, especially in moist localities, must have observed that there is a gradual disappearance of the organic matter. For instance, if you leave a piece of wood in a moist place, under certain conditions of very frequent occurrence which are favourable to this process, the wood gradually gets soft, and becomes transformed into a brown substance, and if you leave it long enough—in this country, several years generally would be needed for this purpose—it gradually disappears. If you were to put a piece of that decomposing wood into a closed glass vessel, and examine the air above it, you would find that the wood was really burning. I am using the word combustion in the ordinary chemical sense—I mean by that word that the oxygen of the air which you have enclosed with the wood is being taken up by the wood, and the products of combustion, carbonic acid and water, are being formed from the substance of the wood. One great class of the processes of fermentation is of that kind. They consist not in a mere breaking up of the materials already contained in the organic substance, but a change of their arrangements, which is due, more or less, to the absorption of oxygen, and this formation of acetic acid or vinegar is a case of that kind. In fact, if we were to leave some ordinary fermented wort in an open vessel, so that the alcohol were left there in the mixture in which it had been formed, we should find that the alcohol would gradually disappear and give place to an acid substance. The process is well known to wine-makers and to brewers, and their art consists, amongst other things, in the avoidance of this process of the oxidation of their alcohol.

While the acetic acid is being formed, oxygen from the air is taken up, and in that respect this process of acetic fermentation differs from the other three processes of fermentation which I have described. When you make alcohol and carbonic acid from sugar, the air takes no part in the process; when you make lactic acid from the sugar, the air is not wanted; and when you make butyric acid from lactic acid, then again the air may be completely excluded and the process will go on without it. But when you make acetic acid from alcohol, you must of necessity allow the free and continuous access of air, and the air gives up some of its oxygen to this fermenting alcohol, to transform it into acetic acid and water by a true process of fermentation.

(*To be continued.*)

CORK FOR POISON BOTTLES.

The accompanying drawing represents a very ingenious contrivance, which has also the merit of being simple. The wooden stopper A has a pin passing through it, one end of the pin being fixed to the plug D, while the other is screwed, so that, by means of the winged fitting C, the stopper A can be forced downwards until it compresses the caoutchouc rings B, making them bulge out laterally (as shown by the dotted lines) and press against the neck, so that the cork cannot be removed until the winged fitting C has been screwed upwards to relieve the pressure.



Lead in Tinfoil.—Tinfoil very rarely indeed consists of pure tin; generally it contains more or less lead. According to the resent analysis of August Vogel, who has examined a great number of samples from very different sources, it contains from one to nineteen per cent. of lead. There are, however, specimens of tinfoil which contain so little lead that it hardly gives a reaction with the appropriate tests. Since tinfoil is so much used for covering articles of diet or of confectionery or of perfumery, it was a matter of some degree of interest to determine whether or not there was any danger of transference of lead from the wrapper to the contents. A number of experiments on soap, chocolate and different kinds of dry sugar, which had been enveloped in tinfoil very highly charged with lead, showed that there was no contamination with lead. Cheese, on the other hand, on account of its being moist and being closely in contact with the foil, did take up lead. Of course the lactic acid of cheese would also favour the taking up of the metal. A point worthy of being recorded in connection with this matter, is the rapid diminution of the lead towards the centre of the cheese. Often plenty of lead was found in the rind and none a little way in the cheese.—*Repertorium für Pharmacie, von Buchner.*

Capsicine.—The fruit of the *Capsicum annuum* contains an alkaloid analogous to conia. The peculiar smell of this alkaloid is recognizable when extract of capsicum is warmed with potash.—*Répertoire de Pharmacie.*

The Chinese in America.—Lum Ling Wau, a native Chinese physician, proposes to settle in New York, and enter upon the practice of his profession. He brings with him his wife; an interpreter, Lu Sing; two Chinese apothecaries, Ah Mok and Ah Sam, and an endless assortment of drugs and medicines.—*Philadelphia Medical and Surgical Reporter.*

BOOK RECEIVED.

THE DUBLIN QUARTERLY JOURNAL OF MEDICAL SCIENCE. No. XCIX. Dublin: Fannin and Co.

We are indebted to correspondents for the following periodicals, containing news' reports, and other matters of pharmaceutical interest:—The 'British Medical Journal,' Aug. 20; 'Nature,' Aug. 18; the 'Chemical News,' Aug. 19; the 'English Mechanic,' Aug. 19; the 'Grocer,' Aug. 20; the 'Chemist and Druggist,' Aug. 15; the 'Chemists and Druggists' Advocate,' Aug. 20; the 'Medical Press,' Aug. 24; 'Gazette Médicale d'Orient,' for June:—from the respective publishers; 'Correspondence with the Board of Trade from Mr. F. H. Breidenbach.'

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

PROFESSOR REDWOOD'S ANNUITY.

Sir,—I am very sorry to find, from the report of the last Council Meeting, that some objection has been made to the annuity granted by the Council of the Pharmaceutical Society to Dr. Redwood. In addition to the annuity, allow me to suggest that a fund be raised to secure to the worthy Professor one hundred pounds per annum, as a mark of respect for his arduous labours in the advancement of pharmacy, and his unwearied interest in the welfare of Pharmaceutical students.

I am respectfully yours,
H. J. HALLIDAY.

Manchester, August 16, 1870.

Sir,—I think the thanks of the whole members of our Society are due to those gentlemen, especially Mr. Woolley, who so strongly, but unavailingly, resisted the motion for an annuity to Mr. Redwood; not that I for one moment wish it to be thought I undervalue the great service and ornament he has been to us all, but this I do think, that it is not just to his fellow-editors for him to be singled out for so signal a mark. Besides I should very much like to know what is the reason of his having been so singled out; perhaps some of those who voted our money away can tell us. If for long services, are there not many men on the Board who have worked as hard and long for the cause? We shall perhaps be called upon to allow them an annuity.

I hope I shall be acquitted of any feeling in the matter other than that of seeing one man, however worthy, picked out of others quite as worthy, and who, if one deserve it, all deserve it.

I am, Sir, yours obediently,
PHARMACEUTIST.

SALE OF DRUGS BY GROCERS.

Sir,—In reference to the remarks from Correspondents in your Journal respecting the sale of drugs by grocers, allow me to offer two suggestions that appear to me likely to go far to lessen the evil.

1st. Let all the chemists of a town or district meet, say one evening in each month, and in a friendly spirit talk over trade matters.

2nd. Let no chemist sell to a grocer any drug at less than the fair retail price. I know an instance of a chemist selling to a grocer 20 oz. syrup of rhubarb for 1*s.* to sell again. As a rule grocers obtain their drugs, in the first instance, from retail chemists, therefore it appears to me we have the remedy in our own hands.

Yours truly,
CHEAP AND NASTY.

Trade Grievances.

Sir,—As a medical man I can thoroughly sympathize with A Country M. P. S. There is no doubt medicine and pharmacy ought both to be elevated into professions instead of presenting the mongrel combinations that exist at present. To do this, the Councils presiding over both callings should be representative in character and executive in action, independent, but at the same time harmonious in combined operations for the welfare of both professions. As we have good models abroad, it ought not to be difficult for our Legislature to arrive at correct conclusions, based on the sound principle of division of labour.

At present our Society of Apothecaries urges a noble and liberal profession to the veriest drug selling, and the chemists in self-defence have to assume a position for which they do not pretend to be qualified, in prescribing for all manner of ailments, at the same time that the greater part have to descend to the meanest trades in order to obtain a livelihood, —at once blasting the noblest aspirations of what should be a body of highly educated, scientific, professional men. As for practical difficulties, I can speak for myself, having practised as what is commonly called a general practitioner for years in more than one neighbourhood, and have always found it an advantage to myself and to my patients to leave my dispensing in the hands of those qualified for the purpose. If the principle is sound, an increased area of operations presents no insuperable difficulties; what is wanted is pressure from above, from those authorized to exercise it; let us therefore individually and collectively agitate for this consummation.

I am, Sir, yours, etc.,

Birmingham. PERCY LESLIE, M.D.

Poison Corks.

Sir,—Many suggestions and various contrivances have been made for the better securing the stoppers of bottles containing preparations of a dangerous character, but I am not aware of any invention yet which has met with such favour as to be adopted by the trade generally. Convinced of the necessity for some precaution, I beg to submit to you a cork which has come to my notice, patented by a Mr. Flemings, of Oxford Street, and which merits some attention, as it can be made to fit any sized bottle, and by its construction would bring any wandering mind to a sense of danger.

I am, Sir, yours obediently,

J. WADE.

*** A drawing of this cork will be found at p. 179.

Pharmaceutical Titles.

Sir,—Your correspondent of last week has, I am sure, the thanks of all those who, like himself, aspire to the Major, and also of those who have attained it, as he clearly points out the justice of allowing those who have passed the Major Examination the title of Fellow, so that others than those connected with the business may comprehend the value of titles so nearly alike, which the majority of people now consider synonymous.

Hoping that the Council will attend to this matter, and, out of simple justice to all, make the title superior, in the proportion that the Major Examination is to the Modified,

I am, Sir, yours obediently,

T. C.

"Rule of Thumb."

Sir,—The question is, which is the most accurate method of dispensing one grain calomel powders, that of weighing each separately, or of weighing a given number, say six, and dividing them by the eye.

If scales were always used delicate enough to turn to the twentieth of a grain, as our first-class dispensers keep them, and if our grain-weights were all of standard quality, it would doubtless be better to weigh each grain separately, at least for inexperienced hands. But I venture to think, in many country districts dispensing scales are not kept up to this high standard of efficiency; the bearings may not be perfectly clean, they may be cleaned and adjusted by unskilful persons. Thus there may be scales used in dispensing that would not turn well even to a quarter of a grain. I used, when in business, to clean my own and test them myself every day. Moreover, when I used to test grain-weights purchased from the makers by a standard set, I frequently found they varied considerably, and had to be adjusted before they could be relied on. Now, by weighing the larger quantity, these possible inaccuracies are reduced to the minimum. If six grains be weighed and vary one quarter of a grain, that variation is divided by six when the powders are carefully divided by the eye, and in the course of the six doses the total taken does not exceed that prescribed by more than the excess which might have accrued on each powder by separate weighing; for since the powder turns or balances the scale, the presumption is in favour of excess rather than of diminution, which excess again would be slightly reduced by the paper, unless glazed paper were used.

Those who are accustomed to use the eye in dividing such powders would probably do so with greater accuracy than by ordinary scales; and in dispensing parts of a grain, such as half, third, or a quarter, I should prefer weighing one grain accurately and dividing, to weighing the fraction itself.

Yours truly,

Plymouth. F. P. BALKWILL, M.P.S.

B. A. (Easingwold).—A very good book for the purpose required is 'How Crops Grow,' lately published by Messrs. Macmillan and Co.

T. M. (Kirkintilloch) will find an answer to his question in the April number (second series), p. 664.

X. Y. (Maidstone).—The preparations are very similar, chloric ether, however, being very variable in strength, and generally weaker than the sp. chloroformi of the B. P.

Messrs. Domeier and Co. (Basinghall Street) have forwarded, on behalf of the German Hospital Committees for the relief of the wounded soldiers of both nations, a circular soliciting donations of "money, carbolic acid (pure and impure), Condy's fluid, permanganate of potash (in substance), quinine, morphia, water-cushions, lint, sticking-plaster," etc.

"Rhatany" (Bristol).—Iron alum is a salt in which peroxide of iron takes the place of alumina in common alum. For the mode of preparation see Watts's Dictionary, vol. iv. p. 596, or any systematic work on chemistry.

T. S. Minett (East Grinstead).—Our correspondent's inquiry in reference to Mr. Schacht's letter shall receive attention.

G. A. (Maidenhead).—No examination is required. Candidates for admission into the Society are proposed according to a form of recommendation, which may be obtained from the Secretaries. The recommendation must be signed by five Fellows, to three at least of whom the candidate must be personally known; and this certificate is read and suspended in the Society's rooms for three ordinary meetings before proceeding the election by ballot.

Inquirer (St. Andrew's).—Probably you will find the information you require in Ure's 'Dictionary of the Arts,' under "Calico Printing."

Mr. Trilfield (Liverpool).—We have received a plan of the arrangement of bottles in his shop.

W. Robinson (Reading).—The guinea retained from the fee of a candidate who fails to pass the examination is forfeited. He must pay the full fee if he presents himself again.

T. H.—Petroleum Act.—The Bill introduced in the House of Lords this Session, for amending the Petroleum Acts, has not passed into law. It was on the 4th instant read a third time and discharged.

ERRATA.—In the list of exhibitors at Newcastle, p. 154,—*for* Krohne and Suzeman *read* Krohne and Sesemann; *for* Mayer and Mottyer *read* Mayer and Meltzer. Page 145, line 26 from top, *for* clearer *read* denser.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to ELIAS BREMRIDGE, *Secretary, 17, Bloomsbury Square, W.C.*

The General Index to the first Fifteen volumes of this Journal may be obtained of the Secretary, 17, Bloomsbury Square, price 2*s.* 8*d.*, post free; bound in cloth, lettered, 3*s.* 8*d.*, post free.

The General Index to the Vols. XVI.–XVIII., Old Series, and Vols. I.–IX., Second Series, may also be obtained of the Secretary, price 3*s.* 3*d.*, post free.

MEDICINAL FERNS.

BY M. C. COOKE.

Ferns have been rather extensively employed in medicine, and some of them have acquired considerable reputation; but it is doubtful whether, with two or three exceptions, they are of any real value. Some are probably inert, others only possess properties which are more highly developed in other substances. On the whole, ferns are by no means important remedial agents, and their enumeration is more matter of curiosity than suggestive of value. The present list, though long, is probably imperfect, at least it contains the most important and popular species.

ACROSTICHUM HUACSARO, *Ruiz.* The rhizome of this species is employed in Peru as "Middling Calaguala," "Cordoncillo" or "Huacsaro." It is substituted for the genuine "Calaguala."

ADIANTUM ÆTHIOPICUM, *Linn.* This is a Cape species. An infusion is sometimes used as an emollient in coughs and diseases of the chest. A syrup is also prepared from it. The Basuto Kafirs, who call it "Ma-o-ru-metsoo," employ its caudex in the shape of decoction for promoting parturition.

ADIANTUM CAUDATUM, *Linn.* An infusion is employed in the Mauritius as a diaphoretic and instead of tea. In some parts of India it forms a portion of the "Hunsraj" of the bazaars, which is used as an astringent and aromatic.

ADIANTUM CONCINNUM, *Kth.* "Culantrillo," or "Jarabe de Culantrillo," is much used in the Caraccas in pectoral diseases, and said to purify the blood. Six ounces of the fronds are macerated in a gallon of hot water for twenty-four hours, then evaporated to a proper consistence and filtered.

ADIANTUM FRAGILE, *Sw.* Named by Lunan as medicinal. Browne says all the species of *Adiantum* are light subastringent vulneraries, and may be administered with great propriety in all relaxations and weaknesses of the fibres, in prurient consumptions and in the ulcerated or relaxed state of the glands, especially those of the breast, as well as in most cutaneous diseases.—*Lunan, Hort. Jam.* i. p. 475.

ADIANTUM LUNULATUM, *Spr.* The "Hunsraj," or "Mobarkha," of the Hindoos has been referred to this species. It is employed in India for similar purposes to the Maiden-hair of Europe, which latter is known under the name of "Gool-i-mairam." Several other species are either mixed with this or substituted for it under the same vulgar name.

ADIANTUM PEDATUM, *Linn.* "Canadian Maiden-hair." This is said to be the most esteemed sort of Maiden-hair, being more aromatic than the European Maiden-hair. It was formerly more employed than at present as a pectoral in chronic catarrhs. Many imaginary virtues have been ascribed to this as well as other ferns.

ADIANTUM TRAPEZIFORME, *Linn.* "Mexican Maiden-hair." One of the numerous species which have been employed for virtues which they were supposed to possess in common with the true Maiden-hair of Europe. It is probably of little or no value.

ADIANTUM VENUSTUM, *Don.* This is another fern said to yield a portion of the "Hunsraj" of Indian bazaars. Considered astringent and aromatic, also emetic in large doses, besides which it is said to be tonic and febrifuge. Employed in Lahore, Kashmir, etc.

ADIANTUM VILLOSUM, *Linn.* One of the species mentioned by Lunan. Piso is said to have recommended it for expectorating tough phlegm.—*Lunan, Hort. Jam.* i. p. 474.

ASPIDIUM CORIACEUM, *Sw.* Bouton states in his 'Medicinal Plants of the Mauritius,' that a decoction of this fern is employed in the treatment of tambave; a few cups of this are given during the day, and the residuum left after the decoction is used as a lotion for bathing the neck, breast and back of the patient at intervals.

ASPLENIUM ADIANTUM-NIGRUM, *Linn.* "Black Spleenwort." The medicinal properties of this fern have been extolled by various old authors, but its use is unknown in modern practice. Ray sums up a catalogue of diseases in which it is supposed to be beneficial.

ASPLENIUM NIDUS, *Linn.* The tender fronds of this species are cut into pieces in the Mauritius and form a decoction which is said to be an excellent depurative. The rhizome is also boiled for coughs. Boughton thinks that this is the *Ceterach* mentioned by Dr. Chapotin as employed in Madagascar.

ASPLENIUM RADIATUM, *Sw.* According to Dr. Birdwood, the "Mor-punkhee" of the Hindoos belongs to this species. It is employed locally in medicine, but its virtues are not specially recorded by him.

ASPLENIUM RUTA-MURARIA, *Linn.* "Wall Rue." Lightfoot says that this fern was at one time sold as an expectorant and deobstruent. It was one of the species employed as a substitute for Maiden-hair.

ASPLENIUM TRICHOMANES, *Linn.* According to Lightfoot, this fern was formerly used as an expectorant by the peasantry of Scotland. This is another of the many substitutes for the true Maiden-hair, now fallen into disrepute. Is the "Myle conday" of the Tamils.

ATHYRIUM FILIX-FEMINA, *Bernh.* The rhizome of this fern has been used as a substitute for that of the Male-fern, and the same virtues as an anthelmintic have been ascribed to it. It is now generally admitted, however, that these virtues were more supposititious than real, and it has ceased to be employed.

BALANTIUM CHRYSOTRICHUM, *Hassk.* Affords the "Pakoe kidang" of Java. The hairs are thicker, long and less soft and silky than those of the "Penawar Jambie" of Sumatra, but are similarly employed. Some of these fern products, consisting of shining brown hairs, have been imported into this country, but never came into use. See notice by Mr. Hanbury in PHARMACEUTICAL JOURNAL for November, 1856.

BLECHNUM BOREALE, *Sw.* "Hard Fern." The rhizome had formerly the reputation of being aperient and diuretic, but has long since ceased to be employed. Its virtues were doubtless imaginary.

BOTRYCHIUM CICUTARIUM, *Sw.* Is fancied by the inhabitants of St. Domingo to be an alexipharmic.

BOTRYCHIUM LUNARIA, *Sw.* "Moonwort." Magical properties have been assigned to this fern. Gerarde says, "It is singular to heale green and fresh wounds. It hath been used among the alchymists and witches to doe wonders withall, who say that it will loose lockes, and make them to fall from the feet of horses that grase where it doth grow, and hath been called of them 'Martagon,' whereas in truth they are all but drowsie dreams and illusions; but it is singular for wounds as aforesaid." Ray commends its virtues in dysentery.

(*To be continued.*)

THE SOURCE OF MUSCULAR POWER.

BY BARON LIEBIG.

The adherents of the doctrine that muscular power is generated by combustion of non-nitrogenous material in the muscles do not deny that the facts already stated have been established by experience, but they explain them in a different manner.

That doctrine is, in part, based upon some facts which Fick and Wislicenus have established by their investigation into the source of muscular force; they found that during the performance of measurable external work, viz. the lifting of their bodies to a certain height, the quantity of urea (or rather of nitrogen) secreted meanwhile and within five hours following, corresponded to a quantity of albumen which would have barely accounted for one-third of the work, supposing the albumen to have been burnt and the heat generated expressed in terms of work. The nitrogen in the fæces was not estimated. During the experiment only non-nitrogenous food was consumed.

The inference drawn from this observation was that the source of muscular power cannot be sought in the metamorphosis of muscular substance and its combustion; but that it must be generated by the transformation of non-nitrogenous constituents of food into oxygen compounds in the muscles.

The calculation made by Fick and Wislicenus seems to be based on the idea that the production of force in muscles is analogous to the case of a gun; it is conceivable that from the volume of the gas formed by combustion of the powder, the projectile force of the bullet might be calculated; or that, from the distance traversed by the bullet, the volume of the gas might be calculated. If the process of force-production were similar to the combustion of gunpowder, then, under the assumption that the force was generated by combustion of muscular substance and that urea was a product of the change, the quantity of urea would in fact be proportionate to the work done; always presupposing that force and urea were produced at the same moment. If in this case, the quantity of urea secreted did not correspond to the work done, it would follow that, if the work were determined by combustion, other and indeed non-nitrogenous materials had taken the place of muscular substance, and combined with oxygen.

However, it cannot be assumed that non-nitrogenous food can furnish any special condition for the production of force, since it may be regarded as certain that two powerful men could have reached the Faulhorn inn without greater exhaustion even if they had not taken any food and if they had drunk only water instead of wine. In regard to the inference itself, this has evidently no special importance; for if they had not eaten any non-nitrogenous food, it might have been assumed that the fat of their bodies had been consumed in the place of such food.

It does not appear to have been ascertained what the experimenters had lost in bodily weight after the experiment. Their conclusions would, of course, be correct only if the assumptions on which they are founded were true. But the case may have been very different.

It may be that the machine which we call organism possesses a much more perfect arrangement than is supposed according to the assumption of Fick and Wislicenus, perhaps one as perfect as a clock, which we are able to provide with force daily by winding it up, just as we provide the body with food every day, or which may be arranged so that in consequence of an accumulation of force, it will work for several days without any further supply of force. For maintaining the action of such a machine it is in both cases necessary, after the lapse of a certain time, to renew the supply of the force that has been expended in producing motion; but once fully wound up, no further supply is necessary within certain limits. Whatever force is expended, within a given time, over and above the supply, must, of course, be made up for after that time by an increased supply, if the original condition is to be restored.

Moreover, it may be that urea is not a product of the combustion of nitrogenous muscular material, and that its formation bears a relation to muscular work totally different from what Fick and Wislicenus have assumed.

From their memoir it is not quite clear how they regard the conversion of heat, generated by combustion of non-nitrogenous material in muscle, into mechanical effect as taking place. Frankland, who has adopted their view, expresses himself very definitely as follows:—

"The combustible food and oxygen coexist in the blood which courses through the muscle; but when the muscle is at rest, there is no chemical action between them. A command is sent from the brain to the muscle, the nervous agent determines oxidation. The potential energy becomes actual energy, one portion assuming the form of motion, another appearing as heat. *Here is the source of animal heat, here the origin of muscular power!* Like the piston and cylinder of a steam-engine, the muscle itself is only a machine for the transformation of heat into motion; both are subject to wear and tear, and require renewal; but neither contributes in any important degree, by its own oxidation, to the actual production of the mechanical power which it exerts."*

This passage represents the process of force production according to the view of Frankland and others who agree with him.

Here urea and uric acid are regarded as the products of the muscle used up.

If this view were correct, it would follow that the muscular machine is one of the most imperfect machines known, considering how large the daily waste in the shape of secreted urea would be. The fire-bars of a steam-engine furnace are not so rapidly used up.

Certainly the wonderful construction of the animal body and its parts will remain long, and perhaps for ever, an insoluble problem; but the processes taking place in its organs are of a physical or chemical nature, and it is unintelligible that oxygen and the combustible materials of the blood should require a command from the central organ in order to enter into combination. The share taken by the voluntary motor nerves in muscular activity must be of a totally different nature.

However, it appears to me unnecessary to submit the views of Frankland, Fick and Wislicenus to closer criticism; for I believe that, on the whole, those who have occupied themselves with the inquiry into the origin of muscular power have formed too easy an estimate of the problem, and that many years will elapse before it is possible to arrive at any definite conclusion as to what is really the nature of the question to be considered.

* *Phil. Mag.* 4th series, vol. xxxii. p. 194.

It is not my intention to enter into controversy, and I shall consider my object attained if the following remarks should contribute something towards throwing light upon the conditions that have to be ascertained in regard to this question.

Scientific men are tolerably clear in their views as to the mode in which oxygen operates in the animal body: oxygen combines with the elements of the food or of the body, carbonic acid, water and urea being regarded as the ultimate products of the combustion. In consequence of that combustion heat is produced, which warms the body and maintains its temperature, or becomes sensible in the form of mechanical effect.

If the heat of combustion proper to the various kinds of food be known, it would express for each, in some sort, its value as a source of power.

"From this point of view," says Frankland, "it is interesting to examine the various articles of food in common use, as to their capabilities for the production of muscular power," and by the determination of the heat of combustion proper to each, he arrives at the result that, for equal weights of food materials in the natural condition, Cheshire cheese represents three times as much force, expressed in food-pounds, as lean oxflesh; sugar two and a half times as much; and butter five times as much.

Here it is throughout assumed that muscular power is generated by the combustion of these materials in the muscles, and that the process of combustion is like that taking place under the boiler of a steam-engine. In this respect, we find two parts by weight of dry potatoes put down as equal to one and a half parts of dry flesh and to two parts of boiled ham (dry), etc. These are certainly most interesting results; in any case they are very unexpected results of the theory.

This is, perhaps, the place to call to mind that the combination of combustible elements of the animal body with oxygen is a process of a totally different nature from the ordinary process of combustion. Carbonic acid is never produced in the animal body by the combination of oxygen with carbon; it is not a product of combustion in the ordinary sense of that term.*

In order to comprehend correctly the difference between the process of combustion under a steam-boiler and that in the animal body, it is necessary to consider how the formation of organic compounds in plants takes place. These compounds are all formed out of carbonic acid; they represent carbonic acid atoms that have been more or less altered. In the animal body those compounds are again converted into carbonic acid, or into what they originally were.

In the formation of these compounds under the influence of sunlight, there is an absorption of heat or sun force. This becomes latent, and in the reconversion of those compounds into carbonic acid that heat is again liberated. This liberation of heat is at the maximum when the reconversion of the compounds into carbonic acid corresponds exactly to their formation.

For example, comparing carbonic acid with sugar in their most simple empirical formulæ, we have—

$\mathrm{C}^{\mathrm{O}}_{\mathrm{O}}$	$\mathrm{C}^{\mathrm{H}}_{\mathrm{O}}$
Carbonic acid.	Grape sugar.

A glance at both formulæ shows that sugar is, in fact, carbonic acid in which one equivalent of oxygen has been replaced by hydrogen. Carbonic acid is not decomposed in the formation of sugar, but it is only altered by the exchange of one of its constituents for something else.

In the conversion of sugar into carbonic acid, it is not the carbon of the sugar that is burnt, but the hydrogen that had been introduced by substitution into the carbonic acid. When this hydrogen combines with oxygen in the animal body and forms water, its place is again taken by oxygen which had been eliminated from the plant. Consequently, sugar can be burnt in two ways and converted into carbonic acid,—either directly, by combination with oxygen at a high temperature, or indirectly, by the replacement of its hydrogen by oxygen at a moderate temperature. The proportion of oxygen is, in both cases, the same,—sixteen parts by weight for every fifteen parts of sugar; but if there be inequality in the work of combustion, by which heat is expended, the heat liberated must also be unequal.

I will continue the exposition of this case, though without assigning any weight to the accuracy of it; my object is merely to show the difference which it is the business of the physicist to elucidate more completely.

If we suppose that, with the above-mentioned formula for grape-sugar, 6 grams of the carbon in 15 grams of sugar combine with oxygen directly, then there would be 6×7838 units of heat developed. But if we suppose that 1 gram of hydrogen were oxidized by 8 grams of oxygen, and that the 8 grams of oxygen introduced were to generate with the rest of the carbonic acid=14 grams carbonic oxide, just as much heat as in its combination with carbonic oxide, we should then have,—

In the first case	47,000 units of heat*	
,, other ,,	68,900 ,, ,,	
Therefore in the latter	21,900 ,, ,,	more.

It may be shown by undoubted facts that differences of this kind do really occur in the quantities of heat generated by combustion.

Frankland determined among other things the heat of combustion of cane-sugar, and found that 1 gram gave 3348 units of heat. Hence it follows that 171 grams of cane-sugar (1 atom) would give 572,508 units.

In fermentation there are produced from sugar carbonic acid and alcohol, and, if no other products were formed, 92 grams of alcohol should be obtained from 171 grams of sugar; in reality, only 88 or 89 grams are obtained,—let us say $88\frac{1}{2}$; the deficiency is succinic acid and glycerine, etc.

According to numerous determinations by exact observers,—Dulong, Despretz and Favre,—1 gram of alcohol yields as the mean 6981 units of heat, and $88\frac{1}{2}$ grams would give 617,818 units.

Consequently, alcohol itself gives, when burnt, 45,310 units of heat more than the corresponding quantity of sugar by the decomposition of which it has been formed. To this must be added the heat generated in the fermentation of sugar; according to the direct determination of Dubrunfaut, this amounts to one-eighth of the heat that would be generated by combustion of the carbon contained in

* See "The Chemical Process of Respiration," *Ann. Chem. Pharm.* lviii. 335.

	Heat units.
* By combustion of the hydrogen	34,533
By combination of 14 grams carbonic oxide with 8 grams oxygen	34,384
Total	68,917

the carbonic acid evolved in fermentation. Consequently,—

	Units of heat.
The alcohol from 171 grm. sugar gives	617,818
171 grams sugar give in fermentation	22,743
Total	640,561
According to Frankland's determination, however,—171 grams of sugar give	572,508
Or less by	68,053

Without taking into account the combustion of other products of fermentation, which would have given from 8000 to 10,000 units of heat, sugar gives nearly one-eighth more heat than Frankland's calculation indicates, when it is burnt otherwise than in the direct way; if we suppose alcohol to be oxidized at a low temperature, first to aldehyde, then to acetic acid, formic acid and lastly to carbonic acid, it is possible that other numerical results might be obtained for its heat of combustion.

In the determination of heat of combustion much depends on the work done in combustion; if part of the heat be expended in overcoming resistances, that part does not appear as sensible heat.

The simple difference of density in the diamond makes the form of carbon less combustible than charcoal, and it gives rise to a difference in the heat of combustion. The calorific power of diamond is less than that of charcoal by 285 units of heat.* This fact is accounted for by the assumption that the diamond in crystallizing has lost heat, which again becomes latent in combustion; moreover, since cohesion is a resistance to be overcome in the combination of carbon with oxygen, another portion of the heat generated is expended in overcoming that resistance, therefore less heat becomes sensible.

The determinations of the heat of combustion for various kinds of food materials by Frankland are certainly applicable for estimating the value those materials would have as fuel for generating steam; but I am of opinion that his numbers have no special significance as expressing the calorific power of food materials in the living body.

This is more especially the case in regard to the determinations of the heat of combustion of nitrogenous constituents of the body, or the albuminates in articles of food, and in regard to the inferences Frankland has drawn from those determinations as to the value of albuminates as a source of power.

These materials are not combustible in the ordinary sense of the term, neither are they burnt in the animal body any more than sugar as such is burnt; in regard to combustibility and their power of combining with oxygen, they are among organic substances analogous to gold and silver among inorganic substances.

As to their combustibility, the chemist knows well how difficult it is to burn organic substances that are rich in albuminates. Even at a red heat maintained for hours or days some portion of nitrogenous carbon remains unburnt. The same difficulty is experienced also with urea and uric acid salts.

Most nitrogen compounds that are not gaseous possess this peculiarity. There is certainly no more inflammable or more combustible substances than hydrogen and phosphorus, but their compounds with nitrogen are entirely uninflammable; for instance ammonia, though it contains half its volume more hydrogen than ordinary hydrogen gas does.

* Favre and Silbermann.

The non-inflammability of these substances obviously is due to the resistance offered by the nitrogen they contain to the action of oxygen. Taking heat also into account, it appears that according to the determinations of Favre and Silbermann, 1 gram of hydrogen in combining with nitrogen to form ammonia developes 7576 units of heat, or nearly as much as is developed in the combustion of 1 gram of carbon to carbonic acid. It must probably be assumed that in the combustion of 5·66 grams of ammonia, containing 1 gram of hydrogen, an equal quantity of heat would be expended in the work of combustion. Perhaps this may be regarded as a reason why ammonia burns with so much difficulty; but it is not the only reason. Very much appears to depend on external conditions; if they facilitate the oxidation of nitrogen, as is the case in mixtures of decaying materials with alkaline bases, then the hydrogen of ammonia burns with great readiness.

In cyanogen and paracyanogen we have two compounds of nitrogen and carbon identical in composition, but presenting a remarkable difference in regard to combustibility, cyanogen being readily combustible, while paracyanogen burns with great difficulty.

Observation shows that 1 gram of carbon in cyanogen developes by combustion 43 per cent. more heat* than 1 gram of carbon does when burnt by itself.

Evidently, therefore, this surplus heat must be rendered latent in the formation of cyanogen, and in fact in the conversion of cyanide of silver into the paracyanide so much heat is developed that the mass becomes red-hot. If the combustibility of cyanogen be due to the latent heat it contains, still that does not explain why the carbon in paracyanogen appears to have lost its affinity for oxygen to such a great extent.

This consideration of the behaviour of some nitrogenous substances may suffice to show that it is not admissible to estimate their efficacy as sources of power according to the amount of heat they may develope by direct combustion.

We may suppose the possibility of maintaining a machine in a state of work by bringing the vapour of chloride of nitrogen in contact with phosphorus in a vessel, and yet it would be next to impossible to determine the work done directly in heat units, for neither chlorine nor nitrogen are combustible substances in the ordinary sense of the term.

Chloride of nitrogen is formed by the action of chlorine on ammonia; if there be excess of ammonia no chloride of nitrogen is formed, but the chlorine then decomposes the ammonia *with considerable evolution of heat.* In the absence of free ammonia chloride of nitrogen is formed *without any rise of temperature.* It is evident, then, that all the heat developed in the former case is in the latter case rendered latent in the chloride of nitrogen; however, in the decomposition of this substance the latent heat does not reappear as heat, but as motive force.

There are many cases in which mechanical or motive effects are produced by some internal or molecular motion. The magnitude of the effect in these cases depends upon the tension in which the parts exist in regard to one another.

* 11,260 heat units.

The behaviour of glass tears affords a good example of such internal tension; if they are scratched at any part of the surface so as to disturb the equilibrium of the parts, the tears fly to powder with great force. In this case there is no alteration in the composition of the glass; the state of tension obtained only in regard to the homogeneous particles of glass, not in regard to its constituents. In the case of fulminating silver or of nitroglycerin, this tension obtains especially in regard to the dissimilar particles or the constituents of the substances.

Nitroglycerin, or fulminating silver, may be heated above 100° C. without undergoing decomposition, while the breaking of a small crystal of fulminating silver, or a slight blow upon nitroglycerin, at once causes the constituents of those substances to assume a state of stabile equilibrium with violent explosion.

If nitroglycerin is dropped upon a red-hot iron it burns completely with a slight hissing, but without any explosion.

In the one case an enormous motive force is developed by the blow, while in the other case heat is generated by combustion. The motive force is the result of an internal molecular motion; the heat is a consequence of perfect combustion of the constituents of nitroglycerin.

These examples are evidently quite inappropriate for elucidating the exercise of muscular force in the animal body, which takes place in a totally different manner; they are intended merely to show that by the alteration of internal arrangement of the constituents of certain compounds great mechanical effects may be produced without any action of oxygen from without.

The albuminates of the plant world are the most complex nitrogen compounds that we know. All the constituents of the animal body are produced from the albumen of the body by an altered internal arrangement of the parts of albumen, or by their separation. In these changes oxygen exercises a determining influence without being the cause of them; and it may be assumed that if these products of albumen be sources of power, the motion they produce depends upon the tension accumulated in them during their formation and liberated in their decomposition, not upon their combustion or upon the conversion of heat into motive force.

It is quite certain that the substance of the membranes and those constituents of bone which furnish gelatin, that blood fibrin, the nitrogenous constituents of brain, the acids of bile, hippuric acid and wine acid, are products of the transformation and breaking up of albumen; but we have no evidence that albumen yields urea, carbonic acid and water as the result of combustion.

All attempts to produce urea from albuminates by oxidation have failed as completely as the attempt to produce alcohol from sugar by chemical means; and probably the conversion of uric acid into urea and carbonic acid may afford a good example of the processes and changes which the albuminates undergo in the animal body.

Uric acid, like albumen, is one of the most difficult substances to burn directly; it is not broken up by concentrated sulphuric acid, or by boiling with hydrochloric acid or potash; but there is probably no other substance of which the constituents are so readily moveable under the simultaneous influence of oxygen and acids or alkalies, none that is susceptible of conversion into such a multitude of products as uric acid is.

By addition of two equivalents of oxgyen in the presence of an acid, uric acid breaks up into urea and alloxan; by further addition of oxygen, alloxan breaks up into urea and carbonic acid. In the presence of a strong base and oxygen, uric acid breaks up into oxalic acid, allantoin and urea; by a further addition of oxygen allantoin breaks up into urea and allanturic acid, this latter substance containing the elements of carbonic acid and urea.

In all these cases urea is produced from uric acid by addition of oxygen; but it is not, in any case, a product of direct oxidation; it is produced by the breaking up of a newly formed and more highly oxidized compound.

(To be continued.)

WHAT IS ENERGY?*

BY BALFOUR STEWART.

It is only of late years that the laws of motion have been fully comprehended. No doubt it has been known since the time of Newton that there can be no action without reaction; or, in other words, if we define momentum to be the product of the mass of a moving body into its velocity of motion, then whenever this is generated in one direction an equal amount is simultaneously generated in the opposite direction, and whenever it is destroyed in one direction an equal amount is simultaneously destroyed in the opposite direction. Thus the recoil of a gun is the appropriate reaction to the forward motion of the bullet, and the ascent of a rocket to the downrush of heated gas from its orifice; and in other cases where the action of the principle is not so apparent, its truth has notwithstanding been universally admitted.

It has, for instance, been perfectly well understood for the last 200 years that if a rock be detached from the top of a precipice 144 feet high it will reach the earth with the velocity of 96 feet in a second, while the earth will in return move up to meet it, if not with the same velocity yet with the same momentum. But inasmuch as the mass of the earth is very great compared with that of the rock, so the velocity of the former must be very small compared with that of the latter, in order that the momentum or product of mass into velocity may be the same for both. In fact, in this case, the velocity of the earth is quite insensible and may be disregarded.

The old conception of the laws of motion was thus sufficient to represent what takes place when the rock is in the act of traversing the air to meet the earth; but, on the other hand, the true physical concomitants of the crash which takes place when the two bodies have come together were entirely ignored. They met, their momentum was cancelled; that was enough for the old hypothesis.

So, when a hammer descends upon an anvil, it was considered enough to believe that the blow was stopped by the anvil; or when a break was applied to a carriage-wheel it was enough to imagine that

---

* Reprinted from *Nature*. This is the first of a series of papers on a subject that is daily becoming more important in its general scientific bearing, while it is treated in so clear and instructive a way that the papers cannot fail to be useful to all who read them carefully.—ED. PH. J.

the momentum of the carriage was stopped by friction. We shall presently allude to the names of those distinguished men who have come prominently forward as the champions of a juster conception of things, but in the meantime let us consider some of those influences which served to prepare men's minds for the reception of a truer hypothesis.

We live in a world of work, of work from which we cannot possibly escape; and those of us who do not require to work in order to eat, must yet in some sense perform work in order to live. Gradually, and by very slow steps, the true nature of work came to be understood. It was seen, for instance, that it involved a much less expenditure of energy for a man to carry a pound weight along a level road than to carry it an equal distance up to the top of a mountain.

It is not improbable that considerations of this kind may have led the way to a numerical estimate of work.

Thus, if we raise a pound weight one foot high against the force of gravity we may call it one unit of work, in which case two pounds raised one foot high or one pound raised two feet high would represent two units, and so on. We have therefore only to multiply the number of pounds by the vertical height in feet to which they are raised, and the product will represent the work done against gravity. The force of gravity, being very nearly constant at the earth's surface and always in action, is a very convenient force for this purpose; but any other force, such as that of a spring, would do equally well to measure work by. Generalizing, we may say, *the space moved over against a force multiplied into the intensity of that force will represent the quantity of work done.* So much for the definition of work, and it is necessary to know what *work* is before proceeding to define *Energy.*

Now what does the word Energy really mean? In the first place it does not mean force.

Two substances may have an intense mutual attraction, in virtue of which they form a very intimate union with one another; but when once this union has been consummated, although the force still continues to exist, the combination is singularly deficient in Energy. Nor does Energy mean motion, for although we cannot have motion without Energy, yet we may have Energy without motion.

By the word Energy is meant the power of doing work; and the energy which a labouring man possesses means, in the strictly physical sense, the number of units of work which he is capable of accomplishing.

This is a subject which at this stage we may attempt to illustrate by reference to a very different department of knowledge.*

The analogy which we shall venture to institute is between the social and the physical world, in the hope that those who are more familiar with the former than with the latter may be led to perceive clearly what is meant by the word Energy in a strictly physical sense. Energy in the social world is well understood. When a man pursues his course, undaunted by opposition and unappalled by obstacles, he is said to be a very energetic man.

By his energy is meant the power which he possesses of overcoming obstacles; and the amount of this energy is measured (in the loose way in which we measure such things) by the amount of obstacles which he can overcome—the amount of work which he can do. Such a man may in truth be regarded as a social cannon-ball. By means of his energy of character he will scatter the ranks of his opponents and demolish their ramparts. Nevertheless, a man of this kind will sometimes be defeated by an opponent who does not possess a tithe of his personal energy. Now, why is this? A reply to this question will, if we do not mistake, exhibit in a striking manner the likeness that exists between the social and the physical world. The reason is that, although his opponent may be deficient in personal energy, yet he may possess more than an equivalent in the high position which he occupies, and it is simply this position that enables him to combat successfully with a man of much greater personal energy than himself. If two men throw stones at one another, one of whom stands at the top of a house and the other at the bottom, the man at the top of the house has evidently the advantage.

So, in like manner, if two men of equal personal energy contend together, the one who has the highest social position has the best chance of succeeding. For this high position means Energy under another form. It means that at some remote period a vast amount of personal energy was expended in raising the family into this high position. The founder of the family had, doubtless, greater Energy than most of his fellows, and spent it in raising himself and his family into a position of advantage. The personal element may have long since disappeared from the family, but not before it had been transmuted into something else, in virtue of which the present representative is able to accomplish a great deal, owing solely to the high position which he has acquired through the efforts of another. We thus see that in the social world we have what may justly be termed two kinds of Energy, namely:—

1. Actual or personal Energy.
2. Energy derived from position.

Let us now again turn to the physical world. In this, as in the social world, it is difficult to ascend. The force of gravity may be compared to that force which keeps a man down in the world. If a stone be shot upwards with great velocity, it may be said to have in it a great deal of actual Energy, because it has the power of doing useful work or of overcoming up to a great height the obstacle interposed by gravity to its ascent, just as a man of great energy has the power of overcoming obstacles. But this stone as it continues to mount upwards will do so with a gradually decreasing velocity, until at the summit of its flight all the actual Energy with which it started will have been spent in raising it against the force of gravity to this elevated position. It is now moving with no velocity—just, in fact, beginning to turn—and we may suppose it to be caught and lodged upon the top of a house. Here, then, it remains at rest, without the slightest tendency to motion of any kind, and we are led to ask what has become of the Energy with which it began its flight? Has this Energy disappeared from the universe without leaving behind it any equivalent? Is it lost for ever, and utterly wasted? But the answer to this question must be reserved for another article.

(*To be continued.*)

* The subject has previously been discussed from this point of view by Messrs. Stewart and Lockyer, in an article in *Macmillan's Magazine*, August, 1868.

M'BOUNDOU OR ICAJA, AN ORDEAL POISON USED AT THE GABOON.

BY MM. RABUTEAU AND PEYRE.

In 1869, one of the authors brought from the Gaboon some roots of M'boundou. They had been dug up by himself from a humid soil in the vicinity of the river Como, about thirty leagues inland. It is only with great difficulty that the plant is to be obtained in the settlement. The places where it is to be found are kept secret with such care by the fetishmen from Europeans, and even from the natives, that up to the present time only a few specimens have been obtained, which have not been sufficient to enable a complete study of its toxic properties to be made.

The roots with which the experiments were made measured at the crown the largest three centimetres in diameter, the smallest about one. They are sometimes found of a larger size. The length varied between fifty and seventy centimetres. The rather thick bark is, both when fresh and when dry, reddish at the surface and of a bright red colour under the epiderm. The wood which it covers is greyish-white and very hard.

The experiments were nearly all made with the bark, —some few, however, with the root-wood,—from which aqueous and alcoholic extracts were prepared. The bark and the wood are both very bitter, their infusions, even when very much diluted, possessing still an extreme bitterness. Treated with a solution of iodine and iodide of potassium, or with phosphomolybdic acid, they gave an abundant precipitate. They contain an alkaloid (perhaps many) which is believed to be the same in the bark and in the wood, since the effects observed upon animals have appeared identical, the only difference noted being that the alcoholic extract has seemed more active than the aqueous extract. A difference, though but a slight one, has been noticed in the effect of the poison when introduced into the stomach from that which follows it when introduced under the skin of animals.

After many experiments made with varied doses of the poison upon frogs, rabbits and dogs, it is believed that the following is the manner of action of the poisonous principle of m'boundou.

Introduced in a very small quantity under the skin of a frog the poison produces only a constraint of the movements,—a sort of paralysis,—which prevents it from jumping except with difficulty. The same effect was observed when, instead of introducing the extract, which is very powerful, under the skin, a little powdered root has been substituted for it. When only a small quantity of the aqueous extract has been introduced under the skin, its effect disappears completely after about an hour.

A dose of three milligrammes of this extract injected under the skin of a frog produces at first the constraint of movements just noticed, but after ten minutes or more it suffers from shocks and tetanic convulsions. These convulsions are not produced spontaneously in general, but are brought on by touching the animal, or simply striking the table upon which it rests. If the dose is stronger—one centigramme, for example—the convulsions appear more quickly; there is rigidity, but it is rarely that the animal can be raised altogether as when one is poisoned by strychnine. There is always a certain relaxation compared with what is observed in the action of strychnine. Moreover, the frog is not rigid after death. This occurs after a period not exceeding three-quarters of an hour, unless the dose has been feeble; in that case the animal, placed in water, recovers completely after a few hours.

If a frog be prepared according to the method of M. Claude Bernard, by tying the lower part of the trunk and excluding the lumbar nerves, then, by introducing the extract under the skin, it is ascertained that m'boundou acts upon the spinal marrow. It is not a muscular poison.

A dose of ten centigrammes of the extract of m'boundou in aqueous solution injected under the skin of a rabbit in two or three different places, in order that the absorption should be more rapid, killed the animal in twenty minutes. Five or ten minutes after the injection, upon being touched, it suffered from energetic starts and shocks that may be compared to electric shocks; at the same time the movements of its limbs, especially of its posterior ones, were much impeded. It died from asphyxia, but its life might have been prolonged by artificial respiration. The same dose injected in another rabbit at a single point did not cause death; at the end of two hours the animal had but feeble shocks upon being touched, and even these disappeared totally. It ate with appetite. This fact proves evidently that the elimination of the poison is rapid.

Fifteen centigrammes of the same extract dissolved in thirty or forty grammes of water, and introduced into the stomach of a rabbit, caused its death at the end of an hour and five minutes. The symptoms, which were the same as the preceding, commenced to manifest themselves ten minutes after the introduction of the poison. With a dose of forty centigrammes the effects were startlingly sudden.

The symptoms observed in dogs were of the same kind, appearing generally, according to the dose, at the end of five or ten minutes. When their appearance was tardy they were easily provoked, as in the case of the rabbits, by raising the animal or simply touching it. As before, the shocks were powerful, the breath was panting, the posterior limbs were paralysed. The uncertainty and difficulty of the movements were more apparent when the aqueous solution of the extract was introduced into the stomach than when it was injected under the skin. A dog which had been made to swallow twenty-five centigrammes of extract dissolved in forty grammes of water called to mind the bar that the Gaboonese wish those who have taken the ordeal beverage to jump over. This animal, sensible to caresses and obeying the voice, could not clear steps eighteen centimetres high. Every time that it made an effort it trembled, and suffered violent tetanic convulsions. At the end of an hour it was still convulsed, even under the influence of fear; but an hour later, that is, two hours after the injection of the poison, there only remained a slight stiffness in its movements, and it ate with good appetite. Its ears and muzzle, which had been hot before, became cool.

A dose of forty centigrammes of extract introduced into the stomach of a dog caused death in twenty minutes. It died of asphyxia, accompanied by convulsions; its sphincters relaxed, causing an emission of urine and fecal matter. A nasal hæmorrhage was observed, which hæmorrhage has also been noticed among the Gaboonese. Rigidity did not set in until about three-quarters of an hour afterwards.

Upon considering these facts, it appears that the active principle or principles of m'boundou produce effects which present a certain analogy with those produced by strychnine, but differ considerably from them under certain aspects. These effects resemble rather those of brucine; but it is remarked that m'boundou did not produce that hoarseness of voice in the dog experimented upon which, contrary to what is generally admitted, the authors have remarked in dogs to whom brucine has been given by them.

M'boundou is an extremely rapid poison, but the experiments tend to show that it is quickly eliminated from the system, and that fatal symptoms may be allayed by artificial respiration.

Some researches upon m'boundou were made in 1861 by MM. Pécholier and Saintpierre.* These experimenters had but a small quantity of root at their disposal; they nevertheless observed the greater part of the symp-

* *Journal d'Anatomie et de Physiologie.*

toms above noted. But the authors cannot agree with them that the poison, after having produced tetanic convulsions, leads to insensibility, paralysis and death. The restraint of the movements was noticed by them first, death occurring in the midst of convulsions.—*Comptes Rendus.*

REPORT OF THE WARDEN OF THE STANDARDS.

In his report for the year ending March 31, 1870, Mr. Chisholm, the Warden of the Standards, gives in a tabular form the number of verifications and reverifications of Local Standards by the Department each year from the 31st March, 1859, to the 31st March, 1870, inclusive. During the last twelve months these have amounted to 1614, being a decrease compared with the previous year of no less than 1067. This is partly accounted for by the change in the law, which now allows remaining county sets of standards to be reverified locally with a set which has been duly reverified in the Standards Department. The number of standards rejected last year as requiring readjustment was 173, or 11 per cent., the proportion in the previous year having been 13 per cent. There were at the date of the report 114 places in the United Kingdom without legal standard weights, and 85 without legal standard measures, in consequence of the requirement of the law that standard weights should be reverified every five, and measures every ten years, not having been complied with. These were cases known to the department, but it is probable that there were others that had escaped official notice. For instance, a set of standard weights and measures from the borough of Lostwithiel, has been recently delivered at the Standards Office for reverification, bearing the date of 1741, and the Exchequer stamp of verification of the reign of George II., which had been in use in the borough up to that time. They appeared to be in good condition considering their age. The weights were deficient; the lb. weight (avoirdupois) wanting 6·5 grains; the measures of capacity were mostly in excess, the half-bushel to the extent of 1¼ gill. The books of the department, which commenced in 1824, contain no record of the verification of any standards for Lostwithiel.

During the past year the reverification of all the official standards has been completed by the most accurate comparisons of the standard measures of capacity, and the gas-measuring standards. In no single instance has any material error been found that could affect injuriously the accuracy of the copies verified for the use of local inspectors.

A set of standard avoirdupois weights is now being constructed of glass by Mr. Oertling and Messrs. Chance, of Birmingham, with a view of ascertaining how far, having regard to the cost, durability and invariability of such weights, the surface of glass not being liable to oxidation, it may be desirable that it should be used as the material for local standard weights.

In pursuance of the recommendations of the Standards Commission, new standard measures of one-sixth and one-twelfth of a gallon, as measure of the wine bottle and half wine bottle, have been constructed and are now being verified. A complete set of new standard imperial measures of capacity, from the quart downwards, including also a series of measures of decimal grain-weights of distilled water at the temperature of 62° F., have been constructed by Messrs. Griffin. These measures are in the form of glass burettes, each of which is fitted with a brass collar and screw at the upper part, so that, being attached to an apparatus made for the purpose, it may be filled with water up to a defining line on the narrow tube of the burette and made to deliver the exact measure.

A complete set of copies of the official imperial standards is now being constructed for presentation to the French Government. When completed and verified, they will be deposited with the collection of standards at the Conservatoire Impérial des Arts et Métiers at Paris.

Increased accommodation has been given to the department by the addition of several fresh rooms to the office, which now includes all the three floors of the old Norman Jewel Tower. From the great thickness of the stone walls of the tower, the rooms in this building are favourable for standard operations, being very free from vibration, and not liable to sudden fluctuations of temperature. The large room in the basement, which has a beautifully groined vaulted roof, is fitted up as a weighing room, with all the finest balances. The adjacent room is fitted for containing all the glass fluid measures and for making comparisons with them. The large room on the first floor is intended to be exclusively used for containing the standard measures of length, the new microscopical comparing apparatus and the vertical comparateur, and for operations with them. The new rooms on the upper floor are to contain the large collection of older standards of an antiquarian or historical character. The old roof of these upper rooms, with its large beams of chestnut wood, has been completely restored, the whole of the interior of the building being made to correspond as nearly as possible with its appearance when originally completed in the reign of Richard II.

Invitations have been issued by the French Government to the English and other Governments to send delegates to take part in the International Standards Commission, with the view that every country in which the metric system has been adopted, or its adoption contemplated, may be furnished with uniform primary copies of the metric standards at Paris of the highest possible accuracy. Twenty-one countries have accepted the invitation, the number of delegates amounting to thirty-five, to whom will be joined ten more appointed by the French Government. The three delegates appointed on behalf of England are the Astronomer Royal, Professor W. H. Miller, F.R.S., and the Warden of the Standards.

The Coinage Act of last session has imposed fresh duties on the Standards Department; new standard weights of the gold, silver and bronze coins, sixteen in number (ranging from the five-pound and the two-pound gold piece down to the farthing, and including silver twopences and pennies), are now being constructed under the provisions of the Act. As soon as these standard coin weights shall have been duly verified and made legal standards by an Order in Council, regulations will be issued under which any copies of the standard coin weights may be verified and marked or stamped in the department; and no weights other than those so marked or stamped are to be deemed just weights for determining the weight of gold and silver coins of the realm.

ANCIENT USE OF ODORIFEROUS PLANTS.

In his introductory address to the Medical Section of the British Medical Association at their late meeting at Newcastle-upon-Tyne, Dr. Rumsey, referring to a remarkable series of observations which Professor Mantegazza has reported to the Institute of Lombardy, made the following remarks:—

"The experiments were not made under the dull sky of Britain, but in sunny Italy. We have all heard how Acron of Agrigentum, and other followers of Empedocles the physicist, employed aromatic and balsamic herbs as preventives of pestilence, often burning them, sometimes planting them round their cities. So also Herodian records (*Langius Jo.*, *Florilegium*, Morbus, p. 1854; Lugduni, 1648) that, in a plague which devastated Italy in the second century—the counsel of the doctors having been taken—strangers crowding into Rome were directed to retreat to Laurentum, now San Lorenzo, that by a cooler atmosphere, *and by the odour of laurel*, they might escape the danger of infection. Some of us may have smiled at the latter part of the advice. Could the scent of herbs and flowers do more than conceal the presence of infectious matter in the air? Mantegazza now replies in the affirmative. He says that in the oxidation of the essences of odoriferous plants a large quantity of ozone is evolved, at least as much as is produced by phosphorus or electricity; also that, in the greater number of these cases, ozone is developed only by the direct rays of the sun, although in others the action, commencing in solar light, is found to continue in darkness. Some details of these interesting experiments have appeared in the scientific periodicals, so I need only mention that among the plants which largely develope ozone on exposure to the rays of the sun, are cherry-laurel, clove and lavender; among flowers, the narcissus, hyacinth and mignonette; and among perfumes, similarly exposed, eau de Cologne, oil of bergamot and some aromatic tinctures. Flowers destitute of perfume are said *not* to produce ozone. The professor, therefore, recommends the cultivation of herbs and odorous flowers *in marshy districts and in places infected with animal emanations.*

"The destruction of the demon Malaria, by a spirit begotten by sunlight out of flowers—if it be confirmed by subsequent observation—not only explains the good effects of what might seem to have been merely speculative or empirical advice, but also affords a beautiful confirmation of an ancient myth by modern science. When Apollo the Healer, by his life-inspiring and health-restoring rays, penetrates the loveliest objects in creation, and draws forth from them a mysterious purifier, a mighty but invisible disinfectant,—the god of Medicine may be said to administer to a plague-stricken people a most potent remedy concealed in the most grateful and attractive forms."

CARDED OAKUM.

The *Lancet*, speaking of the use of carded oakum as a surgical dressing in war, says so many advantages are possessed by it "that we expect it to be largely employed in the military hospitals of France and Germany during the present war. As, however, its qualities are not yet so widely known as they should be, it may be useful at the present juncture to refer to them. The material is simply old rope shredded in prisons and workhouses, and carded by machinery. It is of a bright brown colour, with the well-known tarry fragrance. A little of the oakum is roughly drawn into a suitable shape for covering the wound, then wetted, and applied to it. All discharge is absorbed by the dressing, and any bad odour is effectually destroyed. By dipping it into hot water, and covering it with oil-silk, a convenient antiseptic poultice is formed, easily made, very light and answering perfectly its purpose. It thus supersedes the use of lint, ointments and linseed-meal or bread-poultices. It is easily burnt—no small advantage in a crowded hospital, where bad-smelling applications are a fertile source of disease if not quickly destroyed. Its simplicity of application saves much time and labour—a great consideration where the nursing staff is overtaxed, as must always happen after serious engagements. Its cheapness is another great advantage. Carded oakum can be procured, we believe, for something like 9*d.* per pound, about a fifth or sixth of the cost of lint. In America, during the civil war, carded oakum was largely employed. It has also been in use for some years at the Children's Hospital in Great Ormond Street, and at St. George's during the last twelvemonth its use has superseded other dressings in the hands of several members of the surgical staff."

Mr. T. Westhorpe, of the Falcon Works, West India Road, who manufactures the machine-picked oakum, in a letter to the *Times*, points out that the *Lancet* is wrong in asserting that "the material is simply old rope shredded in prisons and workhouses and carded by machinery." He says, "I beg to say that the material supplied by me, and now used for some time past in the Children's Hospital, St. George's Hospital, the London Hospital and other hospitals, and known as 'marine lint for surgical purposes,' has not a particle of old rope in it. A most careful examination of the marine lint, and also of oakum picked at prisons and workhouses, has been made at my manufactory this day by one of the principal surgeons of our large hospitals. Having inspected various bales taken from some ten tons of the latter, I think I may fairly state his opinion to be that the impurities contained in workhouse and prison-picked oakum, and not to be got rid of by carding, render it anything but a desirable application to wounds. Doubtless in a few days we shall have a report from those who are using the marine lint on the battle-fields."

NEW TEST SOLUTION FOR SUGAR.

J. Loewe recommends the use of glycerin in place of tartaric acid for the preparation of an alkaline copper solution for the detection of sugar. Glycerin entirely prevents the precipitation of oxide of copper, and the solution prepared with it has the advantage of being less liable to alteration when kept than the tartaric solution is.

To prepare a test liquid of this kind 16 grams of sulphate of copper should be dissolved in 64 parts of water; to this solution is gradually added 80 c.c. of soda solution (1·34 sp. gr.), then 6 or 8 grams of glycerin, which redissolves the hydrated oxide of copper that had been precipitated.

This liquid should not become turbid when diluted with two-thirds of bulk of water nor when boiled.

The copper solution may also be prepared by dissolving hydrated oxide of copper in a mixture of glycerin and caustic soda. The hydrated oxide is best obtained by adding soda solution to an ammoniacal solution of sulphate of copper, washing the precipitate and drying over oil of vitriol.

For 6 grams of this hydrated oxide there should be 6 or 8 grams of glycerin, 50 grams of water and 56 grams of soda solution of the strength above mentioned. This mixture is then diluted as may be requisite. The author prefers this solution to the other. It does not become turbid with alcohol.

The solutions will not bear considerable dilution without depositing hydrated oxide of copper, but this may be prevented by increasing the proportion of glycerin or of soda.—*Zeitschrift für analytische Chemie.*

NEW SOURCE OF CITRIC ACID.

Professor O. Silvester, of the Catanian University, has recently discovered that the fruit of *Cyphomandra betacea* contains a large quantity of citric acid.

The plant belongs to the *Solanaceæ*, and it occurs here and there in gardens throughout Sicily. It is a native of Mexico, is frequent in Peru and other parts of South America, where it is called *Tomate de la Paz.* The fruit contains from 1 to 1·5 per cent. of pure citric acid.—*Cosmos.*

Modification of Bones by Earths in the Food.—M. Papillon has recently communicated to the Academy of Sciences in Paris some interesting results of experiments in which pigeons and rats had various earthy salts mixed with their food. After continuing this for several months the animals showed no sign of being affected. On examination of their bones it was found that considerable quantities of strontia and alumina had been accumulated in them according as their food had been mixed with a salt of strontia or alumina.

DECIMAL GRAIN-WEIGHT.

(From the *London Gazette* of Friday, August 12.)

Whereas the Lords of the Committee of Privy Council for Trade have represented to her Majesty that the following decimal series of new avoirdupois grain-weights have been recommended by the Commissioners appointed by royal warrant, bearing date the 4th day of May, 1868, for inquiry into the condition of the Exchequer Standards (now called the Board of Trade Standards) of length and weight, and for other purposes, to be legalized as secondary standards, in pursuance of sections six and eight of the "Standards of Weights, Measures, and Coinage Act, 1866," and that such grain-weights have been constructed, and have been duly verified in the Standards Department of the Board of Trade, their weight in relation to the imperial standard pound having been accurately determined:—

Decimal Grain-Weights.

4000, 2000, 1000 grains.	5, 3, 2, 1 grains.
500, 300, 200, 100 "	0·5, 0·3, 0·2, 0·1 "
50, 30, 20, 10 "	0·05, 0·03, 0·02, 0·01 "

Now, therefore, in pursuance of, and by virtue of the said recited Act of Parliament, her Majesty, by and with the advice of her Privy Council, is pleased to order, and it is hereby declared, that the said decimal avoirdupois grain-weights shall be legal secondary standards of Imperial weight, from and after the time when this order shall have been duly published in the *London Gazette*, pursuant to the said Act.

ARTHUR HELPS.

AMENDMENT OF THE MEDICAL ACT.

The following letter, which sufficiently explains itself, appeared in the *Times* of the 1st of September:—

Sir,—With reference to a recent report in your columns, we beg to state that at the late meeting of the British Medical Association, held at Newcastle-upon-Tyne, we found ourselves compelled to resign our seats on the council of that body.

As members of the General Council of Medical Education and Registration, we had advocated the main provisions of the Amended Medical Bill introduced into the House of Lords by the Lord President of the Privy Council—provisions which, in our judgment, were of the utmost importance to the public weal.

The Bill, it is believed, was withdrawn in the House of Commons by Mr. Forster in consequence of the course pursued by the Direct Representation Committee of the Association. That course was subsequently approved by a vote of the Association at Newcastle.

We, therefore, could not, in justice to ourselves or to the members of the Association, continue any longer to belong to its executive.

The question of the permanent construction of a Medical Council of Education is one of grave importance. It is intimately connected with other questions and interests entirely extra-professional, and it cannot, therefore, be properly dealt with by any hasty or one-sided legislation.

We are, Sir, your obedient servants,
GEORGE PAGET, Cambridge.
WILLIAM STOKES, Dublin.
HENRY W. ACLAND, Oxford.
H. WILDBORE RUMSEY, Cheltenham.
DENNIS EMBLETON, Newcastle-on-Tyne.

A Good Hair Oil.—The *Journal of Applied Chemistry* recommends the following:—Pure fresh castor oil, 2 oz.; Cologne spirit (95 per cent.), 16 oz. The oil is freely dissolved in the spirit, and the solution is clear and beautiful. A very cheap and good dressing is made by dissolving four ounces of pure, dense glycerine in twelve ounces of rose water.

Coloured Rain and Snow.—On the 14th of February a remarkable yellow rain fell at Genoa. The following details respecting it are given in a letter addressed to M. Ad. Quetelet by M. G. Boccardo, Director of the Technical Institute of Genoa, who examined it in concert with Dr. Castellani, professor of chemistry. The quantitative analysis gave the following results:—

Water	6·490	per cent.
Nitrogenous organic substances	6·611	"
Sand and clay	65·618	"
Oxide of iron	14·692	"
Carbonate of lime	8·589	"

Examination under the microscope revealed the presence of a number of spherical or irregular ovoid substances of a cobalt blue colour; corpuscles similar to the spores of *Peziza* or *Permospora;* spores of *Dematiaceæ* or *Spheriaceæ;* a fragment of a *Torulacea (?)*; corpuscles of a pearly colour, concentrically zoned, probably small grains of fecula; gonidia of lichens; very scarce fragments of *Diatomaceæ;* spores of an olive-brown colour; a few fragments of filaments of *Oscillaria*, *Ulothrix*, and *Melosira varians;* a fragment of *Synedra;* a peltate hair from an olive leaf. If, instead of collecting the earth on the morning of the 11th, when it had already been subjected to the action of rain falling for several hours, I had been able (writes M. Boccardo) to observe the phenomenon during the night, at the moment when it was produced, it is very probable that the microscope would have shown the existence of several kinds of infusoria, as has been the case in several similar instances.

The author notes that the direction of the wind at Genoa during the night of the 13th and 14th was from the south-east, and, without being exactly a hurricane, as on the preceding few days, was still very strong. The temperature, previously exceptionally low, had risen, and probably did not fall during the night below + 4° R. (5° C. or 41° F.). The journals state that on that date a tempest devastated the coasts of Sicily. M. Boccardo, following P. Denza, proposes the theory that the dust came from the coast of Africa. "We ought not to forget," he writes, "that, according to Maury's theory of the circulation of the atmosphere, these clouds of dust may have travelled a long distance before touching the soil of Italy, coming from beyond the Atlantic, like those which, in 1846, spread from Guiana to the Azores, over the south of France and the whole of Italy."

In a paper in the *Bulletins de la Société Vaudoise*, No. 62, Dr. C. Nicati gives a *résumé* of various researches respecting the peculiar red snow which occasionally falls in the Grisons. Some of this snow fell, mingled with common snow and rain, during a violent storm from the south-west, on the morning of January 15th, 1867, in various places. The chemical analysis of the melted snow demonstrated the presence of minute quantities of sulphate of lime or gypsum, sulphate of magnesia, organic matters, chlorine, and iron; and microscopic examination detected vegetable fibre, pollen, spores, with here and there diatoms and small crystals. The colour varies from brick-red to a pale yellow. This snow is quite distinct from the red snow of the upper alpine regions, which owes its colour to the presence of the minute plant, *Protococcus nivalis.* After discussing various theories respecting its origin, Dr. Killias expressed his opinion that it is the dust of the desert of Sahara, transported by a sirocco, which gives the colour to the snow of the Grisons. Dr. Nicati gives many interesting particulars, with analyses, of the Algerian sirocco dust, and of the mud-rain in Naples and Sicily; and Professor C. Cramer states that he has discovered, both in the sand of the Sahara and in the red snow of the Grisons, particles of vegetable organisms (especially polythalamia) and minute fragments of animal origin, such as wool, hair, etc. He considers the presence of gypsum in the red snow an incontestable proof of its containing matter conveyed from the desert of Sahara.—*Nature.*

The Pharmaceutical Journal.

SATURDAY, SEPTEMBER 3, 1870.

MR. SIMON ON THE PRACTICE OF PHARMACY IN GREAT BRITAIN.

In addition to the details of the working of the Pharmacy Act to which we last week referred, the medical officer of the Privy Council discusses in his twelfth annual report that section of the Act which declares that the provisions of the Adulteration of Food Act shall extend to the adulteration of drugs, and that every such adulteration shall be deemed an admixture dangerous to health. This section, he observes, has not so far as his knowledge goes yet been acted on. Indeed, seeing that the Adulteration of Food Act is virtually a dead letter, no one, he thinks, could have expected that the extension of it could be very effective. There is, however, cause for congratulation in the fact that a principle of great importance has, in that section, been affirmed by the Legislature. The falsification of drugs he describes as a crime which, in the interest of public health, ought to be very severely punishable and very regularly looked after; for it so frustrates the best medical skill and may so steal away life after life, that it is really a kind of secret poisoning. Yet in the present state of the law, with so many just necessities for the health of the country unfulfilled, and with such great masses of fundamental sanitary laws to be amended or created, it may scarcely be expected that this particular grievance can be matter for immediate legislation. But on this head it is observed that important changes must be made in the kind of local authority needed to protect the public health, before the defects of the administrative machinery can be remedied, or the law relating to adulterations be brought into an efficient state.

Finally, Mr. Simon reports to their Lordships on the Regulations concerning Poisons. Here are his words on this delicate and important subject:—"I also regret to state that the very important power which the first section of the Act vests in the Pharmaceutical Society, to prescribe (with the consent of the Privy Council) regulations as to the keeping, dispensing and selling of poisons, has hitherto remained unexercised by the Society, and that, consequently, the public is still without the protection which such regulations might give, and which notoriously is much needed, against the danger of having poisons dispensed or used in mistake for harmless preparations."

So much has been said on this subject already by readers, writers and speakers in the Society, that it is probably unnecessary for us here to do more than merely lay before our members this official statement. Its weight and importance are apparent. On the other hand, the difficulties and complications which surround the question have also become very apparent. It is now under the consideration of a Committee, and will have to be once more debated by the members at large at a future time.

In an appendix Mr. Simon gives detailed reports from Dr. Christison and Dr. Greenhow on the Examinations of the Society, of which we shall reproduce the most important parts.

LIVERPOOL, SEPTEMBER, 1870.

Possessed of attractions for the technical chemist and the botanist, the geologist and the student of natural history, such as few districts afford, Liverpool is eminently attractive to the hard-worked druggist as well as to the man of science. The local committee are making great preparations to receive their pharmaceutical brethren, and promise a welcome which will doubtless be at least as warm as any previously accorded to the British Pharmaceutical Conference. Under these circumstances we are not surprised to hear that the number of visitors is expected to be very much greater than at any previous meeting, nor are we surprised that a large proportion of the thousand members who have recently joined the Conference are anxious to see what is done at these annual gatherings, and are not unwilling to be convinced of the immense value of this association of men of kindred pursuits.

Let us, then, note for the benefit of those who contemplate a visit to Liverpool and the Conference for the first time, that the Honorary Local Secretary, Mr. E. Davies, Royal Institution, Liverpool, will be happy to forward every information concerning lodging and hotel accommodation.

On taking a retrospect of previous meetings we have been struck by the absence of some well-known men, whose exertions in the cause of true Pharmacy have contributed not a little to foster that *esprit de corps* which is now (poisons and poison regulations notwithstanding) so largely dominant in the trade. The veteran Morson, and the gay, open-hearted Hills, after boldly crossing the Exe last year to make new acquaintances and find old friends with new faces in the fine old city of Exeter, both testified in unmistakable language to the pleasure and profit they derived from their visit.

Cannot our esteemed President and zealous Vice-President follow their example with advantage? The various duties they have regularly to perform in London are known to us, and we would not claim to interfere with their well-earned repose during the holidays, had we not a certain amount of misgiving that the public character and influence of the Pharmaceutical Society throughout the provinces would be in some degree lowered by their absence from the most important professional gathering of the year.

The Society represents something more than its 2500 subscribing Members and Associates: it seeks to be and, we venture to add, is representative of the whole trade; its influence in one form or another is now felt by *every* chemist in Great Britain. It would then be a graceful compliment to its young and prosperous offspring, if the Council were to appoint as one of its numerous delegates to the approaching meeting the chief actor in the struggle for the Pharmacy Act of 1868, the man whose portrait, removed from the Royal Academy Exhibition, we are proud to hear will decorate the walls of the examination room next October. Domestic bereavement, public and private cares of no ordinary kind have been his lot during the last few months, and we would not willingly add further burdens; but our provincial friends, anxious to take a more active part in the working of the Society, naturally desire to make the personal acquaintance of its leading members. Their inclination and willingness to undertake fresh duties cannot be questioned, and in regard to Mr. SANDFORD, we feel so confident that his presence in Liverpool would be of service to the Society, as well as to the Conference, and so gratifying to himself, that we do not hesitate to urge the importance of his not neglecting this favourable opportunity of taking counsel with his constituents and friends.

The Vice-President, Mr. HASELDEN, would bring a large practical experience to bear on the questions for discussion, while, as an active, painstaking and popular member of the Board of Examiners, he would most certainly be cordially received. The views we have advanced in regard to the officers of the Society apply with equal force, *cæteris paribus*, to the Councillors and Examiners generally. Their attendance hitherto has not been so numerous as we could wish, and we are disposed to think that many opportunities for useful work have been for the time lost, owing to the scarcity of the *initiative* element of the Society at former meetings. Never has there been a more appropriate time for those who consider that the duties of *office* necessitate other sacrifices than those of regular attendance at Bloomsbury Square, to show their sympathy with chemists and druggists generally.

We hope to see in the Liverpool list, amongst others new to the Conference, the names of BOTTLE, EDWARDS, BROWN, WOOLLEY, WILLIAMS, ALLCHIN, DARBY, GALE, REDWOOD, etc. Edinburgh may be relied upon for sending JOHN MACKAY. Without his genial spirit, it may be safely affirmed that no Conference, social, political, or otherwise, *can* be complete. We can predict, with some confidence, that all the guests assembled this month at Liverpool, will, on their departure, carry away with them an impression far more lasting than any that can be produced, solely by what our American neighbours designate, "a phenomenal cataract of verbal influences."

ODISSE QUEM LÆSERIS.

We have been reminded by several correspondents that the *Lancet*—which lately gave publicity to the opinion that medical men ought not to be called upon to sit in the same room with Pharmaceutical Chemists at a public exhibition, and that chemists were by no means fit company to be publicly associated with by medical men at the Polytechnic—this week completes, as we presume, its bouquet of compliments by designating the class represented by this Journal as "malefactors" who are in the habit of "prescribing in the dark."

We shall not, however, be at any pains to disclaim the title for which pharmaceutists are thus indebted to the discriminating courtesy of our contemporary for in its more sober moments, or at a period of stricter editorial control, we shall fully expect to see a spontaneous *amende*.

EXEMPTION FROM JURIES.

We desire to draw the attention of Pharmaceutical Chemists to the fact that this is the proper time, for those who desire to avail themselves of their privilege in this respect, to take notice whether their names are included in the List of Jurors affixed to the parish church doors on the three first Sundays in September, and in that case to make their objections as prescribed by the Juries Act, 1862.*

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

We have much pleasure in acknowledging the following additional contributions during the past week, and in thanking those who have already subscribed towards alleviating a calamity which the *Times* has well characterized as a wholly exceptional outburst of the fearful forces which human nature, as much as physical nature, has in store,—a calamity all *are* bound to relieve as one concerning all humanity. We desire, at the same time, to urge upon those who contemplate subscribing, that the pressing nature of the case requires prompt action, and we feel the more impelled to do this because, in the lists of contributions hitherto published, the names of many leading pharmaceutists have yet to be enrolled. This is the case with the Local Secretaries throughout the country, who, of course, cannot be expected to respond so promptly as individuals, since they have the extra trouble of collecting subscriptions. This is a work of time, and while tendering our thanks to those local secretaries who have been the first to send in collections, we trust to finding them before long well supported by their colleagues in other places.

The frightful magnitude of the suffering now being undergone by the wounded soldiers of both armies, is such as to eclipse altogether ideas of nationality or predilections in favour of one side or the other.

W. J. Bates, Macclesfield:—
12 bottles 1 grain opium pills.
12 bottles ¼ grain morphia pills.
6 bottles 2 grain quinine pills.
(each containing 4 dozen pills.)
4 sponges.

James C. Chubb, 102, St. John Street, E.C.:—
12 dozen tin boxes of seidlitz powders.

John Day, 116, Briggate, Leeds:—
8½ lbs. of linen.
2 oz. sulphate of quinine.
2 bottles of Condy's fluid.

M. J. Ellwood, Leominster:—
6 lbs. patent lint, and piece of linen.

Robert Hampson, 63, Piccadilly, Manchester:—
12 gross 1 grain opium pills in bottles containing 4 dozen each.
12 gross ¼ grain morphia pills in ditto.
6 gross 2 grain quinine pills in ditto.
4 2-oz bottles of chloral hydrate.

Proceedings of Scientific Societies.

PARIS.—SOCIÉTÉ DE PHARMACIE.

6th July, 1870.

M. Lefort, President.

M. Bussy suggested that the Society should exchange the report of its proceedings with the several other pharmaceutical societies in France which publish reports: the proposition was referred to a committee.

M. Maget presented a number of specimens of materia medica brought from China by the Marquis d'Hervé de Saint-Denis. M. Jeannel referred to the extended investigation of the subject published by M. Debeaux. A committee was appointed to make a detailed examination of the collection.

M. Bussy presented, on behalf of M. Carles, a memoir on the dissociation that oxalic acid undergoes in a boiling aqueous solution under the influence of a current of gas —oxygen, hydrogen, carbonic acid. The products formed are carbonic acid and formic acid.

M. Planchon laid before the meeting a number of drawings representing the anatomical structure of drugs, remarking upon the great constancy of the general micrographic characters, either in the species of the same genus or in varieties of the same species. He showed that this mode of examination was remarkably adapted for distinguishing the barks known as canella, and pointed out the striking differences existing between those belonging to the family *Laurinaceæ* and those improperly designated by that name.

M. Lefranc read the first part of a paper on inuline.

M. Duroy suggested that the Society should pronounce an opinion on the application of fluid extracts for the preparation of certain syrups.

M. L. Soubeiran read a report recommending that MM. V. Herran, Howard and Zaldivar should be elected corresponding members.

GRANT COLLEGE MEDICAL SOCIETY, BOMBAY.

July, 1870.

A New Indian Remedy.

BY MR. NARAYAN DAJI, *Graduate of the Grant Medical College.*

(*Continued from page* 176.)

Synonyms.—This plant is the *Ailanthus excelsa*, Roxb.; W. and A. Prod. i. p. 150; Roxb. Fl. Ind. ii. p. 450; De Cand. Prod. ii. p. 89: Spr. Syst. i. p. 939; Willd. iv. 974; Roxb. Cor. P. t. 23; Wight's Ill. Ind. Bot. i. t. 67. In the vernacular languages of India it is known by the following synonyms:—

Aralu, Sanskrit; *Araduso*,* Gujaráti; *Mahárúkha*† (lit. great tree); *Mahádunga*, *Mahánimba*,‡ Maráthi; *Peru maram* (lit. great tree), Tamil; *Pedda mán chettu* (lit. great tree), *Pedda mán*, *Pedda mánu*, Telugu; *Arar madára*, Hindi, (Allahabad).

Etymology.—The generic name, *Ailanthus*, is derived from *Ailanto*, the name of *A. glandulosa* in the Moluccas,§ which signifies "the tree of heaven," so called from its

* *Aradusi* is the name in Gujarati of *Adhatoda Vasica*.

† *Mahárúkha* is also the name in Maráthi of *Cinnamomum Tamala* and species; the other synonyms are corruptions of the above. It is so named probably from its immense size.

‡ This name signifies "great Nimba," so named probably from some resemblance of its leaves to those of "Nimba" (*Azadirachta Indica*). *Mahánimba* is also the name of *Melia Azederach*.

§ See Don's 'Gardening and Botany,' vol. i.; Miller's 'Gardener's Dictionary,' vol. i. Ail.

lofty growth. The specific name *excelsa* refers to its great height.

BOTANY.—The genus *Ailanthus* has at different times been variously placed by systematic botanists. It was formerly referred by De Candolle to his tribe *Connaraceæ* of

Ailanthus excelsa, Roxb.

the Order *Terebinthaceæ*.* A closer research led for a short time to its transference to the extensive Order *Rutaceæ*, of which "*Ailantheæ*" was considered a second suborder by Dr. Arnott, and which was partially referred by Meissner to the distinct tribe of *Zanthoxylaceæ*. Bentham and other later systematic botanists have placed this genus in the Order *Simarubaceæ*, an arrangement which is here adopted.

"*Generic character.—Ailanthus*, Desf. Act. Acad. Paris, 1786, 263, t. 8. Flowers polygamous. Calyx small, 5-lobed. Petals 5, valvate in the bud. Disk 10-lobed. Stamens 10, fewer or none in the female flowers; filaments without scales. Ovary 2- to 5-lobed; styles connate, with plumose stigmas; ovules solitary in each cell. Fruit of 1 to 5, oblong, membranous samaræ thickened in the centre round the seed. Seed flattened, testa membranous: albumen scanty; cotyledons leafy, nearly orbicular. Trees. Leaves alternate, pinnate; leaflets oblique; flowers small, in terminal panicles."†

"*Specific characters.—A. excelsa*, Roxb. Trunk perfectly straight, rising like that of the fir-tree to a very great height. Bark smooth, ash-coloured. Branches pretty numerous, ascending. Leaves about the extremities of the branchlets, abruptly pinnated, generally about three feet long. Leaflets short petiolated, from ten to fourteen pairs, obliquely oblong, or somewhat sickle-formed, the nerve runs so as to make the exterior portion twice as broad as the interior, very remotely and grossly serrated or indented, smooth, about four inches long and two broad. Petiole round, smooth. Panicle terminal, very large. Bracts minute. Flowers exceedingly numerous, small, slightly tinged with yellow, hermaphrodite and male mixed."

Hermaphrodite Flowers.—"Calyx as in the genus. Petals five, many times larger than the calyx. Nectary or receptacle is a perforated, glandulous, notched body, which surrounds and in a great measure hides the germs. Filaments ten, shorter than the petals, inserted into the lower edge of the nectary. Germs above, from one to four, very minute, immersed in the perforation of the nectary. Style none. Stigma small. Capsules from one to four, but generally one or two; not connected at the base, linear, oblong, surrounded with a large membranaceous wing, a little twisted at the apex and base. Seed one, flattened."

Male Flowers.—Calyx, corol, nectary and stamens as in the hermaphrodite, but no rudiment of a pistil.*

The tree flowers in the cold season, and ripens its fruit in April and May. Its wood is soft, white and light; it is readily attacked by insects. At Baroda and other places the wood is used for making handles and sheaths for swords and for other light work; in the Circars it is commonly made into catamarans.

HABITAT.—This species of Ailanthus is found in a native state in India and in Ceylon. Roxburgh mentions it as an immense tree, a native of the interior of Coromandel. It flowers during the cold season.† Royle found it around Delhi, along the Jumna, as well as on the Coromandel coast.‡ It is found growing in the jungles of Travancore, Coorg, Mysore, Malabar and Ceylon.§ In the Bombay presidency it chiefly occurs in Gujarat and Kattiawar, particularly so near Ahmedabad, Baroda and Broach; and is thinly scattered over the Deccan.

Its growth is not so rapid as one would believe from the soft nature of its wood. At Mehmoodabad a tree of the age of about seventy years is to be seen. Its circumference at the base measures eight feet. Trees of still larger girth and greater age are seen in other parts of India.

This tree grows on the plains and open valleys, amongst mountains and a few miles inland from the coast. It thrives on a somewhat barren sandy alluvium containing limestone. In Gujarat, particularly about Ahmedabad and Baroda, it flourishes in the neighbourhood of villages where the soil abounds in calcareous matter, which largely enters into the structure of this plant. A somewhat dry climate having a considerable range of temperature appears to be favourable to its growth.

SOCIETY OF ARTS.

ON FERMENTATION.

BY PROFESSOR A. W. WILLIAMSON, F.R.S.

Lecture I.—continued.

Now, the question arises whether this formation of acetic acid ought to be classed, as I am at present classing it, amongst the processes of fermentation. If it is due to the absorption of oxygen, you might naturally inquire whether one ought not to place it amongst the common processes of combustion, and it is right that I should state that by some authorities it is at present so classed. My reason, however, for stating what I have done, that it is a process of fermentation, is this, that it is usually effected by the action of a peculiar organism, called a vinegar-plant, an organism which I shall have occasion to show you hereafter, which does exert in that particular process the function of taking up oxygen from the air and of inducing the alcohol to combine

with it. There are many other processes by which we could get it, but the actual process by which we do get it is a process in which this vital organism, the vinegar-plant, is the agent of its formation. It might be made by mere processes of combustion, but it is made by a process of fermentation.

There is one singular feature in the first and best known of these processes—the alcoholic fermentation—which you will notice when I tell you something of the way in which the processes of fermentation present themselves, even without very great care on the part of the observer. If, for instance, you were to express the juice of some sweet fruit—say grapes—and if you were to leave that expressed juice in contact with the air for a little time, having first squeezed it through some suitable cloth or filter, so as to have it clear, of course there would be no solid particles in it when you put it aside; but, if you leave that in a tolerably warm place, in contact with the air, you would find that little solid particles would appear in this juice, that they increase in number, and that, in proportion as they increase in number, and as the quantity of them becomes greater, so does the process of effervescence—the evolution of gas from the grape juice—become more and more rapid. These little solid particles, which are not present at first in the grape juice, but which gradually make their appearance when it is exposed to the air, are what we commonly call, in the ordinary case of alcoholic fermentation, in this country, yeast—either beer-yeast or wine-yeast; it is the same organism in each case. The peculiarity of the process is this, that these substances—this yeast—which seems to make the sugar into those products which I enumerated to you, does not disappear while doing the work, but is produced by the very process. The more active the production of these yeast-cells, and the more speedy the growth of these yeast-cells, the more effective and rapid is the process of fermentation, and no fermentation of the kind which I am speaking of at present—the alcoholic fermentation—has ever been known to take place in the absence of these organisms. That circumstance I just mention briefly at present, but the fact that these yeast-cells appear whenever the process is going on—and the more they grow the more rapid is the fermentation—has led people to suppose at first, and to believe afterwards, that these yeast-cells were the agents of the transformation, the active substances which decomposed the sugar in contact with the water, and induced the transformation which we noticed. Now, the very fact that one of the two substances which are reacting upon one another chemically (because the changes are chemical in their fundamental nature), should not disappear, but should rather increase by the process, is entirely anomalous—it is entirely at variance with the simplest and best known facts of chemistry, so much so, that if it were not established upon incontrovertible evidence, I believe that most chemists would be inclined to disbelieve it, and to say it cannot be,—it is impossible,—it is a mistake. If you tell me, as a chemist, that this yeast is transforming sugar by its action on the sugar, and that instead of being consumed the yeast is actually increased in quantity by doing that work, I should say it is nonsense—it cannot be, because in all the cases of chemical action which I know best, nothing of the kind occurs, but the very opposite. When one substance acts upon another, each one disappears in the process, and is transformed into a product having other properties. I need hardly give you illustrations of that; but one or two simple cases may not be useless, as serving to fix clearly this important circumstance in your minds.

I will take at first one of a particularly elementary and simple kind,—a process of combustion. I will take a little strip of metal—magnesium wire—and will hold it for a short time in the flame of a spirit lamp, so as to raise it to a sufficiently high temperature. The light you see emitted is due to the combustion of the oxygen in the air with the metal magnesium, which I hold in my hand. This is one of the simplest possible cases of chemical action. The metal has disappeared. The strip of wire is gone, and oxygen from the air disappeared also. At the same time a white powder was formed. I dare say you did not notice it, but here is a quantity of the same substance in a bottle. It consists of oxygen from the air combined with the metal magnesium, and the point is this—that all the magnesium which took part in that process disappeared and went to form this white powder, and all the oxygen which took part in the process also disappeared. The two united together, each disappeared as such and went to form this new product. And, moreover, we can tell, from an examination of the proportions in which the substances combine, exactly what weight of oxygen would disappear for every part by weight of magnesium. If you burn, for instance, three grammes or three pounds of magnesium, you would require exactly two grammes or two pounds of oxygen. For instance, three pounds weight of magnesium would combine with two pounds weight of oxygen, and the product of the two together would be five pounds in weight. I may show you the same thing with soda, not the substance which is commonly called by that name, which is a carbonate of that base. I have here a little pure soda solution in a bottle. I will pour some into a beaker-glass, and I will show you one property which characterizes it, viz. that of changing the colour of this red paper into blue. Now, I will pour some of this acid body, the oil of vitriol, into another beaker-glass. If I put the paper which has been discoloured into this pure acid, it would be dissolved; but I will dilute some of it with water, and then you will see that paper, which has been rendered blue by the agency I have just used, is brought back again to red by the agency of this acid. Now, if I mix the acid with the soda, we shall have audible evidence of violent action going on. I will not go on with the process, but I have purposely taken the two substances in presence of very little water, in order to show you that the heat evolved makes the liquid boil with great violence. I could have avoided that by adding water in the first place, but I wished to show you the vigour with which they unite together. If I were to go on adding acid to the soda, little by little, feeling my way until I had just completed the action, I should have got some water formed and some of the beautiful salt which I have here,—a body which is neither soda nor acid; it is a salt called Glauber salt or sodic sulphate, and all my materials would have disappeared in the process. If I use them in proper proportions, all the acid and soda would disappear and go to form these two other products. I might dissolve some of this sulphate in water, and might put red paper or blue into it and it would not affect either of them; it is perfectly neutral in that respect. The proportion by weight in which this combination takes place is this. If I add 40 parts by weight of soda, and 49 of oil of vitriol in a state of purity, I should have as the result, 18 parts by weight of water, and 71 of sodic sulphate, and if I add together the weight of my materials and the weight of my products, I get the same—89. Nothing disappears in the process; all the acid and all the base which takes part in it is employed. Each particle which took part in the process disappeared as such, and it passed over into another form.

I will mention one other case, because it is somewhat more complex. I may take the case which I was showing you just now, the white marble and hydric chloride or muriatic acid, which I used for making the carbonic acid gas. In that case, I used two materials, carbonate of lime, as it is commonly called, and hydrochloric acid. We get three products; on the one hand is a salt, which is commonly called chloride of calcium, a solid substance used for drying gases, as it has a great affinity for water; another is water; and the third, as I showed you, carbonic acid gas. There, again, we have precisely the same thing. All the marble and all the hydric chloride which takes part in the formation of those three products disappeared as such, and they resolved themselves into other compounds possessing different properties; but the weight of the products is equal to the weight of the materials. That rule holds good throughout all ordinary cases of chemical action.

On the other hand, in fermentation it is not so; one of the active substances is formed, and the more active the fermentation, the more does it grow. In fact, if you want to get yeast, you must go to a place where the breaking up of sugar into alcohol and carbonic acid is going on; or if it is in the south, you must go to where wine is being made, you go to a wine-maker, and get the yeast from him. The only way of getting yeast is from that process of fermentation which sets in spontaneously under the conditions I named to you.

I ought, however, in justice to the wonderful process which I alluded to, to give you two or three other particulars regarding it. I showed that sugar is broken up by the ferment into these products, but no case is known of pure sugar—and when I say pure sugar, I mean sugar in the purest form in which we have it—being decomposed by yeast. If you were to put some ready-made yeast—thriving, growing, yeast—into a solution of chemically pure sugar, some of your yeast would decompose, some of it would resolve itself into other products, and other parts of it would be absorbing those products which are present in the liquid, and whenever the process is to be carried on advantageously and rapidly, it is customary to add some saccharine liquid—some other substance capable of nourishing the yeast. When I want good fermentation I do not take water to dissolve my sugar and put yeast into it, but I boil some of this malt, which is one of the best materials for the purpose, in water, and take a decoction of malt or decoction of yeast and put the sugar into it. In such a liquid there are several bodies which we know; and I may safely say that there are a great many others which we do not know, and there is no doubt that their presence is of considerable importance to the chemical change which takes place. There are substances which I shall presently have occasion to show you and to speak of, formed by the germination of the grain, by the formation of the malt, which are related somewhat to this body which I have here. This was some pure wheat flour—every kind of flour would not do—and it is supposed that some people mix other materials with flour. It was kneaded up with water, pressed together, and, whilst the pressure was being continued, water was allowed to trickle over it. I have in another bottle some of the water that flowed over it. There is a white substance deposited from this water, which is commonly known and much used by the name of starch, and starch is, in its chemical composition, first cousin to sugar; it is a substance which passes over very readily into a kind of sugar by a process I shall presently have occasion to allude to. But the little ball of flour while being kneaded had the starch washed away from it, and I have left, as the result, a substance which is commonly known by the name of gluten. If I were to describe it in chemical language, I should say it is something like flesh, or the muscular fibre of animals, for, in chemical composition, it approaches very nearly to that. When barley is malted, and kept in a warm place for some time, the grains begin to germinate and decompose, and some bodies are formed from this gluten, which is partially broken up. The malt contains also some sugar made from that starch—grape sugar, as we usually call it.

If we had only these extreme cases, I really do not know what we should do. If we had in our science one set of bodies which appeared so constantly to act at variance with the general laws which the others obey, I think we could not call chemistry a science. I have taken two or three examples to show you the definite proportions which we find to regulate the ordinary process of combination. I might have taken thousands, but the point is that this law does not appear to apply at all to these chemical changes which we call fermentation. One of the active substances in fermentation is being formed, it is increasing, not disappearing at all, and the contradiction is so strong and manifest that the only way out of the difficulty will be to do something of the kind which I was speaking of some time ago, that is to say, see if we cannot get some intermediate facts which will serve to connect the extreme ones; to see if we cannot get at first something between the two classes, and then try to get some further links between them. There are processes of chemical change—I will not call them processes of fermentation, for I do not know whether they are, but which are analogous to it, and some of them are very interesting and very beautiful. I have here a substance called amygdalin, made from bitter almonds. It is a bitter-tasting substance and consists of four elements which it is not necessary that I should name. In this other bottle I have a paste formed of sweet almonds, which have been crushed with a pestle and mortar, and I will put some of it into the warm distilled water in this flask. Into the mixture I will put some of this amygdalin. If I were to leave it without that addition, there would be very little change; the substance would gradually subside, but there would be no product given off in the way you will presently see. After letting it stand for a few minutes, I will pour some of the mixture into an open vessel, and we shall be able, without difficulty, to perceive a fragrant smell, which is due to the presence of a liquid of which I have a quantity here, a substance known by the name of oil of bitter almonds. If we were to perform the same experiment on a large scale, and macerate some of this amygdalin with almond paste, put them together with warm water, distil the mixture and collect what comes over, we should find that water would pass over and with it would be a few drops of oil of bitter almonds, and the amygdalin would be decomposed in the process. There is in the sweet almond paste a substance which I cannot describe in better terms than by comparing it to that gluten which I showed you just now. It is very similar to it in its composition, and by the contact of this, the synaptase, as it is called, with the amygdalin, the elements of the amygdalin are broken up into several products; one of them is the oil of bitter almonds, another is prussic acid, which generally accompanies the oil, the third is a variety of sugar of the kind which is called grape-sugar and there is probably also some formic acid. Here we have the breaking-up of a complex body—amygdalin—into several simpler bodies by the action of the body called synaptase; but there is not in the process, as far as I know, any living organism at work. There is a substance which is somewhat similar to these living organisms, but there is no organized structure, as far as our knowledge goes at present.

Take another experiment. I have here something which is not a *blanc mange*, although it looks something like it; it was made by boiling potato-starch with water. We let it cool, and then turned it out; some was put into a flask with two or three ounces of crushed malt. It was warmed to a temperature of 60° Centigrade for about an hour; there was no boiling. The substance was then squeezed through a cloth to keep back the husks of the malt, and here is the liquid which ran through. It is perfectly liquid, and its consistency is entirely different from that of starch, from which it was made; it is quite sweet to the taste, and there is a large quantity of sugar in it. There is also another body which we class with the sugars; that is, there is in this liquid a good deal of a kind of gum, which we call dextrine, which would easily pass into sugar. The starch, when it was being converted by the action of the malt into those soluble bodies, did not, so far as we know, break up into simpler substances; the process was of a different kind. It assimilated the water—the starch combined with the water, and at the same time divided itself, some of it forming one and some the other product. Here, also, there was not, as far as my knowledge goes, any ferment or any organized cells in the liquid. If they were present it was an accident, and was not essential to the change which took place. I am the more confident in saying that no ferment was there present, for we can get, and we very often do get, precisely the same formation of starch without any malt at all. If, instead of warming some of that starch with the infusion of malt, I had mixed it with a little—about five per cent.—of that strong sulphuric acid, and had heated it, it would have been dissolved almost like sugar in water. In fact, there are now in Germany, and also in England, manufactories in which starch is converted, by the action of dilute sulphuric acid, into grape-sugar, and the same change which we get by organic substances —that is the point—we also get by the action of this mineral acid.

Another change of the same kind I may mention, especially as the subject of it is in itself interesting. I have here a substance which people have been accused of making for the purpose of adulterating quinine. It is made from willow-bark, and is believed to possess febrifuge qualities, so that there was some little excuse for what I have mentioned. This substance is called salicine, and when heated with dilute sulphuric acid, in the same way as the starch when so heated was converted into sugar and dextrine, this salicine breaks up in a way which I might compare with that in which some bodies are broken up by fermentation.

Another case of the same kind is afforded by tannin, a substance extracted from gall-nuts, and which is present in oak and many other barks. It is used for combining with gelatine, which is the principal constituent in hides, to form leather. If we dissolve this tannin in water, and leave it in an open vessel, it will get mouldy; and if you examined it after some time you would find none of it left. It would all disappear, just like sugar in the process of fermentation, and in place of it you would find, in that particular process, a body which you might easily crystallize out from the liquid, and which I have here; it is called gallic acid. It is a body resembling tannin in some respects, for instance, in the property of forming, in combination with iron, a dark substance, which is used in suspension in water, for writing-ink. But it will not do to form leather in combination with gelatine. If you left the tannin in an open vessel, it would decompose, and there would be left gallic acid, and some other material which was formed at the same time would have disappeared. By boiling tannin with dilute acid, we get the process performed more regularly. Upon boiling some tannin with dilute sulphuric acid, you would find that water would be taken up by it, the tannin would combine with water, and it would break up into sugar and gallic acid, the process being exactly like that which I mentioned in the case of salicine. There is a most direct analogy between the process of breaking up which sulphuric acid effects upon tannin and that of fermentation. I ought to say, when telling you of the decomposition of the tannin, that it is effected by little animal organisms present in the liquid, and it appears that they are the agents of the transformation.

Then there are some other processes of considerable importance, from their occurrence in the animal economy —processes which I believe must be classed between those experiments which I showed you a little while ago and the process of fermentation,—I mean processes which occur in the operation of digestion. I have here a gelatinous solid, which contains a substance called pepsine, which was made by dissolving the inner lining of a pig's stomach in diluted hydrochloric acid at about blood-heat. The inner lining of the stomach of that and similar animals is dissolved gradually, and that solution possesses the property of dissolving muscular fibre, white of egg, and other similar substances; it is, in fact, artificial gastric juice, and it would, for instance, dissolve that lump of gluten which I showed you just now —which looked something like india-rubber—and when this pepsine dissolves albumen by digestion, for the process is doubtless of the same kind as that which occurs in the animal economy, it does so by breaking it up into bodies which are no doubt simpler than itself, bodies which we do not know accurately and fully. They are called peptones, for it is common enough to give names to bodies even before one knows them well. I do not know whether it is a good plan, but it is customary. These bodies are a good deal similar to those which are present in malt, and in such like mixtures which have undergone vital changes.

Then I will give you one or two other cases of similar processes. Here is a singularly beautiful acid, called hippuric acid, which decomposes with very great readiness if left in the liquids in which it is originally found. When that organic mixture is exposed to the air, it undergoes a process of putrefaction. The general appearances which take place in the liquid while the substance is decomposing would certainly be described by anybody as a putrefactive process, and there is formed by its decomposition some of this other beautiful acid, called benzoic acid, because it was originally obtained from the fragrant gum benzoin. At the same time there are other products given off which decompose. Now, we can by mineral substances effect the same decomposition of that hippuric acid. A German chemist, to whom we owe many researches in these matters, showed, some years ago, that if you boiled hippuric acid with dilute sulphuric acid, it takes up water, and breaks up into benzoic acid, and this crystalline substance, called glycocol or sugar of glue. It got that name from the circumstance that it was obtained originally from glue by a decomposing action, and it has a sweet taste. It has no analogy to sugar in its nature, but it has that superficial resemblance that it is rather sweet.

This hippuric acid affords another case of a body which is broken up either by putrefaction, or by the action of dilute sulphuric acid. It affords a strong argument, and other cases I have adduced afford, like it, an argument that the action of these organic substances resembles the action of sulphuric acid. If we get the same change in several cases by the action of an organic body as by the action of a mineral body, the fact certainly goes some way towards showing that the two substances must be, in their mode of action, generally alike. There is another case, that of urea, which in contact with water forms a carbonate. That may be done by either class of re-agent.

There are, however, some chemical processes even simpler than these, and for that reason they are better known to us, which really may be studied with advantage side by side with those I have mentioned, and they will, I think, afford us, on further consideration, a key to the explanation of these processes. I will only mention two. One is a process which is well known in its general features, and it is a process of breaking up truly analogous to those I have mentioned, but a perfectly simple breaking up of alcohol into two substances, both of them well known now, one being water, and the other ether. It is a process which consists in dividing the elements of alcohol in such a way as to get nothing formed but these two products, though side by side with this change there are some secondary changes which do not belong to the process. This change is effected solely by the action of oil of vitriol or sulphuric acid. It has been long known, and it was a subject of wonder for some time that, if sulphuric acid is mixed with alcohol and heated, you can distil off some alcohol from the mixture in the form of these two products; then you may add some more alcohol, and if you distil that off, it is also broken up into ether and water; then you may add some more again, and you may go on adding alcohol to that original quantity of sulphuric acid, and it will decompose each successive portion into these two products. There is no limit known to the extent to which sulphuric acid will effect that change. You perceive, therefore, that this, in its general features, is a process analogous to those which we were considering at first.

I may illustrate that by an experiment. First, I will show you how we discover the presence of sulphuric acid. The common test is, to add some salt of baryta—this which I have here is a chloride—to the sulphate, when we get at once a precipitate, sulphate of baryta. The sulphuric acid, in making the ether, passes over into a compound that does not possess this property. I have some of it here. It is a clear liquid, and on mixing it with the same re-agent I used just now, you see that it will not form the precipitate; I put some of the same baric chloride into it, but, as you see, the liquid remains clear. But I can bring back my sulphuric acid to its original state. Mr. Taylor, my assistant, was heating some of it just now, and it has been standing so long that it has returned to its original state already. It has returned from the state in which it does not precipitate baryta to the state in which it does. There is in the process a successive departure of the sulphuric acid from its ordinary state, and a return to that original state; it is a kind of circle or cycle. The substance passes over into a compound which does not precipitate baryta, and then it returns again to its original form, and that is the key to the anomaly. When the sulphuric acid has effected the decomposition of one portion of alcohol into ether and water, it comes back again to sulphuric acid, becomes exactly what it was in the beginning, and is able to recommence precisely the same combination. I will give you another example of it. I have here a substance used in one of the commonest manufactures, that of oil of vitriol, in which the same operation occurs. I have there a substance at work called nitric oxide. It is converting a quantity of sulphurous into sulphuric acid. In principle it would so convert an infinite quantity, but in practice it is limited by convenience. It acts by carrying oxygen from the air to one portion of sulphurous acid and then to another, and thus it goes on, and effects successive oxidations of a great number of particles of sulphurous acid, forming sulphuric acid from them, and it does that in virtue of a process perfectly analogous to that which I just now mentioned. The gas, after one operation, returns to the same state in which it was in the beginning of the first operation; it is a cyclical process. I have here some of the nitric oxide combined with oxygen, and when in that state it has the red colour which you see in the flask. If we blow a little sulphurous acid into it, the red colour will disappear as the nitrous acid gives up the oxygen, the nitric oxide itself being a colourless compound, but in combination with oxygen it is red. As the sulphurous acid passes into it, the nitric oxide parts with the oxygen and becomes colourless, but on again blowing in a little oxygen it returns to its former red colour. This shows you that there are processes, of simple, normal, chemical action, somewhat analogous to those fermentive properties which I formerly described. Each one of these processes takes place in perfectly definite proportions, the peculiarity being that one material which takes part in them returns at the end of one operation to the same state in which it was at the beginning of the operation, so that the processes are cyclical, and this re-agent is able, by acting successively on a large quantity of particles, to repeat its action very frequently upon them, and beyond what would appear to be its definite combining proportion. You see this red compound of nitric oxide and oxygen has lost a great deal of its red colour. I will not wait until it is completely bleached, but will blow in a little oxygen, when we shall get a return to the original deep red colour. This is the ordinary process by which sulphuric acid is made on a large scale in lead chambers. The sulphurous acid is allowed to remain a considerable time in the chamber, and is passed on from one to another, as it is acted on by the nitric oxide, which passes through the successive stages of its action by a process which I should be glad to name cyclical, as I shall have occasion again to revert to a similar process of the same name. At our next meeting I shall have to analyse some of the best known, and also some less familiar instances of cyclical action, that we may arrive at a conception of their nature.

Parliamentary and Law Proceedings.

In the County Court of Yeovil, *August 16th*, 1870.

The Pharmaceutical Society *v.* Colmer and Wife.

BEFORE CHARLES SAUNDERS, ESQ., JUDGE.

The defendants were husband and wife, and were sued for the penalty of five pounds, incurred by their using the title of Chemist and Druggist, neither of them being registered under the Pharmacy Act, 1868.

Mr. Flux (of London) appeared for the Society, and Mr. Wood (of London) appeared for the defendants.

Mr. Flux, in opening the case, said that the action was brought in the exercise of powers which the Society used with reluctance, as was shown by the fact of the case being but the third which had been brought under the statute. The defendants' course of conduct had rendered the action a necessity, because the title was used by them with distinct knowledge that they were violating the law; and upon the customary application being sent to them before action, they replied by a letter so defiant that to avoid the issue of a plaint was a virtual impossibility. The letters having been admitted, he read them as containing an admission that the defendants were using the title chemist and druggist, and then referred to the sections 4 and 15 of the Act of Parliament, as showing that the defendants had incurred the penalty, and that the register proved itself, and was conclusive in favour of the plaintiffs. As, however, the defendants were, by their attorney, prepared to admit the use of the title, he asked the Court to accept and record the admission, and also, as the defendants desired an opportunity of cross-examining the Registrar, he (feeling it desirable, in a matter of the kind, to pursue the most open course) should put the Registrar in the witness-box, and ask him a few formal questions, in order to afford the other side the opportunity for the cross-examination.

The Judge (to *Mr. Wood*).—Do you admit that the defendants used the title Chemist and Druggist?

Mr. Wood.—I do.

The Judge.—Then I shall take a note of the admission. What have you to say?

Mr. Wood then raised a technical objection to the form of the particulars of debt, but that was overruled.

Mr. Elias Bremridge was called, and proved that he was the Registrar of the Pharmaceutical Society of Great Britain and brought the action with the sanction of the Council of that Society.

Cross-examined by *Mr. Wood.*—I was appointed Registrar, and was authorized to bring this action by resolutions of the Council, which are recorded in minutes.

Mr. Wood (to the *Judge*).—I raise the objection that the facts of the witness being the Registrar and being authorized by the Council, can only be proved by production of the minute-book.

Mr. Flux.—I submit, Sir, that the witness derived his authority not from the record of the resolutions in the minute-book, but from the resolutions themselves as they were orally passed; that the witness is acting in the exercise of powers cast upon him by the Legislature; and that he is not to be called upon to prove his authority by the production of any minute or other books.

The Judge.—I consider that the objection is untenable and shall allow the case to proceed. It is never required of officers of the army or others acting in public capacities that they shall produce their commissions or other written authorities. It is enough for me that the witness is acting in the capacity of registrar in the bringing of this action, and that no evidence calling his status in question has been given; but I will take a note of the point, in order that Mr. Wood, if he pleases, may look into authorities and bring the subject before me by way of motion for a new trial.

Mr. Flux.—Perhaps your Honour will take judicial note of the fact that in the Register of Chemists and Druggists there is printed the full name of the witness, with his description, "Secretary and Registrar of the Pharmaceutical Society of Great Britain."

The Judge.—I will do so.

Cross-examination continued:—I received from the defendant Mrs. Colmer, forms filled up according to Schedules C and D of the Act. The one was signed by her and the other was signed by a person purporting to be a duly qualified medical practitioner and whom I believe to be a son of the defendants; they were dated 30th November, 1868. I received afterwards similar papers dated the 20th March, 1869, and signed by the male defendant and by the same medical practitioner, and I afterwards received papers dated 6th April, 1869, also signed by the male defendant, giving his address as of a place in London, and purporting to be signed by a duly qualified medical practitioner.

The male defendant tendered to me £5 as provision for fees upon the registration of his name.

Re-examined.—I was not satisfied by either of the sets of papers, and I did not enter the names of the defendants or either of them upon the Register of Chemists and Druggists. The judgment exercised by me upon the papers was so exercised *bonâ fide*. The cases of the defendants are not the only cases, by many hundreds, in which papers in due form failed to satisfy me. I have informed both of the defendants, over and over again, that they have not been placed on the Register. The statute gives an appeal to the Council, but no appeal by either of the defendants has ever been made.

Mr. Flux.—That is my case, your Honour.

Mr. Wood then, without calling witnesses, addressed the Judge upon the facts, and contended that, it having been elicited upon cross-examination that each of defendants had sent to the Registrar forms in accordance with Schedules C and D of the Act of Parliament, it was thus proved that the defendants were, by force of the clause numbered 5 in the Act of Parliament, chemists and druggists, and as such entitled to be registered; but that whether they were registered or not, they were chemists and druggists within the meaning of the statute, and not exposed to the penalty for which the action was brought.

Mr. Flux contended that the published Register was conclusive against the defendants that the Registrar had exercised *bonâ fide* a *quasi* judicial function, and that it was not contemplated by the statute, or in accordance with the practice of the law, that the *bonâ-fide* decision of the Registrar should be revised by a Judge sitting in a Court; that the issue before his Honour was not whether the defendants were entitled to be placed on the Register, but whether not being on the Register, and using the title Chemist and Druggist, they had incurred the penalty under the statute. He then referred to the preamble, and the sections 1, 5, 13, 15 and 26 of the Statute, arguing that they were consistent with each other, and only consistent with the construction of the 13th and 15th sections for which he contended, namely, that having regard to the admission of the defendants that they used the title Chemist and Druggist, the only question for the Court was whether they were upon the register; and then read M'Call's case and Marwood's case, as reported in the March number of the PHARMACEUTICAL JOURNAL, and the opinion of the Attorney-General therein referred to.

The Judge: It is a rule of construction in relation to Acts of Parliament of this kind, that the Court shall advance the remedy intended by the Act. Now I find that this Act has been passed to protect the public in the matter of the sale of poisons; that the preamble says, "It is expedient for the safety of the public that persons keeping open shop for the retailing, dispensing, or compounding of poisons, and persons known as Chemists and Druggists, should possess a competent practical knowledge of their business." I find also, that by section 13, provision is made for a register of the qualified persons, and the Register is made evidence. It is admitted that the defendants use the title Chemist and Druggist, and the Register —published in accordance with the Act—is in my hands, without their names appearing in it. I cannot adopt the view which has been contended for in the interests of the defendants, and I consider that the plaintiffs are entitled to recover the penalty provided by the fifteenth section.

Judgment for the plaintiffs.

Generation of Heat by Fungi.—Dutrochet has observed that there is more heat generated by *Boletus æneus* than by any other vegetable, with the exception of Arum. This phenomenon is, however, by no means confined to *B. æneus*, but is, I believe, common to all Boleti; and when decomposition has set in, the heat evolved is considerable, but even when perfectly young and fresh all the Boleti give out heat. Whilst packing up the three large and beautiful specimens of *B. colopus*, Fr., exhibited by me at the last meeting of the Royal Horticultural Society, I noticed the decided heat evolved from the specimens. At the time of packing, my plants were perfectly fresh and young, and after being placed in a light paper box for a short time, the heat evolved was apparent to the hand. I tested the heat with a thermometer, which stood outside the box in a shaded room at 70°, this after being placed in the box with the Boleti for half an hour rose to 75°. This fine species, though I believe rather rare elsewhere, is common in early autumn in Epping Forest, where it grows in company with another beautiful species, *B. pachypus*, Fr. Both attain here very large dimensions, and the former is extremely beautiful; the tubes are at first brilliant yellow, then orange; the stem deep carmine with a rich maroon base; flesh immediately changing to bright blue when cut or broken.—*W. G. Smith in Gardeners' Chronicle.*

Effects of Godfrey's Cordial.—An inquest has been recenly held, at Nottingham, on a child five months old, who having suffered from diarrhœa, had Godfrey's Cordial administered to it by its mother. The child succumbed and a *post-mortem* examination showed that death had been accelerated by opiates. A verdict in accordance was given and the mother was reprimanded by the coroner for her conduct in administering the "remedy."—*Medical Times and Gazette.*

BOOK RECEIVED.

SNUFF TAKING: its Utility in Preventing Bronchitis, Consumption, etc. By JOHN C. MURRAY, M.D., F.A.S.L. London: Churchill and Sons. Newcastle-on-Tyne: D. H. Wilson.

The following journals have been received:—The 'British Medical Journal,' Aug. 27; the 'Medical Times and Gazette,' Aug. 27; the 'Lancet,' Aug. 27; the 'Medical Press,' Aug 31; 'Nature,' Aug. 25; the 'Chemical News,' August 26; 'Journal of the Society of Arts,' Aug. 26; 'Gardeners' Chronicle,' Aug. 27; the 'English Mechanic,' Aug. 26; the 'Canadian Pharmaceutical Journal' for August; 'Répertoire de Pharmacie' for August; 'Revista Farmacéutica' for June; 'Notes upon Books,' from Messrs. Longman.

We have received from a correspondent the 'Glasgow Daily Herald' for Aug. 18 and 20.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

HOSPITAL DISPENSING.

Sir,—The *Lancet* finds fault with your editorial comments in regard to the above topic. Whilst the *Lancet* takes medical affairs under its especial charge, the PHARMACEUTICAL JOURNAL may surely be allowed to criticize the dispensing arrangements of the hospitals and dispensaries without being accused of a sinister motive. The safety of the poor is as much the interest of the State as that of the rich, and I know of no valid reasons why lotions, liniments, etc., of a deleterious character should not therefore be supplied to out-door patients in "poison" bottles. If it became the rule to do so, the poor are not so ignorant as not to become aware why such bottles are given them, and they would soon learn to keep them for their legitimate use. To provide such bottles the funds of the hospitals are available.

The majority of the members of the Pharmaceutical Society have indeed objected—rightly so, I think—to any interference with the internal arrangement of their pharmacies, believing that the individual pharmacist can best provide for the safety of the public by storing poisons in his own way, and according to the special circumstances he has to deal with. The *Lancet* has forgotten to note the errors of the class which it essays to represent. "Those who live in glass houses should not throw stones." How many medical men—dispensers of their own physic—send out mixtures, lotions, etc., in one description of bottle! Will they consent to submit their surgeries to inspection, or their pharmaceutical knowledge to the test of our examinations? Let me also inquire whether medical men are less liable than chemists and druggists to poison people by mistake? I trow not. Whilst the *Lancet* is advocating penal enactments against those who are assumed to be so presumptuous as to invade the domain of the surgeon and the physician, let the PHARMACEUTICAL JOURNAL draw attention to "unqualified" pharmacists. Their name is legion, and they abound most in that body of which your contemporary is the accredited organ. "A fair field and no favour" is the motto of yours truly,

August 29th, 1870. MINOR ASSOCIATE.

PLASTER-SPREADING.

Sir,—In your issue of August 13th there is a paragraph relating to the fixing of paper margins in plaster-spreading. No doubt the suggestion there made is effectual as regards adhesion, but will it not be open to the objection of leaving a sticky margin liable to discoloration? The plan I have used for some years past is to cut out the margin, in one piece, from brown paper, thoroughly soak it in water, then lay it out flat on the counter, and remove the superfluous moisture with a cloth; the other side, which will be quite wet, is laid on the skin, and firm pressure applied with the cloth. If this be properly managed,—and it requires but little practice,—sufficient adhesion takes place, so that, when the paper is removed, a clean and smooth margin is left, free from stickiness. This method I know to be followed by many dispensers, but still it may be a wrinkle to others.

Liverpool. T. H. HUSTWICK.

PROFESSOR REDWOOD'S ANNUITY.

SIR,—I quite agree with every word of the letter addressed to you by Mr. Halliday. He happened to be a fellow-student of mine at Bloomsbury Square; and, though I do not know whether the students of that session were specially favoured by Dr. Redwood, I believe few of them would object to the vote of the Council as regards his annuity, or fail to regard with surprise the opposition it received at the Council meeting.

I could say a good deal upon this point, but, with your permission, I will simply state that much of the voting upon that occasion by some of the "*new blood*" was entirely at variance with the way I should have voted myself, and is far from the way I expected they would act.

W. Y. BREVITT.

Wolverhampton, August 27th, 1870.

Sir,—Though anonymous letters should be passed over in silence, as productions which the author himself is ashamed of, still, since "Pharmaceutist," in last week's Journal, assumes to award the "thanks of the whole members" (*sic*) of our Society to those gentlemen who so strongly resisted the motion for an annuity to Mr. Redwood, I, for one, desire to be excepted from such company, preferring to range myself on Mr. Halliday's side. I see nothing to be proud of in curtailing the moderate salaries and incomes of those who have spent their best years in teaching us. If some of their pupils claim to be more clever now than their former teachers, this, if true, would only prove that teacher and pupils have both done their duty; in a properly-regulated mind it would produce a sense of gratitude, not a desire for persecution.

J. SCHWEITZER.

86, *King's Road, Brighton, August 27th*, 1870.

HOW TO DRIVE AWAY MOSQUITOES.

Sir,—In the last Journal you have a paragraph headed "How to Drive away Mosquitoes." I was last autumn at Venice in the "mosquito season." The special curtains round the bed quite failed to exclude the blood-thirsty villains, so I went to the "Farmacia Reale," and was supplied with some pastilles to burn. They appear to be composed of coarsely-powdered *Pyrethrum roseum*, made into a mass (with solution of olibanum or other odorous gum), rolled out about half an inch thick, and roughly cut into conical pieces one and a half inch long. The attractive label, "Sonni tranquilli," is not to be withstood by sleepless foreigners. I nearly choked myself by burning three or four at a time inside the mosquito nets, and the only appreciable effect was that the wretches were driven mad, and attacked with insatiable fury. Directly the candles went out they charged through the clouds of incense, and the morning light showed on blistered face and half-closed eyes how little they care for what you euphoniously term "the immemorial and most beautiful rite of burning frankincense." I send you the remnant of a box—possibly, the museum has no specimen of these pastilles. Yours obediently,

WM. MATTHEWS.

12, *Wigmore Street, August 24th*, 1870.

[*** The virtue of mosquito curtains depends upon their being properly arranged, and carefully tucked in all round the bed. Of course if this be done with one or more mosquitoes inside the curtain, the other tenant of the bed is likely to suffer.—ED. PH. J.]

Co-operative Trading.—Our correspondent "Anti-Stores" appears to be under some misconception in regard to the price-list he mentions, which is one advertised by a grocer's firm, not by a co-operative store. The prices quoted are, in some instances, very low, but it seems nevertheless to be a case of fair competition,—always provided that the goods are of proper quality.

Mr. B. M. Johnson informs us, with reference to Professor Tuson's paper on pepsine, that he has once been supplied with pepsate of lead instead of pure pepsine.

M. R. J. (Chipping Sudbury).—Application should be made at Apothecaries' Hall.

A. B. (Hertford).—The question is a legal one. You should consult your own Solicitor, or apply to the Solicitor to the Excise at Somerset House.

James Batham (Manchester).—The formula for Syr. Ferri Phos. c. Quinia et Strychnia (Easton) is given at page 125 of the last edition of Squire's 'Companion to the Pharmacopœia.'

Mr. J. Coles, of Coleshill, has forwarded a copy of the enclosed prescription, in order to elicit through these columns the opinion of the trade as to how he ought to have dispensed it.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. CHURCHILL, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

THE SOURCE OF MUSCULAR POWER.

BY BARON LIEBIG.

So far as anything is known of the processes of oxidation that take place at temperatures not exceeding the heat of the body, the conversion of non-nitrogenous substances into carbonic acid and water, as well as the conversion of nitrogenous substances into carbonic acid, ammonia and water, takes place in the same way that urea is formed from uric acid. There are formed products containing less hydrogen and more oxygen, until at last the most highly oxygenated product yields carbonic acid by a further addition of oxygen. Thus alcohol is converted first into aldehyd, then into acetic acid; this again into formic acid, which then yields carbonic acid.

The highly complex nitrogenous compounds always undergo at first a breaking up into products that on the one hand contain a larger amount of nitrogen, while the others are free from nitrogen, or contain a smaller amount of it with a larger amount of carbon. These products are then converted, like uric acid and non-nitrogenous substances, into carbonic acid, ammonia and water.

Urea may be regarded as carbonic acid, in which one equivalent of oxygen is replaced by amidogen, or as ammonia in which the third equivalent of hydrogen is replaced by carbonic oxide.

$$C\left.\begin{matrix}O\\NH_2\end{matrix}\right\} \text{ or } N\left.\begin{matrix}H_2\\CO\end{matrix}\right\}$$

In the animal body oxidation of non-nitrogenous compounds takes place in the presence of alkalies, and in many cases I believe the law of oxidation discovered by Kolbe also obtains. This explains the formation of substances containing little or no oxygen out of others that contain much.*

From what has been said it will be intelligible that muscular power, if its source is in the muscles, does not originate by combustion taking place in the same way as in the furnace of a steam engine; it can only be the result of a material transformation, that is to say, of motion taking place in the interior of the muscles.

A closer consideration of the behaviour of yeast-cells is perhaps calculated to afford a more definite idea of the process that takes place in the living muscle.

Whatever view one may hold in regard to the mode in which the yeast-cell acts upon sugar, it is at least certain that within the yeast-cell there is motion, by means of which it acquires the capability of performing external work, consisting in the breaking up of a carbohydrate and similar compounds. This work, however, is chemical not mechanical, as it would be if a piece of wood were split.

Some notion of the magnitude of the force exerted in the action of yeast may be formed from the fact that a particle of yeast will bring about the conversion of at least sixty times its weight of sugar, or, as I believe, even upwards of a hundred times its weight.

This breaking up of sugar is accompanied by a considerable evolution of heat, and by a mechanical effect. According to Dubrunfaut's direct determination, 1 gram of sugar evolves in fermentation 127 units of heat; in addition to this, the carbonic acid gas disengaged has to overcome the pressure of the atmosphere, thus performing work that must be taken into account as corresponding to 2482 gram-meters for each gram of sugar.

Assuming then that yeast decomposes sixty times its weight of sugar, it follows that if the evolution of heat and the exercise of force be referred to the yeast alone, without regard to the sugar, each gram of yeast is capable of developing $6 \times 127 = 7620$ units of heat, and a mechanical effect equal to 148,960 gram-meters, or very much more than it would produce by combustion, and that is done without the access or co-operation of oxygen.

Supposing a system of pipes and vessels as delicate as the blood-vessels in the muscles, and the walls of those vessels to be forming entirely of yeast-cells, with a stream of sugar solution moving through these vessels, we should then, by the determination of the heat generated and the mechanical action produced, be forced to regard this apparatus as a very enormous source of heat and power.

If we knew no more of sugar and of the behaviour of yeast in fermentation than we know of blood and muscle in the work performed by muscles, we should not be in a position, by the determination of the decrease of weight in the system and of the heat of combustion of the substances that the system consists of, to form any conception of the magnitude of the causes acting in it.

If in place of sugar solution we suppose that a current of beer-wort (which includes conditions for the multiplication of active yeast-cells) flowed through the system of yeast-cells, then the loss of weight undergone by the working cells would be made up for by the production of new cells; the system would increase in mass and circumference, while its action would be proportional to its largest section.

On the presumption that in the alteration undergone by sugar in its passage through the supposed system of cells, we might undoubtedly ascribe the carbonic acid and the heat produced, as well as the mechanical effect (which are indications of an oxidation process) to combustion, then we might compare the process to that taking place under the boiler of a steam-engine, and the parts of such an engine with the apparatus consisting of cells.

However, this representation would be entirely false: the oxygen of the air may take part in the process of fermention, as in the conversion of alcohol into acetic acid, but it is not the determining cause of it; the carbonic acid evolved and the heat developed are not products of combustion.

The cause to which all these actions must be ascribed lies in the mobile cell contents and in the motion to which that is subject.

If we compare the behaviour of a muscle with that of the yeast-cell, we know that a constant metamorphosis or motion is taking place in it, and that this goes on even when the muscle is separated from the body. During this alteration the muscle is capable of performing a certain amount of mechanical work; the internal or molecular motion in the muscle is quite independent of the exterior motion of the mass; it takes place during rest and in the absence of irritation, without the muscle showing any sign of external motion; but the latter is dependent upon the internal motion, and when this has attained a certain magnitude the power of the muscle for performing mechanical work is extinguished.

This behaviour corresponds exactly to that of the yeast-cell; the transformation of its cell contents is quite independent of the sugar.

* Ann. Chem. Pharm. lxx. 318.

The most distinguished physiologists have occupied themselves with measuring the absolute muscular force, and they have found that it is proportionate to the largest section of the muscle.

Even the severed muscle exercises its capability of doing work, though there may be no stream of blood moving through it and conveying oxygen or combustible elements, but without any command from the central organ the potential energy becomes active force; heat is generated and carbonic acid evolved, together with certain other products, by the accumulation of which, in the interior of the muscle, it becomes tired. The simple removal of those products, by injecting a weak solution of salt, again sets up the capability of doing work for some time.

The difference in the behaviour of a muscle in the living body from that of one severed from it is, that the capability of performing work continues in the living organism, while it is speedily exhausted in the muscle that has been severed from the body.

However, the explanation of the continuance of the capability to perform work is not the first but the second question that has to be considered here.

The duration of this state depends upon the circumstance that the muscle is always being restored to its original condition, while the products that interfere with its working capability are incessantly removed from it; still a muscle remains for a time capable of performing work in the absence of all conditions for its nutrition.

A frog's heart, entirely freed from blood by injecting a weak solution of salt, will continue to work for twelve hours and more just as in the living body. In this condition we can scarcely compare it with anything else than a bent spring that gives out in motion the force it has acquired by its tension. The mechanical tension depends upon an altered position of the ultimate particles of the spring; the motion ceases when those parts have been again restored to their original position. In a manner quite similar, we see that with the mechanical effects produced by a muscle there is an alteration in the arrangement of its particles, and in the absence of all other causes that determine performance of work, it is impossible to avoid the opinion that the motion of these particles is the source of muscular power just in the same way that the change in the condition of the contents of the yeast-cell is the cause of the breaking up of sugar in fermentation.

It is known to physiologists that all the blood may be removed from a frog by injecting a weak solution of salt, and that the animal will nevertheless move, jump and breathe like a living frog for hours. In reality the animal does not, in this case, behave differently from its leg after separation from the body, though the phenomenon is one that must astonish any one who is not a physiologist.*

* I recently received a letter from my friend Professor O. N. Rood, of New York, in which he communicated to me the following case: Professor Agassiz has been occupied for some time in catching sharks for the purpose of studying their anatomical structure, and on one occasion a shark that had been hooked struggled in the usual violent manner before it was landed; but on dissection the animal proved to be almost entirely destitute of blood. Closer examination showed that it had been attacked by a parasite, and the gills were in some places eaten through, so that nearly all the animal's blood had been extracted, and its place taken by sea-water. Agassiz mentioned this fact in order to show that the shark may retain its power undiminished for some long time after having lost nearly all its blood.

It is indeed scarcely possible to do otherwise than think that the force of the most complex constituents of plants and animals, manifesting itself in motion, rests in their composition; and that this force comes into action in a definite direction in consequence of the physiological arrangement of those constituents, —or, in other words, their conformation in the organs of the living body, which are built up of these materials.

In order to understand this, it is only necessary to remember that the yeast-cell, in causing fermentation, loses a part of its nitrogenous constituent, which does not in itself possess the power of causing fermentation, though it acquires that power when it has served for the construction of a new cell, and has regained its original arrangement.

It is not easy to form any conception as to whether, and in what way, heat may be concerned in the performance of work by muscles; the difficulties in this respect will, perhaps, be less when we are better acquainted with the substances by the metamorphosis of which muscular work is done.

The unaltered composition of syntonin and albumen in muscle appears to prove that there is no breaking up of them in the muscle, and consequently we must assume that it is by substances of very much higher tension that the performance of work by muscles is brought about. It may be that these are products which originate from albumen by the action of oxygen, taking up heat in their formation, as is the case in the formation of chloride of nitrogen. The fact ascertained by Pettenkofer and Voit, that, in a state of rest, there is an accumulation of oxygen in the body without any corresponding formation of carbonic acid, may perhaps be taken into account in regard to this point.

It is conceivable that, in the breaking up of these substances, the heat taken up or rendered latent may be converted into its mechanical equivalent; in this case the performance of work must be preceded, or at least accompanied, by a development of heat by oxidation, possibly of non-nitrogenous substances.

The existence of such compounds in muscle is perhaps indicated by the fact that Frankland was not able to determine the heat of combustion of creatin, because it always exploded violently in the tubes, just as some cyanogen compounds do when they are burnt with nitre or chlorate of potash. As regards cyanogen, we know that in its formation there is a very considerable amount of heat absorbed. However, it must not be supposed that there is yet any ground for saying whether, or in what manner, creatin may be concerned in the production of muscular force.

Helmholtz's observation that there is a sensible rise of temperature in the working muscle separated from the living body, may perhaps lead to a solution of this problem when the collateral conditions of the rise of temperature shall have been more accurately ascertained.

The most difficult thing, which may perhaps never be explained, is the influence of the nerves upon muscular work. A muscle, as an apparatus for performing work, evidently behaves in a manner similar to the apparatus for producing electricity in electric fish.

In these animals electricity is produced by a metamorphosis in the small voltaic couples, and a certain store appears always to be maintained, which is, in the state of rest, distributed in the apparatus for the production of the force, or is applicable for other purposes in the animal; the force is not generated at the moment of its application.

It is evidently dependent upon the will of the animal, determined by the nerves, to bring about such an arrangement in the parts of its electrical apparatus that the distributed free electricity may be collected and applied in giving shocks. Frequent discharges fatigue the animal, and rest as well as food are requisite in order to renew the accumulation of electricity.

The nerves in the muscular apparatus appear to act in a similar manner; under their influence the metamorphosis which is constantly going on receives a special direction in such a manner that the existing molecular motion is converted into a motion of mass.

Any more detailed explanation of the processes taking place in muscles by which contraction is determined, and upon which their capability of performing work depends, would have to be regarded as hazardous in the present state of our knowledge.

The only points in regard to which we are no longer in doubt are that the muscular force is not produced like the motive power in a steam-engine, and that the simple assumption of its being produced by combustion of non-nitrogenous or nitrogenous substances in muscle leaves us without any help in regard to this obscure subject; it is a mere formula without meaning which perplexes more than it asserts.

When a constituent of a muscle produces a mechanical effect, it must undergo chemical alteration from its soluble and mobile constituents; there must be other compounds formed gradually, and this must continue so long as the muscle is capable of performing work. Subsequent more exact investigation will render this more intelligible; and for the present it may be said with certainty that among the products thus formed urea is not one, for it is not to be detected either in the living muscle or in muscle that has been separated from the body.

Hence it necessarily follows that muscular work and the production of urea do not bear any direct relation to each other, consequently the work performed during a certain time cannot be measured by the quantity of urea secreted during that time.

The astonishing observations of Dr. Parkes* do not, as I believe, admit of any doubt in regard to this point. I regard them as the basis of the true law by which we have to judge as to the metamorphosis of muscle in the animal body.

These experiments were made upon two healthy soldiers (S. and B.) of dissimilar bodily weight. During sixteen days they consumed in their food equal quantities of nitrogen. Their food consisted of bread, meat, vegetables, etc., in such proportions that their bodily weight was maintained almost constant. The experiments were divided into five periods. During the first period both men did their usual work; during the second they remained for the most part at rest and in bed; during the third period they did their ordinary work; during the fourth period they were put to severe exertion, on the first day making a march of twenty-four English miles over level ground, and on the second day a march of thirty-five miles; during the fifth period they did their usual work. The quantities of urea secreted during these five periods were as follows:—

		Grams.
I. *Ordinary Work.*		
Mean of 4 days.	S. . . .	36·374
,,	B. . . .	37·134
II. *Rest.*		
Mean of 2 days.	S. . . .	38·348
,,	B. . . .	39·100
III. *Ordinary Work.*		
Mean of 4 days.	S. . . .	36·223
,,	B. . . .	37·534
IV. *Severe Exertion.*		
Mean of 2 days.	S. . . .	38·643
,,	B. . . .	40·328
V. *Ordinary Work.*		
Mean of 4 days.	S. . . .	40·811
,,	B. . . .	38·909

These results seem to me to demonstrate unmistakably that the nitrogenous compounds eliminated during muscular exertion are ultimately excreted as urea, and that this does not take place completely at the time the work is done, but at a later period.

During the second period the quantity of urea excreted by both individuals while at rest was increased; during the third period it was the same as in the first period; it increased considerably during both of the days of marching; while in the fifth period of ordinary work it was always higher than during the first and third periods.

Conformably with these results the bodily weight decreased during the second period, while it increased during the third period, again decreased most considerably during the fourth period, and was restored to its original state during the fifth period.

Dr. Parke's memoir on the excretion of nitrogen during rest and work with non-nitrogenous diet also contains a large number of remarkable results, which cannot be discussed here with one exception.

The loss of weight suffered by both individuals during a long march was very considerable, both with ordinary diet and with non-nitrogenous diet.

In the case of S. the loss of weight during this period amounted to 5 pounds and 4 pounds; in the case of B. it was $4\frac{3}{4}$ and $1\frac{1}{2}$ pound. The reason for this loss of weight cannot be doubtful. Both individuals may have lost fat by a greater consumption of oxygen during the severe work; but the greater part of the loss was undoubtedly water; not, indeed, liquid water that could be replaced by drinking, but water that was combined in the muscles and tissues, and had been set free in consequence of the metamorphosis or consumption of muscular substance; the slow restoration of the bodily weight and the necessary co-operation of the food prove that the tissues, which in their natural condition had retained the water eliminated, were altered in their character; four days elapsed in the case of S. and B. before they had again acquired their original weight.

The animal organism has frequently been compared to a railway locomotive in which, by the joint action of air, water and fuel, heat and power are produced. In reality air, water and food, which may in a certain sense be regarded as fuel, are necessary conditions for the production of heat and

* 'Proceedings of the Royal Society,' No. 94. 1867.

power in the animal body also, but they serve for other purposes as well.

The iron and copper of which the parts of the locomotive mechanism consist are not supplied by the fuel, and for the production as well as the maintenance of those parts an external force is consumed on the work of many artisans.

The difference between the animal machine and the locomotive consists in the circumstance that food is requisite not only for maintaining its temperature and producing force, but also for providing the material for the maintenance of its working parts, or building up its organs; even this does not take place with expenditure of force. For the construction of these organs in the proper form and character for performing the work belonging to them, there is required a certain amount of force as in the working up of the copper and iron in the locomotive, though in a different way; but for the production of this working force a certain quantity of material must be consumed.

Moreover, the arrangement of the animal machine is such that its own parts and constituents serve to supply at their own cost its requirements in heat and power, even when food is entirely withheld.

Of the total quantity of force capable of being generated in the animal body, a portion is applied in performing interior work, comprising

a. All involuntary motions of the blood and of respiration, etc.

b. For working up the food into those substances which serve for the construction and restoration of organs, especially the parts of the body.

And it is only the portion remaining after these operations have been performed that is available for the performance of external work.

(*To be continued.*)

MEDICINAL FERNS.

BY M. C. COOKE, M.A.

Ceterach officinarum, *Willd.* "Rusty Spleenwort." Is still employed in Tunis and other parts of North Africa, as well as in Turkey. It was the Cetherak of the Persians. At one time it was strongly recommended in this country in jaundice and diseases of the spleen.

Cibotium Barometz, *Sw.* Yields the "Penawar Jambie" of Sumatra. It is a similar substance to "Pulu" and employed for like purposes. This is the Scythian Lamb of old writers, of which such marvellous stories were told.

Cibotium glaucum, *Hook. et Arn.*; C. Chamissoi, *Kaulf.*; C. Menziesii, *Hook.* "Pulu." All these, if really distinct, are natives of the Sandwich Islands, and yield the substance called "Pulu," which is the silky hair found clothing the rhizome and lower portion of the stalk or stipes. It has been recommended as a styptic. For further particulars, consult 'Pharmaceutical Journal,' Series 2, Vol. I. p. 501.

Davallia tenuifolia, *Sw.* In the Mauritius this forms the basis of the compound remedies used by empirics for tambave, and is often administered internally in decoction without any admixture, and also in the form of a lotion and bath.

Helminthostachys dulcis, *Kaulf.* This fern, Dr. Lindley states, is regarded in the Moluccas as a slight aperient; it is used as a pot-herb, and its young shoots as asparagus.

Lastrea athamantica, *Moore.* Found growing on grassy hills and in moist places near Port Natal. The Zoolu Kafirs, writes Dr. Pappe, who know it by the name of "Uncomocomo," use it as a vermifuge; and its caudex, given in the form of powder, infusion or electuary, has been proved to be excellent in helminthiasis and especially in the cure of the tapeworm.

Mohria thurifraga, *Sw.* Grows abundantly on the Cape mountains, Cape of Good Hope. When bruised it smells of olibanum. In some parts of the colony, Dr. Pappe states that the dry leaves are pulverized and made with fat into an ointment, which is cooling and very serviceable in burns and scalds. The vernacular name is "Brand-boschjes."

Nephrodium Filix-mas, *Rich.* "Male-fern." This is one of the few ferns which continue to maintain their character and position for their remedial properties. The rhizome of the Male-fern has risen rather than fallen in estimation as an anthelmintic, and as such finds a place in pharmacopœias and in regular practice.

Nothochlæna piloselloides, *Kaulf.* Has been employed in India to subdue sponginess in the gums, according to Dr. Lindley; but whether still in use we have no evidence.

Ophioglossum ovatum, *Sw.* This fern, in the Mauritius, enters into the composition of a popular remedy given in tambave.

Ophioglossum vulgatum, *Linn.* "Adder's-tongue." "The leaves of adder's-tongue," writes Gerarde, "stamped in a stone mortar, and boiled in oyle olive unto the consumption of the juice, and untill the herbes be dry and parched, and then strained, will yield a most excellent greene oyle, or rather a balsame for greene wounds, comparable to oile of St. John's wort, if it do not farre surpasse it by many degrees; whose beauty is such that very many artists have thought the same to be mixed with verdigrease.

> "For them that are with newts or snakes or adders stung,
> He seeking out an herb that's called adder's-tongue,
> As nature it ordain'd its own like hurt to cure,
> And sportive did herself to niceties inure."

Osmunda regalis, *Linn.* "Royal Fern." A native of Europe. The rhizome was formerly employed medicinally, but seems to be of little or no value. It is affirmed to be tonic and styptic, and to have been serviceable in cases of rachitis.

Polypodium Calaguala, *Ruiz.* According to Ruiz, the rhizome of this species constitutes, in Peru, the "Genuine Calaguala," or "Ccallahuala," or "Slender Calaguala." It is said to possess deobstruent, sudorific, diuretic, anti-venereal and febrifuge virtues, and is frequently used to thin the blood, promote perspiration, and to mitigate rheumatic and venereal pains.

Polypodium crassifolium, *Linn.* The rhizome of this species is called "Thick Calaguala," "Puntupuntu," or "Deer's-tongue." It is employed in Peru in the same manner, and for the same purposes, as the "Genuine Calaguala."

Polypodium phymatodes, *Linn.* This is the "Male-fern," or "Fougère mâle" of the Mauritius. A decoction of the stems is used as an aperient and refrigerant. Mixed with barley and milk, it forms a beverage often recommended by doctors after inflammatory diseases.

POLYPODIUM VULGARE, *Linn.* "Common Polypody." This common European fern was at one time in high repute. A decoction of the fronds was formerly administered to children for worms, cold and whooping-cough. The ancients attributed many virtues to this plant,—Dioscorides, for limbs out of joint and chaps between the fingers; Pliny, for chaps on the toes; and others to purge melancholy. It is the "rheum-purging Polypody" of Shakspere.

PTERIS AQUILINA, *Linn.* "Common Bracken." Native of Europe. The rhizome is said to be astringent and anthelmintic. Lindley says that it has been used with some success as a substitute for hops. Its esculent qualities must be very poor, although it is said to be sometimes eaten. The ancients used rhizomes and fronds, in decoction, in chronic disorders arising from obstructions of the viscera and spleen. It is sometimes employed abroad in dressing and preparing kid and chamois leather.

SCOLOPENDRIUM VULGARE, *Sm.* "Hart's-tongue." Old herbalists seem to have had great faith in this fern. Lightfoot says that in Scotland it was used by the country people for burns and scalds; and Ray writes of it as applied in the form of ointment to wounds and ulcers. In France it is employed as an astringent in diarrhœa and hæmorrhage.

UNDETERMINED INDIAN FERNS. Several fern products employed in India have been enumerated, but at present without accurate identification. Amongst these are "Iskoolikundrion," a species of *Scolopendrium;* "Doonditarus," a species of *Dryopteris;* "Surkhus" or "Bitarus," probably a species of *Pteris;* and "Bisfaij" or "Bulookunboon," which is referred to a species of *Polypodium.*"

NEW ALKALOIDS OF OPIUM.

BY O. HESSE.

The author has succeeded in extracting from opium several new alkaloids. When an aqueous infusion of opium is precipitated by caustic soda or limewater in excess, there remains in solution a substance which may be separated by ether. This substance gives with dilute sulphuric acid a purple colour like rheadine. The coloration was observed formerly by Merck, but he did not isolate the substance; what he described under the name of porphyroxine being, according to the author, a mixture of several alkaloids which he has now separated by the following method.

The alkaline liquor is shaken with ether, and after acidulating the etherial solution with acetic acid, the ether is evaporated off. What remains is mixed with a dilute alkaline solution gradually and stirred meanwhile, so that the resin which separates may clot together. If this operation is properly conducted the alkaloids remain in solution.

After twenty-four hours the precipitate is separated, the liquid mixed with slight excess of hydrochloric acid, and then with ammonia, which precipitates the bases. The whole is then shaken with chloroform, the solution, thus obtained, acidulated with acetic acid, the chloroform driven off and the residue neutralized with ammonia. This throws down a resinous reddish-coloured precipitate which becomes crystalline and consists of impure lanthopine. After twenty-four hours the filtered liquid is mixed with caustic soda, very little more than sufficient to decompose the ammonia salts present; it is then shaken with ether several times to separate the codeia that renders it turbid. This alkaloid is dissolved by ether more readily than the other bases—meconidine, codamine, laudanine, and another which the author designates *x*. Ether does not extract these latter from the solution containing fixed alkali until after chloride of ammonium has been mixed with it.

When the etherial solution of these bases is allowed to evaporate very slowly, laudanine crystallizes first, the other three bases remaining as an almost amorphous residue after the ether has evaporated. But if, before the ether has evaporated off entirely, the mother liquor be mixed with solution of bicarbonate of soda, crystals of codamine are deposited on further evaporation of the ether.

The mother liquor from which codamine has separated is then mixed with acetic acid and with chloride of sodium, which precipitates chlorhydrate of meconidine, while the base *x* remains in solution. The latter is entirely separated from meconidine by repeatedly dissolving the hydrochlorate in water, shaking with bicarbonate of soda and ether, and then evaporating the etherial solution.

Meconidine, as left on evaporation of an etherial solution, is in the form of a yellowish varnish. It melts at 58° C., cannot be sublimed, dissolves in alcohol, ether, benzol, chloroform and acetone. It blues litmus paper, is destitute of taste, but its salts are bitter.

A solution of a salt of meconidine gives with potash a flocculent precipitate soluble in excess of the precipitant. The solvents of meconidine do not extract it from this solution. A large excess of ammonia or of lime will also dissolve meconidine; but ether will separate it from these solutions. Strong acids decompose meconidine, especially with the aid of heat, producing a rose coloration that afterwards becomes purple. Acetic acid alters meconidine only when boiled with it, and then only partially. Concentrated sulphuric acid dissolves it with olive-green coloration.

Meconidine is distinguishable from rheadine by its solubility in potash and by its composition, $C_{21}H_{23}NO_4$, while rheadine is $C_{21}H_{25}NO_6$.

The salts of meconidine are very instable, the hydrochlorate and the hydriodate are amorphous, soluble in water and in alcohol. The chloraurate is a dirty yellow amorphous precipitate. The chloromercurate, white and amorphous; hydrochloric acid gives it a rose colour. The chloroplatinate $(C_{21}H_{23}NO_4HCl)2PtCl_4$ is an amorphous yellow precipitate.

Laudanine.—This base, crystallized from boiling dilute alcohol, forms colourless hexagonal prisms. It dissolves in benzol, chloroform and in boiling alcohol; cold alcohol dissolves only $\frac{1}{540}$th. It has an alkaline reaction.

The salts of laudanine are bitter. Potash and ammonia throw down from solutions a white precipitate soluble in excess of alkali. Chloroform extracts the base readily from its ammoniacal solution. Protochloride of iron colours the salts green, and dissolves them. Oil of vitriol dissolves them with an orange coloration, nitric acid with a rose colour, which becomes dark violet when heat is applied.

Laudanine has the formula $C_{20}H_{25}NO_3$; it melts at 163° C., and does not sublime.

The hydrochlorate forms colourless prisms soluble in water and in alcohol.

The chloroplatinate is a yellow amorphous precipitate slightly soluble in boiling water. The chloromercurate is a white precipitate soluble in boiling water. The hydriodate is very soluble and crystallizable. The iodomercurate is a white amorphous precipitate, melting in boiling water and soluble; it is very soluble in alcohol. The sulphate crystallizes in needles; the oxalate also crystallizes, but is sparingly soluble in cold water.

Codamine, $C_{19}H_{23}NO_3$.—This base is purified by converting it into sulphate, decolorizing with charcoal and shaking with ether after addition of ammonia. The base crystallizes from ether or alcohol in hexagonal prisms terminated by pyramids. It is slightly soluble in water, more so in chloroform and in benzol. Its solutions are alkaline and destitute of taste. Generally the salts are amorphous and bitter. The base melts at 121° C., then it decomposes, giving a beautiful crystalline sublimate.

Concentrated sulphuric acid produces a green coloration with codamine, nitric acid gives a bluish-green that becomes violet when heat is applied. Alkalies precipitate the base and an excess dissolves it; bicarbonate of soda also precipitates it in the form of white flocks, which aggregate into a resinous mass.

Lanthopine, $C_{23}H_{25}NO_4$.—This base is purified by treating the hydrochlorate solution with charcoal, precipitating the hydrochlorate with chlorate of sodium, decomposing that salt with ammonia and crystallizing from chloroform. The base then appears as a white powder, consisting of microscopic prisms scarcely soluble in alcohol and very slightly soluble in benzol or in ether. It has no taste nor any alkaline reaction. It dissolves only in a large excess of acetic acid. It is precipitated from its solutions by potash and dissolved by excess of potash. On the addition of chloride of ammonium to this solution the base is separated. This base gives no colour with chloride of iron, differing in this respect from morphia. Concentrated nitric acid transforms it into a red resin; sulphuric acid gives a violet coloration. Heated to 190° C. the base becomes brown; it melts at 200°.

The hydrochlorate of lanthopine $C_{23}H_{25}NO_4HCl + 6H_2O$ forms a gelatinous mass composed of very small crystals, which aggregate together in drying to a horny mass that swells up in water and finally dissolves. Boiling water dissolves the salt, setting free part of the base. The chloroplatinate forms a yellow crystalline powder insoluble in alcohol; it contains one equivalent of water. The hydriodate is gelatinous and soluble. The iodomercurate is soluble in boiling water and in alcohol. The sulphate forms very slender needles.

Thebaine.—This base, discovered by Thibouméry, is contained in the precipitate I obtained in the manner described at the commencement of this article. That precipitate is dissolved by acetic acid, the solution decolorized with charcoal and then mixed with powdered tartaric acid; after twenty-four hours the crystals of tartrate of thebaine that have formed are collected and recrystallized from boiling water. Then the base is set free and crystallized from alcohol. Pure thebaine has no taste; it melts at 193° C.

The acid tartrate forms slender prisms soluble in boiling water and boiling alcohol. The salt requires 130 parts of water at 20° C. for solution. The neutral salt is readily soluble in water and alcohol; it may be prepared by using excess of the base, and then separating it with ether.

The hydrochlorate requires 15·8 parts of water at 10° C. for solution; it is anhydrous at 100° C.

Thebenine.—This base is formed by an isomeric transformation of thebaine under the influence of boiling hydrochloric acid. A solution of 10 parts thebaine in 200 parts of hydrochloric acid (1·04 sp. gr.) is heated to boiling, and then diluted with an equal volume of water. Gradually crystals separate; these are washed with cold water, and redissolved in boiling water mixed with acetic acid; on cooling this solution fine crystals of hydrochlorate of thebenine separate as colourless laminæ that are soluble in boiling water or boiling alcohol, and in 100 parts of cold water. Nitric acid dissolves these crystals with a yellow coloration and evolution of nitrous fumes; the solution mixed with water gives a yellow amorphous precipitate soluble in ammonia. The hydrochlorate of thebenine $C_{19}H_{21}NO_3HCl+3H_2O$ is bitter, but does not appear to be poisonous, while thebaine is extremely poisonous. The chloroplatinate is amorphous and yellow. The chloromercurate forms long colourless prisms. Sulphate of thebenine separates on adding sulphuric acid to a solution of hydrochlorate as a white crystalline powder, but slightly soluble in boiling water, insoluble in cold water or alcohol. It is anhydrous at 100° C.

Thebenine itself is amorphous, insoluble in ether or benzol, slightly soluble in boiling alcohol. It is insoluble in ammonia, but soluble in potash. It absorbs oxygen rapidly, and the potassic solution soon becomes brown in contact with atmospheric air. Sulphuric acid colours thebenine blue, while thebaine gives a dark red colour with the acid.

Thebaicine.—This is probably a second isomer of thebaine, formed by the action of strong acids and heat. Ammonia gives, after this treatment of thebaine, an amorphous yellow basic precipitate, insoluble in ether, benzol, water or ammonia, slightly soluble in boiling alcohol, from which, however, it does not crystallize. Potash dissolves it, and the solution turns brown in contact with air. It dissolves with red colour in nitric acid, and with a blue colour in oil of vitriol. The sulphate is resinous, as well as the hydrochlorate.

The first precipitate contains also papaverine, and this base is present in the mother liquor from which tartrate of thebaine has separated. It is precipitated with ammonia and treated with a little alcohol, which renders it crystalline and dissolves an amorphous base. It is then converted into oxalate, which is crystallized from boiling water. The base may be considered pure if it dissolves without coloration in oil of vitriol. Papaverine crystallizes in colourless prisms, soluble in 258 parts of cold ether; it crystallizes from benzol and melts at 147° C. It dissolves in acetic acid without neutralizing it; potash and ammonia separate it from this solution as a resinous mass that gradually becomes crystalline, but is insoluble in excess of the alkali. Nitric, sulphuric or hydrochloric acid, added to the acetic solution, separate the corresponding salts in a crystalline form.

The author assigns to papaverine the formula $C_{21}H_{21}NO_4$, instead of $C_{20}H_{21}NO_4$ adopted by Merck and Anderson. This formula is confirmed by the analysis of the hydrochlorate and of the chloroplatinate. The former dissolves in 37 parts of water at 18° C., and the latter is a dark yellow crystalline precipitate. The chloromercurate forms colourless rhomboidal laminæ. The iodomercurate is crystalline and soluble in boiling alcohol.

The author concludes his memoir by stating the relations which the new bases bear to those previously known. The new bases exist in very small amounts in opium. A sample containing 8·3 per cent. of morphia gave 0·0058 per cent. of laudanine, the same quantity of lanthopine, and 0·0033 of codamine.

Codamine and laudanine are homologues of morphia and of codeia. Lanthopine is the superior homologue of papaverine. Related to the latter two, as oxidation derivatives, are cryptopine and narceine on the one hand, rheadine and rheagine on the other.

It has been stated incorrectly that cryptopine is soluble in potash. Oil of vitriol colours cryptopine dark green.—*Annalen der Chem. und Pharmacie,* cliii. 47.

WHAT IS ENERGY?

BY BALFOUR STEWART.

II.

In our first article it was shown that energy, or the power of doing work, is of two kinds, namely, energy due to actual motion, and that due to position. We ended by supposing that a stone shot vertically upwards had been caught at the summit of its flight and lodged on the top of a house; and this gave rise to the question, What has become of the energy of the stone? To answer this we must learn to regard energy, not as a *quality*, but rather as a *thing*.

The chemist has always taught us to regard quantity or mass of matter as unchangeable, so that amid the many bewildering transformations of form and quality which take place in the chemical world, we can always consult our balance with a certainty that *it* will not play us false. But now the physical philosopher steps in and tells us that energy is quite as unchangeable as mass, and that the conservation of both is equally complete. There is, however, this difference between the two things—the same particle of matter will always retain the same mass, but it will not always retain the same energy. As a whole, energy is invariable, but it is always shifting about from particle to particle, and it is hence more difficult to grasp the conception of an invariability of energy than of an invariability of mass. For instance, the mass of our luminary always remains the same, but its energy is always getting less.

And now to return to our question, What has become of the energy of the stone? Has this disappeared? Far from it; the energy with which the stone began its flight has no more disappeared from the universe of energy than the coal, when we have burned it in our fire, disappears from the universe of matter. But this has taken place:—the energy has changed its form and become spent or has disappeared as energy of actual motion, in gaining for the stone a position of advantage with regard to the force of gravity.

If we study this particular instance more minutely, we shall see that during the upward flight of the stone its energy of actual motion becomes gradually changed into energy of position, while the reverse will take place during its downward flight, if we now suppose it dislodged from the top of the house. In this latter case the energy of position with which it begins its downward flight is gradually reconverted into energy of actual motion, until at last, when the stone reaches the ground, it has the same amount of velocity, and, therefore, of actual energy, which it had at first.

Let us now revert, for a moment, to the definition of energy, which means the power of doing work, and we shall see at once how we may gauge numerically the quantity of energy which the stone possesses, and, in order to simplify matters, let us suppose that this stone weighs exactly one pound. If, therefore, it has velocity enough to carry it up one foot, it may be said to have energy enough to do one unit of work, inasmuch as we have defined 1 pound raised 1 foot high to be one unit of work; and in like manner if it has velocity sufficient to carry it 16 feet high, it may be said to have an energy equivalent to 16 units of work or foot-pounds as those units are sometimes called. Now, if the stone be discharged upwards with an initial velocity of 32 feet per second, it will rise 16 feet high, and it has, therefore, an energy represented by 16. But if its initial velocity be 64 feet per second, it will rise 64 feet high before it turns, and will, therefore, have energy represented by 64. Hence we see that by doubling the velocity the energy is quadrupled, and we might show that by tripling the velocity the energy is increased nine times. This is expressed in general terms by saying that the energy or quantity of work which a moving body can accomplish varies as the square of its velocity. This fact is well known to artillerymen, for a ball with a double velocity will penetrate much more than twice as far into an obstacle opposing its progress.

Let us now take the stone or pound-weight having an initial velocity of 64 feet per second, and consider the state of things at the precise moment when it is 48 feet high. It will at that moment have an actual velocity of 32 feet per second, which, as we have seen, will represent 16 units of work. But it started from the ground with 64 units of work in it: what therefore has become of the difference—or 48 units? Evidently it has disappeared as actual energy; but the stone, being 48 feet high, has an energy of position represented by 48 units; so that at this precise moment of its flight its actual energy (16), *plus* its energy of position (48), are together equal to the whole energy with which it started (64).

Here, then, we have no annihilation of energy, but merely the transformation of it from actual energy into that implied by position; nor have we any creation of energy when the stone is on its downward flight, but merely the retransformation of the energy of position into the original form of actual energy.

We shall presently discuss what becomes of this actual energy after the stone has struck the ground; but, in the meantime, we would repeat our remark how intimate is the analogy between the physical and the social world. In both cases we have actual energy and energy of position, the only difference being that in the social world it is impossible to measure energy with exactness, while in the mechanical world we can gauge it with the utmost precision.

Proteus-like, this element energy is always changing its form; and hence arises the extreme difficulty of the subject, for we cannot easily retain a sufficient grasp of the ever-changing element to argue experimentally regarding it. All the varieties of physical energy may, however, be embraced under the two heads already mentioned, namely, energy of actual motion and of position. We have chosen the force of gravity, acting upon a stone shot up into the air, as our example; but there are other forces besides gravity. Thus, a watch newly wound up is in a condition of visible advantage with respect to the force of the mainspring; and as it continues to go it gradually loses this energy of position, converting it into energy of motion. A cross-bow bent is likewise in a position of advantage with respect to the spring of the bow; and when its bolt is discharged, this energy of position is converted into that of motion. Thus again, a meteor, a railway train, a mountain torrent, the wind, all represent energy of actual visible motion; while a head of water may be classed along with a stone at the top of a house as representing energy of position. The list which represents visible energy of motion and of position might be extended indefinitely; but we must remember that there are also invisible molecular motions, which do not the less exist because they are invisible.

One of the best known of these molecular energies is *radiant light and heat*,—a species which can traverse space with the enormous velocity of 186,000 miles a second.

Although itself eminently silent and gentle in its action, it is, nevertheless, the parent of most of the work which is done in the world, as we shall presently see when we proceed to another division of our subject. In the meantime we may state that radiant light and heat are supposed to consist of a certain undulatory motion traversing an ethereal medium which pervades all space.

Now, when this radiant energy falls upon a substance, part of it is absorbed, and in the process of absorption is converted into *ordinary heat*. The undulatory motion which had previously traversed the thin ether of space has now become linked with gross palpable matter, and manifests itself in a motion which it produces in the particles of this matter. The violence of this rotatory or vortex-like motion will thus form a measure of the heat which the matter contains.

Another species of molecular energy consists of *electricity in motion*. When an electric current is moving along a wire, we have therein the progress of a power moving like light with enormous velocity, and, like light, silent in its operation. Silent, we say, if it meets with no resistance, but exceedingly formidable if it be opposed; for the awe-inspiring flash is not so much the electricity itself as the visible punishment which it has inflicted on the air for daring to impede its progress. Had there been a set of stout wires between the thunder-cloud and the earth, the fluid would have passed into the ground without disturbance.

The molecular energies which we have now described may be imagined to represent motion of some sort not perceived by the outward eye, but present nevertheless to the eye of the understanding, they may, therefore, be compared to the energy of a body in visible motion, or actual energy as we have termed it.

But we have also molecular energies which are more analogous to the energy of position of a stone at the top of a cliff.

For instance, two bodies near one another may be endowed with a species of energy of position due to *opposite electrical states*, in which case they have a tendency to rush together, just as a stone at the top of a cliff has a tendency to rush to the earth. If the two bodies be allowed to rush together, this energy of position will be converted into that of visible motion, just as when the stone is allowed to drop from the cliff its energy of position is converted into that of visible motion.

There is finally a species of molecular energy caused by *chemical separation*. When we carry a stone to the top of a cliff, we violently separate two bodies that attract one another, and these two bodies are the earth and the stone. In like manner when we decompose carbonic acid gas into its constituents, we violently separate two bodies that attract one another, and these are carbon and oxygen. When, therefore, we have obtained in a separate state two bodies, the atoms of which are prepared to rush together and combine with one another, we have at the same time obtained a kind of energy of molecular position analogous on the small scale to the energy of a stone resting upon the top of a house or on the edge of a cliff on the large or cosmical scale.

(*To be continued.*)

GINSENG.

BY JOHN R. JACKSON.

Amongst the most extraordinary medicinal plants which have from time to time been celebrated in different ages and countries, the Ginseng of the Chinese is one of the most curious. This drug is the dried root of *Panax Schinseng*,' Nees, a small plant, frequently with a creeping underground stem or rhizome. It is a native of China, and so highly is it esteemed that it forms a large article of internal commerce and realizes almost fabulous prices. As much as 300 taels of silver, which is equal to about £100 of our money, is about the average price of a single tael (640 grains) of the drug. Though it has been proved by our own chemists to possess no medicinal virtues, other than being mucilaginous, aromatic, slightly bitter and saccharine, it is nevertheless esteemed as a most invaluable root by the Chinese, who believe it produces the most extraordinary effects upon the human system, invigorating and restoring the fatigued and wearied body to a marvellous degree, and bringing back youth to the aged and strength to the weak. Be this as it may, it has held its position with the Chinese for a very long time, and still continues to be highly prized. In the year 1709 we read that a body of Tartars, numbering some 10,000, were sent by the Emperor of China in quest of the root, with instructions to bring home as much as they could find, two pounds of the best of which was to be given by each man to the Emperor, and the remainder they were to sell for the same weight of fine silver. The Chinese name, Jinsang or Ginseng, implies "Wonder of the World," and the generic name Panax is derived from the Greek panakes or panacea, a cure for all diseases. Both words, therefore, refer to its supposed extraordinary powers. The Ginseng plant grows in the mountainous parts of China, but the best quality, or that which is most esteemed by the Chinese, is obtained from the Corea; Manchuria also produces a good variety. A species of Panax named *quinquefolia*, growing in North America, has roots similar to those of the true Chinese Ginseng, with which plant indeed it is often confused. These roots are, however, on comparison, more slender than those of *P. Schinseng*. The Americans at one time exported them to China in large quantities as a substitute for the Chinese drug.

The Commissioner of Customs of Newchang has sent home some very interesting remarks on the trade and cultivation of Ginseng, which remarks will no doubt be worth giving in his own words; he says:—

"It is difficult in discussing the trade of the chief port in Manchuria to avoid noticing the strange root in which every native in China, from the Emperor to the humblest coolie, places such implicit faith. Fine Manchurian Ginseng is only found in the upper valley of the Usuri, where ruined towns and forts mark the cradle of the race which seven centuries ago ruled over China from the Yellow River to the Great Wall, which was forced back by the valour and genius of Genghis, and which 400 years afterwards again swept into China to occupy and retain the Imperial throne. But Ginseng loves moisture and the densest of the forests, which cling to the slopes of the hills; it nestles in recesses to which the rays of the sun have never penetrated, and which are as pathless now as in the days when the Golden Tartars were dwelling in and cultivating the plain. The genuine Manchurian Ginseng consists of a stem from which the leaves spring, of a centre root, and of two roots branching off at the same point from each side of the centre root. The stem somewhat resembles the head and neck, and the side roots the shoulders and arms of a man; the main root represents the body, and a fork, which the main root frequently forms, the legs.

"The Chinese, with a not ungraceful feeling, believe that a plant which thus expands into the human form amid thickets and jungle on which the foot of man has never trod, must be intended to alleviate the sufferings of the human race. Its precious qualities are increased and intensified by age, and a plant is of no great value until it has been growing and gathering strength for at least an ordinary lifetime. The age, and consequently the value of a plant, are ascertained by a careful examination of the upper portions of the centre and side roots. These portions should be covered with rings, and the thicker and more numerous the rings the greater the age. The value of Ginseng in no way depends upon its length, thickness, or colour. I myself have seen here a delicate root weighing but 6 mace, which cost 50 taels. The upper portions of the root also possess the greatest healing power; the stem, which appears above ground, on the other hand, ought not to be eaten. It is supposed to be baneful rather than beneficial.

"In former years, the collection of Ginseng was in the hands of some forty merchants, who, on payment of a heavy fee, obtained the necessary authority from the Tartar General of Kirin. In addition to the fee, each merchant was bound to hand over to Government a certain weight of the object of his search. The search is continued from the end of April to the end of September. In it the merchants employed the outlaws whom the fear of punishment had driven to take refuge in these wilds, and who were compelled by their position to be faithful servants. These men underwent great hardships and incurred great dangers. Forced to wander far from the little patches of millet they had raised for their support, they were even menaced by starvation, and by the wolf, the tiger and the leopard; and not unfrequently the hardships were endured and the dangers were incurred in vain.

"In the time of Tankouang, Ginseng was becoming yearly more scarce and plants of any great age were rarely found. Finally, in order to arrest their utter extinction, the collection of the wild root was prohibited by Imperial edict. Steps were taken in Kirin to carry this order into effect, and measures were adopted to prevent the admission of the interdicted plant into China. Nevertheless, a very small quantity is still clandestinely collected—to a considerable extent, however, in Russian territory. The cultivation of Ginseng, though allowed, is not encouraged; it is, in fact, hardly recognized as Ginseng, as the tariffs of the various native custom-houses class it under the general heading of medicine. This course is not altogether unreasonable. The side branches of the cultivated plant are frequently broken off, and its premature growth and the means made use of to expedite its development often efface the resemblance from which it derives its name.

"With a view to produce a false appearance of age, hair is tied tightly round the upper portions of the root, but a practised eye can easily detect the deception. Ginseng is cultivated in Manchuria and in the Corea. The average Corean-cultivated Ginseng is superior to the average Manchurian; 84 piculs 27 catties of Manchurian Ginseng were exported in foreign vessels during the past year: the value was not two taels a catty."—*The Gardeners' Chronicle.*

NITRITE OF AMYL.*

Nitrite of amyl, $C_{10}H_{11}ONO_3$, was first discovered by M. Balard. It is an amber-coloured liquid, smelling and tasting like the essence of ripe pears. It was more fully investigated in 1859 by F. Guthrie, who specially noticed that it possessed the property of causing flushing of the face, throbbing of the carotids, and acceleration of the heart's action. He suggested that it might be found of value as a resuscitative in drowning, suffocation and prolonged fainting.† The substance attracted very little attention, however, till it was taken up by Dr. B. W. Richardson at the meeting of the British Association for the Advancement of Science, held at Newcastle in the year 1863; he read a report on "The Physiological Properties of the Nitrite of Amyl," and showed that when inhaled it produced an immediate effect on the heart, increasing the action of that organ more powerfully than any other known agent. If a little of the nitrite was dropped on bibulous paper, and its vapour inhaled through the nostrils, the action of the heart was instantly excited, the cutaneous surface became red, and the face was deeply flushed, assuming a bright crimson colour. Carried further, the nitrite excited the breathing and produced a breathlessness like that caused by sharp running or rowing. It did not cause anæsthesia. It could then, Dr. Richardson said, be considered (like chloroform twenty years previously) as a physiological curiosity, and looking at its intensity of action, he could not, at that time, recommend its use in medicine.

In 1864 the result of further researches was reported by Dr. Richardson to the British Association, at Bath. After an elaborate series of experiments he had found that nitrite of amyl is absorbed by the body, whether introduced by the skin, the stomach, the lungs, or by inoculation; that after absorption its effects are immediately seen on the heart and circulation; and that it might be considered the most powerful excitant of vascular action yet discovered.§ In 1867,|| and again in 1870,** Dr. Lauder Brunton advocated its use in cases of angina pectoris. In the discussion which followed the reading of the second communication before the Clinical Society of London, Dr. Anstie reported a case where a gentleman, who had suffered severely for twenty years from spasmodic asthma, and for four or five years from attacks of angina pectoris, a few seconds after one long inspiration through one nostril from a half-ounce bottle of the drug, "passed from a state of agony into a state of calm repose." It has also been used successfully in cardiac disease brought on by acute rheumatism, paroxysmal attacks of colic and traumatic tetanus. These cases show that in nitrite of amyl we have an agent of remarkable power and rapidity of action against some forms of severe suffering and pain. At present we know little of its powers for good or the limits to its employment; but enough is known to justify and encourage further research into its properties.

WATER SUPPLY.

Professor Frankland, in his report on the quality of the metropolitan water supply during the month of August, states that all the samples taken were clear and transparent when drawn from the mains of the companies, except that supplied by the East London Company, which contained suspended particles among which living organisms were found. The water abstracted by the Chelsea and Lambeth Companies from the Thames below its junction with the Mole exhibited nearly twice as much previous sewage or animal contamination as that abstracted by the other companies above the junction.

The water supply of Birmingham appears to be in much need of the improvement for which powers were obtained in the last Session of Parliament. The analysis by Dr. Alfred Hill of the supply to the borough on the 3rd inst. shows that it was "highly charged with nitrogenous organic matter," and that it was also "turbid and bright green with minute vegetation." Dr. Frankland urges that until the new supply is provided every exertion should be used to render the quality of the present supply less objectionable, by sand filtration for the removal of suspended impurities. The proportion of chlorine in the Birmingham water has increased from 1·41 part in 100,000 on the 10th of May to 7·44 parts in 100,000 on the 3rd inst.—*Registrar-General's Report.*

THE AMMONIA CURE FOR SNAKE-BITE.

Professor Halford, of the University of Melbourne, in a paper read before the Medical Society of Victoria, has reviewed at length the history of twenty cases of snake-bite treated by his method of injecting liquor ammoniæ into the veins during the last eighteen months. The *British Medical Journal* says that these cases were all in the hands of different practitioners in the colony, who have each reported on them. Recovery followed in seventeen cases. In thirteen of these, the practitioners in attendance expressly report that the patients were in a dying condition, and, in their belief, would soon have died, but for the employment of this remedy in the manner prescribed. The method employed was that introduced by Dr. Halford, and first brought to the knowledge of the profession here by him, in its pages, through Mr. Paget; viz., by injecting dilute ammonia—say, at the least, thirty minims of the liquor ammoniæ B. P., specific gravity 959—into a superficial vein; the vein being first exposed, and its coats pierced with the nozzle of a hypodermic syringe. Dr. Dempster, Dr. Rae, Dr. Langford, Mr. Dallimore and Dr. Meyler, each in his own words, and from the observation of separate cases, describe the curative effect as being immediate, and the recovery from collapse to be so rapid and startling as to be "almost magical." This method of treatment, of which such remarkable effects are detailed, has been sharply criticized; but Professor Halford successfully vindicates the claim of the snakes to be considered highly venomous—almost as much so, he intimates, as some of his London critics. They included the tiger-snake, the brown and black snake of Australia, which are affirmed to be as deadly as the cobra and rattle-snakes of India. Strong testimony to the efficacy of the treatment in saving life was borne by Australian practitioners who took part in the discussion, and vindicated Professor Halford's claim to be considered as the discoverer of a means of rescuing many from an otherwise inevitable death.

The *Medical Times and Gazette*, speaking of an article which has appeared in the *Melbourne Argus* on Professor Halford's claims in respect to his treatment of snake-bite, and referring to the misstatements on this subject in another medical journal, says, "It is almost impossible to understand how those statements could have been made and persevered in so ungenerously and unjustly."

The Victims of Scarlet Fever.—It is to be hoped that the plain manner in which the *British Medical Journal* has put before the public the price we pay for legislative inaction in sanitary matters will lead to such strong pressure upon the Home Secretary before next session that he will be compelled to lift a finger for the preservation of our lives. Four hundred and seventy thousand persons have died of scarlet fever and its allied disease, diphtheria, in the last twenty-two and a half years. Had these victims of one type of zymotic disease been soldiers whose lives had been sacrificed on the battle-field to inefficiency at the War Office, the whole nation would quiver with indignation; yet there can be little doubt that by far the larger proportion of those who have died of scarlet fever might have been alive now but for the utter inefficiency of our complicated sanitary laws and the neglect of domestic legislation which it is the business of the Home Office to initiate. One simple measure alone which we have before pointed out would probably have saved half if not three-fourths of the lives thus wasted. Disinfecting establishments in each district are the first steps necessary to put a stop to this horrible mortality. Under present arrangements bedding and clothing are allowed to spread infection far and wide. Among the poor, in nine cases out of ten, no steps are taken to disinfect these articles, and among the wealthier classes the very steps taken to purify the bedding of scarlet-fever patients only serve to disseminate the infection more widely, for the upholsterer who takes away the mattresses mixes them with other goods of the same kind, and for every family whose furniture is thus purified probably another family is attacked. Then, again, those who are able to afford it have the walls of the room in which the patient has been lying stripped of their paper, but no care is taken to see that the paper itself is destroyed. Until we have disinfecting establishments, with proper officers attached to them to see to these matters, fever will continue to spread and carry off its thousands; and until we have a Home Secretary who will make it compulsory on local authorities to take such measures as are dictated by common sense and experience for preventing the spread of infection and enforcing better house arrangements with the view of reducing the chances of disease, we shall still continue to die of scarlet fever at the rate of not less than 40,000 a year, that being the estimated number of deaths for last year, a rate which is annually increasing at compound interest.—*Pall Mall Gazette.*

The Defence of Paris.—The *Journal Officiel* publishes the following note:—"The Minister of Public Instruction has appointed a committee of *savants*, who are to concert with the military authorities means for applying to the defence of Paris all the latest results of physical and chemical science. M. Berthelot, Professor of Organic Chemistry at the Collége de France, is President of the Committee. Two Deputies, MM. Dorian and Genelot, represent the Corps Législatif. The first meeting of the committee was fixed for Saturday, September 3, at the Ministry of Public Instruction. Persons who may have communications to make or plans to suggest are requested to apply to M. Berthelot. Another committee, specially charged with the medical questions relating to the defence of Paris, is being organized under the presidency of M. Sée, Professor of the Faculty of Medicine." The *Opinione Nationale* comments upon the foregoing notice:—"We entirely approve the arrangement thus proposed. Since scientific barbarism is being hurled against us, it is the task of civilized science to defend us."—*Times.*

Thebolactic Acid.—Buchanan has obtained from opium an acid possessing the composition of lactic acid. According to his results, it appears to be identical with ordinary lactic acid. It does not affect polarized light, and in this respect differs from the acid discovered by Wislicenus.—*German Chemical Society.*

The Pharmaceutical Journal.

SATURDAY, SEPTEMBER 10, 1870.

STATE AID FOR PHARMACEUTICAL EDUCATION.

Though the existence of social distinctions in English society is a fact which must be recognized, we consider it by no means desirable that the lines which separate classes should be further deepened, still less that they should receive any extra impress or sanction through the operation of the law which notoriously professes to regard all classes and individuals as equal.

Schemes for the benefit of a particular class or section of the community may, indeed, have their peculiar recommendations, and custom would seem to indicate that sometimes they have; but we are disposed to think that the limited operation principle, as it may be termed, ought to be confined to measures that are of private and voluntary nature. No more logical objection, perhaps, could be urged against one section of the State associating in some good work for the benefit of another section than could be brought against any average form of private charity; but we hold that when the whole State, through its Executive or Government, moves to some work of amelioration or progress, the entire community should be regarded as eligible to participate in the benefit thereby conferred.

We are quite aware that practical legislation cannot always be carried out exactly in accordance with theoretical conviction; law-making is often of necessity tentative. There is, therefore, all the more reason for gratulation when changes are made that bring practice and abstract right closer together. We think this has recently been the case in regard to a matter affecting the interests of pharmacy, though perhaps the case we refer to can scarcely be called so correctly a change as the authoritative interpretation of a somewhat ambiguous statement.

We published in our impression of August 20, a correspondence between Mr. G. F. Schacht, the Hon. Sec. of the Bristol Pharmaceutical Association, and the Science and Art Department of the Government, and we now desire to call especial attention to that correspondence as containing a decision of great importance in more ways than one.

It is well known that amongst various methods adopted for the general diffusion of scientific knowledge, the Government has fostered the formation of science classes throughout the kingdom by a plan which, so far as it has been carried, yields most promising results. Briefly described, this plan consists in giving money payments to teachers in proportion as they succeed in passing their pupils through the ordeal of a certain annual examination, conducted by appointed professors. The teachers are thus enabled to demand from their pupils much smaller fees than would otherwise be necessary.

The published regulations, however, appeared to indicate that these money payments were only to be allowed when the student belonged to the operative class. The mischief likely to be produced by such a limitation (did it really exist) is obvious; for in many localities the classes conducted under the auspices of the Science and Art Department are the only opportunities existing in the whole neighbourhood for systematic study of science.

Considering how many persons above the operative class are in need of scientific education, but unable to obtain it except by some such means as that afforded by the Department of Science and Art, we are at a loss to perceive on what ground they should be excluded from participating in its advantages, while these are freely offered to persons of inferior social position.

It will be seen from the reported proceedings of the Bristol Pharmaceutical Association in last week's number, that Mr. Schacht and his friends at Bristol, putting a broader interpretation upon the intention of the Science and Art Department, have made free use of the science classes of their neighbourhood for the benefit of their students in pharmacy, reviving, indeed, the Botanical Class, and calculating upon receiving the aid of the Department in their endeavour to give scientific education to their apprentices and assistants. The decision contained in the correspondence already referred to fully justifies the course they had taken.

We would fain hope that this decision is a step towards such a perfect identification of practice with principle as we think desirable, so that these classes might become great centres of scientific education for students of every station and degree—so many colleges, indeed, of a grand national university.

Something of the kind may possibly be developed in the future; in the meantime there is no longer room for doubt that these classes are open, with all their systematic and economic recommendations, to the Pharmacists of this kingdom.

We are enabled to state that on the recommendation of the Committee appointed to consider the subject of provincial education, the Council has ordered an abstract of the returns lately sent in by the several provincial associations to be published. The Council has also invited the British Pharmaceutical Conference to bring forward the subject for discussion at its meeting next week. This will afford an opportunity for interchange of opinion amongst those best acquainted with the requirements of the case. Considering the vast importance of the subject, nothing could be more calculated to emphasize the hope we expressed last week as to the Society being represented at the Conference by its President and Council.

THE BETTS SUITS AGAIN.

Mr. Betts appears to share with the British soldier his proverbial characteristic of not being able to perceive when he is beaten; for, as will be seen from a letter in our correspondence columns, that persevering litigant is again returning to the charge, and notwithstanding the decision of the late Vice-Chancellor James, reported in this Journal some weeks ago, he is about to resume his crusade. We understand that Mr. Betts will not accept the adverse and condemnatory judgment of the Vice-Chancellor, but that he will appeal to the Lord Chancellor, and perhaps to the House of Lords. If he should not succeed in either quarter, it is difficult to conceive what further steps Mr. Betts may not take, but doubtless his inventive capacity would even then be equal to the occasion. If, however, he should succeed in obtaining a judgment in his favour, he will have obtained a means of levying patent royalty, which, if not quite novel, would be at least out of date, and sufficiently unusual in modern times to afford an interesting case for those who concern themselves with the working of the patent system.

However, the general facts of the case are too well known to need further mention, and beyond complying with the request of our correspondent to publish his letter, it is not our intention to deal with the subject. We must nevertheless take this opportunity of correcting a misapprehension that might arise from, and be suggested by, certain remarks of Mr. Betts at the late trial as to the position of the Pharmaceutical Society in regard to this litigation. It is not in any way a case between Mr. Betts and the Society, nor has it ever been; indeed, the Society has nothing to do with the matter. Many of its members, no doubt, are among the vast number of those who were either attacked or threatened by Mr. Betts, and for that reason only the Society, as a body, sympathizes with the defence offered to his attack, not only by members of the Society and druggists generally, but also by the great mass of grocers, oilmen, wine merchants, or any other traders who sell bottles covered with capsules.

The Central Working Committee of the Association for Giving Relief to the Sick and Wounded in the present war, has really determined to send out six surgeons "whose expenses will be paid, though their services, in other respects, will be gratuitous," and a Correspondent of the *Medical Times and Gazette* commenting on the fact, remarks that, in other words, a committee representing the charitable portion of the wealthiest community in the world, proposes to exercise their charitable feelings at the expense of the six young men in question, whose toil and risk will go unrewarded. From inquiries we have made we are enabled to state that this is not a correct view of the case, The Committee has not contemplated engaging surgeons or paying for services rendered by professional men, its action being limited to accrediting competent volunteers who may be disposed to give their services gratuitously. There are many reasons to induce surgeons especially to embrace this opportunity of doing good service in the cause of humanity, and there does not appear to be any just ground for complaining of the course taken by the Committee.

But, though this is a case entirely exceptional, we may in a general way take the opportunity of expressing our opinion that the practice of rendering "honorary services" in professional matters is, as a rule, both vicious and sophistical. It too often happens that those who render "honorary services," and affect to be superior to the rule that the labourer is worthy of his hire, do so in reality with the object of some ulterior advantage to themselves. In such cases "honorary service" is but a sham and a device, by which those who happen to have means to admit of their practising it, may gain an unfair advantage over others who are less fortunately circumstanced in that respect. As a case in point we may refer to the late proceedings of the British Association Sewage Committee, which, after collecting a large sum of money to enable its members to conduct an important public inquiry, has become impressed with the idea that the services of its members must be "honorary,"—the result being that the members of the Committee finding themselves reduced to the alternative of working at their own cost or not at all, most of those who previously took an active part in the work to be done, have been debarred from continuing their labours. It yet remains to be seen what, under these circumstances, is to be done with the money collected from various towns throughout the country, and what may have been the object of collecting that money, if the functions of the Committee were to be "honorary!"

There seems to be still some unpleasant feeling lingering in Edinburgh, consequent upon the selection last year by the British Association of Liverpool in preference to that city as the place of meeting for 1870. This has been shown lately by a letter which has appeared in the *Glasgow Daily Herald* relative to the announcement in a contemporary of the probable selection of Sir William Thompson as the next president. That journal, alluding to the saying attributed to Sir R. Murchison, that no person lower in the scale than a "live duke" would be sufficient to bring together a large meeting of the British Association in Scotland, remarks, "Sir Roderick may probably remember how far his prescription was successful when it was tried; and if he will help us to have the meeting in Glasgow, with Sir William Thompson in the chair, we will try to show him the reverse of the medal."

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

The following contributions have been received since last week :—

	£.	s.	d.
John Attfield, 17, Bloomsbury Square	1	1	0
John Beddard, 46, Churton Street, S.W.	1	0	0
C. F. Bevan, Harwich	0	5	0
Thomas Burn, Ranelagh Terrace, Pimlico	0	5	0
John Carr, 171, High Holborn	1	1	0
Thomas Crowther, Tickhill	1	3	2
Thomas Elvey, 8, Halkin Street, S.W.	1	0	0
Messrs. Fincham, 57, Baker Street, W.	1	1	0
R. H. Forster, Dover	0	2	6
W. Fox and Son, 109, Bethnal Green Road	2	2	0
G. C., London	1	0	0
John Lasham, Romford	0	10	0
John W. Lasham, ditto	0	5	0
Henry Lawrence, Godalming	0	10	0
W. B. Randall, Southampton	1	1	0
Thomas Robson, Brighton	0	10	0
W. H. Smith, Brighton	0	5	0
W. C. F. Sparrow, Ranelagh Terrace, Pimlico	1	1	0
R. Turner, 5, Chippenham Ter., Harrow Rd.	0	9	0
C. P. Usk	0	10	0

Hearon, Squire and Francis, 5, Coleman Street :—
- 4 oz. chloral hydrat.
- 4 oz. bottles tinct. opii.
- 1 lb. chloroform.
- 1 oz. quinine.
- 4 8 oz. bottles of sal volatile.
- 1 doz. assorted bandages.

Bradley and Bourdas, 48, Belgrave Road, S.W. :—
- 3 lbs. chloroform in ½ lb. bottles.
- 3 lbs. laudanum in 4 oz. bottles.
- 4 lbs. sal volatile in ditto.
- 5 lbs. syrup chloral hydrate in ditto.
- 12 gross ¼ grain morphia pills in bottles containing 4 dozen each.
- 6 gross 1 grain opium pills in ditto.
- 4 gross 2 grain quinine pills in ditto.
- 1 dozen large honeycomb sponges.
- 1 dozen carbolic acid and Condy's fluid.
- 6 yards adhesive plaster.
- 6 lb. lint.

Robert Hampson, 63, Piccadilly, Manchester :—
- 12 gross 1 grain opium pills in bottles containing 4 doz. each.
- 12 gross ¼ grain morphia pills in ditto.
- 6 gross 2 grain quinine pills in ditto.
- 4 2 oz. bottles of chloral hydrate.

Harvey and Reynolds, Leeds (2nd donation) :—
- A quantity of waterproof material, and a small quantity of lint.

J. E. Lidwell, High Street, Notting Hill :—
- 10 yards bandages.
- 2 lbs. lint.
- Quantity of linen.

John Mills, Eastgate Row, Chester :—
- 24 doz. 1 grain opium pills.
- 24 doz. ¼ gr. morphia pills.
- 24 doz. 2 gr. quinine pills.

W. Smeeton, Commercial Street, Leeds :—
- 3 doz. bottles, each containing 4 doz. 1 grain opium pills.
- 6 bottles, each containing 4 doz. 2 grain quinine pills.
- 2 doz. 2 oz. bottles of laudanum.
- 2 doz. 2 oz. bottles of sal volatile.
- And a quantity of lint.

R. Turner, 5, Chippenham Terrace, Harrow Road :—
- 6 boxes 1 grain opium pills, 4 dozen in each box.

Subscriptions should be sent to Mr. Bremridge, Treasurer to the Fund, 17, Bloomsbury Square.

Proceedings of Scientific Societies.

BRITISH PHARMACEUTICAL CONFERENCE.

PROGRAMME OF PROCEEDINGS.

Liverpool, Royal Institution, Colquitt Street, September 12 *to* 20, 1870.

A Reception Room, where members and visitors may assemble, write letters, and obtain information, has been provided by the Local Committee, at 16, Adelphi Hotel, Lime Street.

The Exhibition of Objects relating to Pharmacy will be open throughout the week in the room over the Savings Bank, 93, Bold Street. Members and other visitors will be admitted to the Exhibition and the meetings on writing their name and address in the doorkeeper's book.

Monday, September 12.

The Executive Committee will meet early in the evening.

JOHN ABRAHAM, Esq., V.P., Chairman of the Local Committee, will receive the Officers, Resident Members, and Visitors prominently known in connection with pharmacy, at his house, 141, Smithdown Lane, at 7.0 P.M.

Tuesday, September 13.

The Conference will meet at 10.0 A.M., adjourning at 12.30 P.M.; the meeting will be resumed at 2.0 P.M., adjourning at 4.30 P.M.

The business of this day will comprise:—

Election of Members.

(Nearly one thousand names of candidates have been received by the Secretaries.)

Report of Executive Committee.

Financial Statement.

Reception of Delegates from Pharmaceutical Societies and Associations.

The President's Address.

The following and other papers will then be read:—

1. Report on the Purity of the Yellow Bees'-wax of Trade. Edward Davies, F.C.S.

2. Saccharo-Chirettine: a New Preparation of Chiretta. David S. Kemp, F.C.S.

3. On the Strength of twenty-four Specimens of Saccharated Carbonate of Iron. Mr. J. J. Nicholson, Sunderland.

4. Chloral: Note on the Best Forms for Internal Administration. Joseph Ince, F.C.S., F.L.S.

5. The Apprenticeship and Early Training of Pharmacists. Mr. F. B. Benger.

6. (Not yet received by the Secretaries.)

7. Analysis of Bitter Cassava Juice, and Experiments in Elucidation of its supposed Antiseptic Properties. Professor Attfield.

On Tuesday evening, at 6.0 P.M., a dinner, at the 'Adelphi Hotel,' will be given by the Local Committee to the President and Officers of the Conference. The Local Secretary, Mr. Davies, requests that gentlemen desirous of being present will communicate with him during the day, either at the Royal Institution or at the 'Adelphi Hotel.'

Wednesday, September 14.

The Conference will meet at 10.0 A.M., adjourning at 12.30 P.M.; resuming business at 2.0 P.M., and adjourning at 4.30 P.M.

The business of this day will comprise:—

Election of Members.

Reception of Letters of Invitation to the Conference for 1871.

Papers to be read:—

8. A Century of Old Books. Joseph Ince, F.C.S., F.L.S.

9. A Few Notes on Aloes. William A. Tilden, B.Sc., F.C.S.

10. Sulphite of Zinc. C. R. C. Tichborne, F.C.S.

11. The Storing of Poisons. Mr. Edward Smith, Torquay.

12. Ammoniacal Salts from Gas-Liquor; purified to fit them for use in Pharmacy. W. L. Scott, F.C.S.

13. The chemical constitution of Sulphurated Potash. John Watts, D.Sc.

14 to 21. Papers are expected from Messrs. Greenish (lint), Benger (apparatus for maintaining constant temperatures in laboratory operations), Linford (a new hydrometer), Scott (purity of commercial alkaloids and lithium salts), and from other members.

Thursday, September 15.

On Thursday there will be an excursion to Widnes and Runcorn at 1.30 P.M. from Lime Street Station. Messrs. Hutchinson and Co. and W. Gossage and Sons, at Widnes, and the Runcorn Soap and Alkali Company have liberally thrown open their works to the inspection of members, and the party will have an opportunity of inspecting the magnificent bridge recently built over the Mersey by the London and North-Western Railway Company. At 7 o'clock a collation will be provided by the Local Committee at Halton Castle, a ruin on an eminence commanding an extensive view of the surrounding country. Members of the Conference and subscribers to the local fund will be provided with tickets, entitling them to a return railway ticket at 1*s.* 6*d.*, on application to Messrs. Clay and Abraham, 87, Bold Street, not later than Tuesday evening.

Tuesday, September 20.

Election of Officers for 1871. Appointment of Place of Meeting for 1871.

By the kindness of the committee of the Lyceum, No. 1, Bold Street, the news room of that institution will be open to members of the Conference during the week.

SOCIETY OF ARTS.*

On Fermentation.

BY PROFESSOR A. W. WILLIAMSON, F.R.S.

Lecture II.

We left off last week at a point at which we had come to recognize a difficulty, which we did not, to any appreciable extent, succeed in solving. By considering in succession a certain small number of processes in which substances induced chemical changes in others which were in contact with them, we classified them, beginning with some very complex cases—cases in which substances of formulæ so long that, even if I ventured to give you chemical formulæ at all, I should hesitate to give you their formulæ—took part in the decomposition, and gave rise to products themselves having formulæ of no small complication. From those we passed to the consideration of some bodies less complex in their structure, and undergoing changes very much like those which we at first considered, but having this remarkable peculiarity that, in these somewhat simpler cases, the changes were effected not only by organic bodies comparable to ferments, but also, in certain instances, by simple mineral bodies, such as the acids. In this intermediate class we found that the same effects are produced, sometimes by diastase, or such-like bodies, and sometimes by sulphuric acid. Then we came to some still more simple cases of decomposition, produced solely by bodies of such simplicity that we chemists have got a tolerably definite idea of them. I gave two cases which, I believe I may say, are pretty well understood. The resemblance between the different terms of that long series served, as I think it will be admitted by those who followed the chain of reasoning, as an argument in favour of there being some great resemblance in the process which takes place in these changes in the successive terms of the series; and I propose, before we proceed further in the study of these wonderful decompositions, to analyse somewhat the nature of these changes in the simple cases which we last considered, in order that we may get, if possible, something like a master-key—a very simply-formed piece of iron—which will open a variety of locks. The two cases which I allude to were, first, the formation of ether and water from alcohol by the action of oil of vitriol; and, secondly, the ordinary process of making oil of vitriol in the so-called lead chambers; and I think it will be admitted, even from the very brief and imperfect statement which I was able to make, that we have evidence of the fact that the active substances do return, after they have been doing one bit of that work, to the point from which they started before doing it. I gave a couple of illustrations of that fact. Sulphuric acid is converted, while making alcohol into ether and water, into a substance called sulpho-vinic acid, which differs from it in a good many properties, and then it comes back again to sulphuric acid. Just so with nitric oxide, in the process of making oil of vitriol; it first takes up oxygen and assumes the form of those red fumes, then hands that oxygen over to the sulphurous acid which is in contact with it, thus coming back again to the state of nitric oxide from which it had started. Hence the term which I have suggested for this process is cyclical, to denote the fact, which I consider essential, the leading

* Cantor Lectures.

fact that it is a cycle, the idea of which implies that the road by which it returns is not the same by which it goes, and I want that idea to be suggested by the word. In the case of etherification, I wish I could lawfully use formulæ on the black board, but it would not do, for I am sure that the greater number of my audience will agree with me that it would be a liberty which I ought not to take; but chemists are in the habit of denoting, by the aid of formulæ, particulars which require to be fully explained. I mention that because, excluding that ordinary process, the particulars of my argument must, of course, be omitted, inasmuch as I do not use the language by which alone those particulars can be conveyed. When the sulphuric acid acts upon alcohol, and transforms it, by a succession of these cyclical processes, into ether and water, the general kind of process is this:—A little particle of the acid—because each one acts like the rest, and we had better consider one as a sample of the rest—first takes something from a contiguous particle of alcohol, and then it hands over this something to another particle of alcohol. That which the acid takes in the first instance is called, in our ordinary language, ethyl. It is a group consisting of carbon and hydrogen, very much like hydrogen gas—it is a group of those elements, and behaves in a manner closely analogous to hydrogen itself. The acid, in doing that particular work which we have to consider, first takes a particle of this ethyl from one particle of alcohol, and whilst it does so, it gives to the alcohol something in exchange; that something is hydrogen. And by doing this, the sulphuric acid which has taken up this ethyl is converted into sulpho-vinic acid; it has gone half round the circle, in fact. The remainder of its journey consists in reversing, in another way, with another particle of alcohol, that very same kind of interchange which it had undergone in the first instance, that is, it gives up again this little portion of ethyl which it had taken, and resumes hydrogen in place of it. Just as that is the general process when sulphuric acid acts upon alcohol, forming it into ether and water, so in the other process, which I just now reminded you of, there is a similar action, only there is this difference—of course, I speak within those narrow limitations which are imposed upon us by our very imperfect knowledge of even these best-known processes—but, as far as we know, the nitric oxide merely takes up oxygen, but gives up nothing in exchange. Those red fumes which you saw were really nitric oxide *plus* oxygen, not nitric oxide in which oxygen had replaced something else, and that was a difference between the process in that case and in the one to which I just now referred. Then, again, it simply gives up that oxygen to the particle of sulphurous acid.

The illustrious Liebig, to whom we owe, in this order of phenomena as in every other order which he has touched, some of the most valuable ideas which have guided our researches, suggested many years ago, for the explanation of the phenomena of fermentation, a theory which certainly has rendered very great service, and not the less so from the fact that it has been replaced by one more perfect. In building a house, it is certainly no proof that a scaffolding is unnecessary that in the final structure the scaffolding is not maintained; and so in the progress of our science, as in every other science, each part of the work must be judged from its usefulness in aiding the carrying on of the building, even though the particular substance which was placed there at the time does not finally form part of the structure itself. Liebig's explanation really is classic, and well worthy of a few minutes' consideration. He classed together a considerable number of cases of chemical action which bore, at least upon their surface, a considerable resemblance to one another, and he saw in them something in common, and by this one resemblance which they had he classed them, considering it to be their essential characteristic feature. For example, there is a substance which is made, by a process of oxidation, of a compound something like lime. It is called baric peroxide. Thenard had found that the oxygen which is here taken up by the baryta can, by a particular process, be passed over to water, so that, in fact, Thenard, from this oxide of baryta, made, by a process which I will repeat on a small scale, some oxidized water, or peroxide of hydrogen, as it is commonly called. Here is some of the peroxide suspended in water, and by adding an acid hydrogen salt, the hydric nitrate, in small quantities (for if I add it in too large quantities, I should destroy the peroxide, which is a very tender substance, and requires to be treated tenderly), I should gradually transfer the oxygen from the baryta, with which it was at first combined, to the water which is here present. This oxidized water, or peroxide of hydrogen, gives up the oxygen which it has just taken up very easily indeed; in fact, the difficulty is to prevent it doing so. Amongst processes of that kind, I will show you one simple one. I will pour into the water in this large beaker-glass some of the solution which I have just prepared, and then add to it a few drops of this red liquid, which is a solution containing chromic acid combined with potash. You see, no doubt, that although I have only added half-a-dozen drops, there is evidence of a chemical change, and the deep blue colour which is formed by the contact of the two liquids is due to the formation of a new compound. The chromic acid, which has a red colour, takes up oxygen from that peroxide of hydrogen, forming a blue compound. I have purposely chosen this particular instance, because the process is a slow one, and we have time to see its intermediate changes. I will leave the glass here, and in a few minutes you will see the blue colour will have disappeared, and in place of it we shall have a dirty green colour, hardly visible. Whilst that change takes place, if we were to take means to examine carefully what was going on, we should find that oxygen gas passed off, and if we examined the green substance present at the end of the process, and compared it to this original red chromic acid, we should find that it consists of chromic acid *minus* oxygen. The peroxide takes away oxygen from this chromic acid, and yet the chromic acid has got hold of its oxygen pretty firmly; it requires a considerable amount of energy to tear away even that part which is torn away by the process. But at the same time the oxygenated water is losing part of its oxygen. The deoxidation of the peroxide induces the chromic acid to give up some of its oxygen; the one body induces in the other a change similar to that which itself is undergoing. The peroxide of hydrogen is losing oxygen, and it makes the chromic acid also lose oxygen. To state the process in general terms, I may well use the expression of Liebig, and call it contagious action. There are many other cases of similar processes. Here is a bit of rotten wood; if I were to moisten it and put it into a convenient flask, leaving room for a quantity of air, closing the mouth of the flask with a good cork, and leaving it for a day or two, also putting with the air a little hydrogen gas, which, you know probably, is capable of combining with oxygen, I should, on examining the mixture of air and hydrogen after it had been in contact some time with this rotten wood, find that the hydrogen had been removed from the air, and at the same time the oxygen of the air which had been mixed with it had disappeared. Now this wood is actually undergoing a process of combustion; it is actually absorbing oxygen, or being burnt, very slowly indeed, but still at a rate which is not unimportant, if you want it to last for any length of time. De Saussure, who noticed this, attributed the oxidization of the hydrogen gas to the fact that the wood is itself undergoing oxidation. I will take another case of the same kind. I will put into a little flask some of that peroxide of hydrogen, and will show you another decomposition of it, which is rather more convenient in one respect than the one I first took, as it will show us something more of the process. Into this little flask I put some of the same oxidized baryta which I used just now, and I will fit up the flask in such a manner that the gas, which will come off in a tolerably large quantity, can be collected for examination. I will then put in contact with it a substance called silver oxide, first driving out of the flask all the air which it at present contains. Having driven out the air, I put in a few drops of the nitrate which I employed in the first instance, and then I will put in a solution of silver oxide, which is, in some respects, a good deal like this chromic acid, at all events in one important respect, for it has oxygen, which it can give up under sufficiently strong pressure. You now see there is a great deal of effervescence going on, and the gas which is coming off from the little flask is rising into this jar, where we shall very easily be able to ascertain whether it is oxygen by the ordinary test. I should have been glad, if it had been convenient to do so, to give you one other instance in which a remarkable fact was discovered by Professor Brodie, viz. a case of an action of this kind, where the oxygen taken from the peroxide is in quantity exactly equal to the quantity of oxygen from the other body. Whilst that gas is collecting, I must enter shortly upon a theoretical question, apologizing for doing so, not that I am ashamed of it, for it is one of the most important theories we possess, but on account of the brevity with which I am compelled to treat it. Oxygen, in the free state, is admitted by chemists to consist of two little atoms linked together. In each of the compounds which I used there was one little atom of the kind. One atom leaves each of them, and when I get free oxygen, I affirm that there has been a process of combination, that the oxygen from the one substance actually combined chemically with the oxygen from the other. This is a theoretical result which has been, in great part, established by Sir Benjamin Brodie, with the help of materials from various sources. What I mentioned in the other case holds good equally in regard to chromic acid and the other cases in which there was apparently no definite proportion of the kind. There is an actual chemical combination between the oxygen of one substance and that of the other, it is not merely that the one substance is compelled to decompose because the other is decomposing; there is between the one substance and the other an interchange, so that a constituent from each one combines with a constituent from the other. To do justice to the importance of this fact I should need to describe a great number of chemical reactions, which at present would be impracticable, but you may take my word for it, that the kind of process which I have described is now known to be one of the commonest in chemistry. The other day, when I mixed two of the commonest substances, there were interchanges between the constituents by a process perfectly analogous to that which takes place here. Here it happens, by an exceptional circumstance, that the element which from the one body combines with the element of the other is of a like kind, whereas, as a rule, you find that unlike elements unite together in these processes. Thus it is that the anomaly which Liebig noticed ceases to be an anomaly, and is brought back to a case of common regular chemical action by the aid of that theory to which I have just alluded.

To return to our experiment. This glass vessel is now full of the gas, and by applying a taper which has been lighted and blown out, but is still glowing, we shall find, on putting it into the jar, that it immediately ignites, which is the ordinary test of oxygen gas. By the aid of that theory, which has been discovered since the time of Liebig's suggestion, this one case of apparently anomalous action has been proved to be a perfectly normal and regular case of combination, and the same kind of thing has been done with regard to other cases of the same description. A number of other processes which he classes with these may be shown to be due, not to any exceptional force that is at work in these cases, not to the force of any particular contagious action among chemical substances, but to the ordinary forces which induce chemical combination in the cases best known to us. Liebig's theory of contagious action has been alluded to, by a high authority in this country upon philosophical matters, as being a law of chemical action of a generality comparable to the law of gravitation in astronomy, and for that reason, if for no other, it must be of considerable importance to know what bearing our most advanced knowledge has upon that law. I dare say you see the connection between it and the case of fermentation. I will not go into particulars, further than is necessary in order to show you the general analogy.

First, I will take the case of alcoholic fermentation, as being the case best known. The ferment consists of little cells—which I hope I shall be able to show you at our next meeting—each one containing several chemical compounds, but itself a little living being. I will not say at present whether they are animals or plants. When you have these little organisms in water, or sugar, or in any moist substance, they are constantly, and of necessity, undergoing decomposition. You may arrest the decomposition by various agents, but if you do so, you kill them, or suspend their activity as yeast. No case is known to us of their acting like yeast without undergoing at the same time a process of chemical decomposition,—being broken up into simpler substances than those which were contained in them. I pointed out, last week, that the sugar which is being decomposed by the yeast is by that process being broken up into substances which were contained in it, and that was what Liebig noticed. He said that this yeast is a substance which tends to decompose,—it is breaking up into simpler substances, and it induces in these particles of sugar which are in contact with it a decomposition similar to its own. The action which it is undergoing is contagious, and passes over to the contiguous particles of sugar; and he adduced cases like that of oxygen, as affording analogies among simple well-known bodies. I think what I have said with regard to the case of oxygen will be sufficient to show you that in those simple cases the idea of contagion is certainly not applicable.

A foreigner, who was describing some time ago the luxuriance of the crops in America, spoke of a bushel of *mice* being sown in a field, and a hundred bushels of *mice* being reaped. Of course, what he meant to say was *maize*, or Indian corn; but I am reminded of that anecdote by the necessity I am under for a moment of asking you to consider for a while some living beings under their general functions only. Suppose you had a bushel of actual English mice, and you put them into a granary full of corn. There clearly would soon be a great change. You are supposed to know nothing more about the particular organization of these little beings than you know about the particular organization of the little yeast-cells. You know that these little things eat grain, and that in place of the grain which they eat there appear various products of decomposition, which can be easily collected and examined. They give off carbonic acid, and so forth, and if you examined the state of that granary after a time, you would find a chemical change, or rather a set of chemical changes, going on in the organisms of these mice. The substance of which they consist would be actually wasting away; they would be giving off carbonic acid, and nitrogenous and other products. And if you also examined the state of the corn which was there at first, you would find that it finally passed over into these same products; and I say that the theory of contagious action is as much applicable to the action of the bushel of mice in the granary full of wheat, as to the action of the yeast cells upon a solution of sugar. There is in the one case, as in the other, an assimilation by the living organism of the material upon which it acts. The materials undergo certain changes, of which the general results are known to us, but of which the particulars are, I may say, in the main almost completely unknown. As to the processes by which these products are formed, it is as well to say that we do not know them. We know a little here and there about them, but it is nothing compared to our ignorance; therefore the resemblance is the more striking, and if we were to believe in the contagiousness of chemical action as applied to the case of the assimilation of sugar by a ferment, and say the ferment gives off alcohol and carbonic acid, and that sugar is also resolved into alcohol and carbonic acid, we should really be describing in its general features a process analogous to that which I have just now mentioned; such a general analogy would be readily admitted by those who go into the particulars of the process, but I think it is of particular importance to have in addition to it something more practically useful to guide us in understanding chemical reactions. For that purpose I will take one or two chemical reactions of an exceedingly common kind. For instance, I will again take that chromic acid solution which I just now employed. Here you see is the green residue which I told you would be produced; I again take some of this chromic solution, throw some of it into water in this jar, so as to visibly tinge the water red; I will slightly acidulate the liquid by oil of vitriol, and I will then pour into the mixture (which I will describe as chromic acid dissolved in water, for the potash which was present is taken away from the compound by the sulphuric acid), a substance which I will merely describe as being greedy of oxygen, sulphurous acid. If Liebig's theory of contagious action were generally true in chemical action, you would no doubt expect that this sulphurous acid, in taking up oxygen, would make the chromic acid also take up oxygen. It is quite possible for the chromic acid to do so, for that blue substance which we had in this jar at first was nothing but chromic acid with oxygen added to it. But instead of this, we shall have at once a reduction of the chromic acid to deep green, which I dare say appears to you almost black. It is precisely the same thing as that pale, dirty green which you saw before, but in its concentrated state. There is no oxygen taken up by the chromic acid, but it at once loses oxygen. This sulphurous acid wanted to combine with oxygen, and it tore away at once some of the oxygen from the chromic acid, and there was in this chromic acid a process, not similar to that which the sulphurous acid underwent, but a process precisely opposite to it—one combined with oxygen while the other lost oxygen,—and if you examined the liquid, you would find that the sulphurous acid which took part in the process, and has taken up oxygen, is now in the form of sulphuric acid. Again, I have here some granulated zinc, which will very easily evolve hydrogen, particularly when its activity is stimulated by throwing a little copper vitriol on to it. After adding a little water, I will throw in a little oil of vitriol, so as to get an evolution of gas. Then I have here a solution which I think must look black to you, except at the edges, which is a solution of a beautiful salt called permanganate. It is used for deodorizing certain fetid waters, and I might compare it to the chromate I was using just now. It consists of an acid of the metal manganese. If I throw some of that into the mixture which I have just prepared, and leave it for a short time, and then examine it, we shall find that, instead of being induced to give off hydrogen like the other body, which is doing so vigorously, we shall find it will do the opposite, and will combine with hydrogen; and the colour which belongs to it, and which can be recognized so easily, will disappear, because hydrogen will be taken up by its oxygen, and it will be reduced and brought down to a substance containing comparatively little oxygen. There, again, as in the previous case of the chromic acid, we find that there is a kind of chemical polarity in the general mode of action, that the one substance acted upon does precisely the opposite of the other. There is no tendency in this case to do the same thing, but the two substances acting upon one another do precisely the opposite, the one taking up what the other loses. Not only is that the case in the instance of the action which I have mentioned here, but in a great number of other cases of considerable interest and importance,—bodies which act chemically with considerable energy when allowed to do so, are prevented by others from so doing when those others are trying to do the same thing. If, for example, we put metallic copper into nitric acid, the copper would dissolve with immense energy: it would undergo what I might call a process of combustion. Again, if I put mercury in contact with the acid, the same thing would occur; it would be dissolved almost as rapidly as the copper. But if I put the two together into nitric acid, the copper prevents the mercury from undergoing combustion; and so far from encouraging it to do the same thing, it actually takes from it the power which it possessed before of undergoing a combination of that kind. And more than that, if I take mercury which has been burned—a solution of mercury in the form of corrosive sublimate,—and put copper into it, the copper will actually unburn it, or make it come back again from the point at which it had got, and throw down the metal. You can see the process which takes place; on putting a strip of clean red copper into the solution, it becomes grey, and throws down the mercury from the solution. So far from encouraging the mercury to oxidation, it makes it do the opposite to that which it otherwise had a tendency to do.

Again, I will take some of this solution of copper—it ought to be some of the very solution which is being made here, where copper is being dissolved at the expense of mercury—and if I put into it a piece of common iron, perfectly clean and white, it will very speedily combine; and I cannot express its functions in combining better than by saying that it will make copper uncombine, for the copper which was burnt is now being unburnt.

If we go carefully, with the knowledge of their particulars, through the best-known chemical processes, we find that there is, as a rule, a force at work which I might describe as polarity—a tendency among contiguous particles which are acting on one another to assume functions which can be best characterized as being opposite to one another. Whatever the one is doing, the other is doing as nearly as possible the very opposite of it, and any tendency to do like work I know not of. There are, however, cases which would appear to be favourable to the notion of contagious chemical action. If I blow out that gas-burner, still letting the gas escape, and then bring near to it a burning splint, it will set fire to the gas, and the same with a candle-wick if I bring close to it a burning match—the match, which is burning, communicates to the wick the process which it is undergoing,—but the explanation is this, it does so merely because of the high temperature which it has attained. If by any other process, such as concentrating the rays of a powerfully-heated surface by means of a lens, I raise the temperature of the gas to that point at which it is capable of combining with the oxygen of the air, it will do just as well. The accident that the high temperature is communicated by the burning splint has nothing to do with the process.

(*To be continued.*)

Hypodermic Injection of Calomel for Syphilitic Diseases of the Eye.—Professor Quaglino and Dr. Soresina give the details of a considerable number of cases where this plan of treatment has been successful in various ophthalmic diseases of syphilitic origin. The calomel was sometimes injected hypodermically into the temples, sometimes into the arm, great benefit being obtained in every instance.—*The Practitioner.*

Parliamentary and Law Proceedings.

ALLEGED EXTENSIVE FRAUDS ON THE REVENUE.

Clerkenwell Police Court, *September 6th.*

John Sutton, of 15, Regent Square, St. Pancras, was summoned before Mr. Cooke, for alleged frauds upon the Inland Revenue Department.

From the evidence it appeared that an officer of stamps went to No. 15, Regent Square, and there found the prisoner exposing for sale drugs and medicines which by law were chargeable with stamp duty. There were no less than 337 bottles containing drugs and medicines so liable, to which the paper cover, label, or stamp provided by the Commissioners of Stamps had not been affixed. The penalty for the offence is £10 in each instance, and the defendant had thus subjected himself to a fine of upwards of £3000.

Upon the application of the defendant's solicitor, the magistrate adjourned the hearing of the case for a fortnight.

The Growth of the Mistleto on the Oak.—In the volume of Transactions issued lately by the Woolhope Naturalists' Field Club, there is a photographic illustration of the Mistleto Oak of Deerfold Forest, one of the few known instances of the growth of this parasite on the Oak. Dr. Bull, in speaking of it, says, "This very interesting tree grows in the hedgerow of a field called the Harps at Haven Aymestry, in the ancient forest of Deerfold, on the property of the Messrs. Fortey. It was discovered in the spring of 1869, but the Mistleto must have been growing on the Oak for some years. The Oak is of the variety *sessiflora*, and may be some fifty or sixty years old. At 5 feet from the ground it measures 3 feet 8 inches in girth. The Mistleto is a female plant, and grows high up in the Oak on the main stem of the tree, after it has bifurcated. It forms a large spreading bunch, with a diameter of 3 feet 6 inches, and springs out from the Oak in a single stem nearly 4 inches in circumference. The Mistleto is also growing on a Thorn in the hedge immediately below the bunch in the Oak, and has probably sprung from a seed dropped by the birds from above. The great rarity of the growth of Mistleto on the Oak is proved by the fact that there are but eight examples which have been well authenticated as existing at the present time. They are to be met with in the following localities:—Eastnor Park, Herefordshire; Tedstone Delamere, Herefordshire; the forest of Deerfold, Herefordshire; Frampton-on-Severn, Gloucestershire; Sudbury Park, Chepstow, Monmouthshire; Burningfold Farm, Dunsfold, Surrey; Hackwood Park, Basingstoke, Hants; and one near Plymouth."—*Gardeners' Chronicle.*

A New Preparation of Cotton for Stanching Hæmorrhage.—Dr. Ehrle, of Isny, calls attention, in the *Schwabischer Merkur*, to a simple preparation of cotton, which he has found of great service in surgical operations followed by great effusion of blood. The mode of preparation is as follows:—American cotton of the best quality should be cleansed by boiling it for an hour in a weak solution of soda (about 4 per cent.), then repeatedly washed in cold water, pressed out and dried. By this process it will be perfectly disinfected and adapted to more ready absorption. After this it should be steeped once or twice, according to the degree of strength required, in liquid chloride of iron, diluted with one-third water, pressed and thoroughly dried in the air, —*neither in the sun nor by the fire*,—then lightly pulled out. The cotton so prepared will be of a yellowish-brown colour. It must be kept very dry, as it is affected by the damp. Lint may be similarly treated, but the fine texture of the cotton renders it preferable. When placed on a fresh wound, it causes a moderate contraction of the tissue, and gradually coagulates the blood in and beyond the injured veins, thus closing the source of the effusion. This property of the chloride of iron is increased by the dryness of the cotton and the extended surface offered for the development of the chemical action.

A New Eye Salve.—The following ointment is recommended by Dr. Williams, of Cork, after long experience, in cases of granular lids, and all cases of chronic ophthalmia:—

℞ Arsenici Sulphureti gr. ij
Unguenti Citrini ʒij
Axungæ Præparatæ ʒvj.
M. bene.

In cases of "granular lids" the upper eyelids should be everted, and a piece of ointment the size of a hemp-seed should be applied with a camel-hair pencil to the diseased conjunctiva.—*Dublin Quarterly Journal of Medical Science.*

Poisoning from Arsenite of Copper on Wall-paper.—A case of poisoning is reported in the *Lancet* which illustrates the danger of using arsenite of copper for decorating paperhangings. A retired master mariner, living at St. David's, was seized with what appeared to be an attack of English cholera. The symptoms, which were very severe, were not subdued until after twelve hours' medical treatment. Upon inquiry, it appeared that he had been employed during the whole morning of the previous day in removing the paper from the walls of a room previous to having it repapered. The paper last put on was a purple one, but underneath it was another of a green colour, which had been on the walls about fifteen years. He had much difficulty in removing this; indeed, nearly the whole of it had to be scraped off by a knife. This operation caused a great deal of dust to rise from the paper, frequently compelling him to close his eyes in consequence. He must thus have inhaled a considerable quantity of arsenite of copper, which occurred thickly on the paper, and was easily rubbed off. The symptoms also indicated inhalation of the poison. Previous to the attack he had been a strong, healthy man, and had never suffered from cholera or cramp, although he had been abroad a great deal.

Power of Opium to Relieve an Exhausted Frame.—Dr. Barnes, in 'A Visit to Scinde,' says:—"On one occasion I made a very fatiguing night march with a Cutchie horseman. In the morning, after having travelled thirty miles, I was obliged to assent to his proposal of halting for a few minutes, which he employed in sharing a quantity of about two drachms of opium between himself and his jaded horse. The effect of the dose was soon evident in both, for the horse finished a journey of forty miles with great apparent facility, and the rider absolutely became more active and intelligent."—*Food Journal.*

Indian Hemp in Menorrhagia and Dysmenorrhœa.—Dr. Silver publishes several cases of these affections in which the tincture of Indian hemp has proved of great service, because he thinks its value in them is not sufficiently known.—*The Practitioner.*

The following journals have been received:—The 'Brithis Medical Journal,' Sept. 3; the 'Medical Times and Gazette', Sept. 3; the 'Lancet,' Sept. 3; the 'Medical Press,' Sept. 7; 'Nature,' Sept. 1; the 'Chemical News,' Sept. 2; 'Journal of the Society of Arts,' Sept. 2; 'Gardeners' Chronicle,' Sept. 3; the 'English Mechanic,' Sept. 2; the 'Practitioner' for September; 'Union Pharmaceutiaue' for August; 'Repertorium für Pharmacie' for September; 'Medical Mirror' for September; the 'Pharmacist' for August; the 'Food Journal' for September; 'Journal of Applied Science' for September.

We have received the 'Ulverston Mirror' for Sept. 3 from Mr. H. W. Mackereth.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

THE BETTS CHANCERY SUITS.

Dear Sir,—Will you kindly insert the accompanying in the next number of the PHARMACEUTICAL JOURNAL?

Yours truly,
W. T. COOPER.

"LONDON, 1st *September*, 1870.

"DEAR SIR,—We have again to address you on the subject of the BETTS SUITS, partly in the nature of a report of what has been accomplished, and in part to show that more remains to be done.

"The *Times* of June 30th, the *Standard* of July 2nd, the PHARMACEUTICAL JOURNAL of July 9th, and the *Chemist and Druggist* of July 15th contain reports of the proceedings which resulted in the dismissal of the Bills filed by Mr. Betts in these suits; but since those dates the plaintiff has brought the cases before the Lord Chancellor, and obtained an order under which he has appealed. We are advised that, if the appeals be properly contested, the defence will continue successful, and for that object we need and earnestly solicit your co-operation.

"So long a time has passed since the Betts Suits were instituted, and our Committee and Defence Fund formed, that the general consternation which once prevailed has passed away, and perhaps to an extent become forgotten; we therefore venture to remind you of the facts.

"Twenty-five Bills in Chancery were filed against chemists, perfumers, mineral-water dealers and others, vendors of capsuled articles. A person in the employ of Mr. Betts went into a shop and bought there a single bottle, the cork of which was covered with a capsule bearing the name and address of the person who manufactured the article and affixed the capsule. The retailer, having bought and sold the article in the ordinary course of his trade in perfect innocence, then received a letter from Mr. Betts's solicitor, stating that he 'was instructed by Mr. Betts to commence proceedings for an infringement of his patent by the use and sale of his metallic capsules on bottles, which capsules had not been made by Mr. Betts, but of precisely similar materials.' The retailer replied, 'As I have never capsuled, or caused to be capsuled, any bottle or pot in my establishment, perhaps you will have the goodness to let me know in what way I have infringed the patent;' to which the answer was, 'I beg to state that the sale by you of the capsules on bottles is the infringement complained of. Any person supplying you is equally liable, and the time will come when you will be interrogated as to who has supplied you, when and in what quantities;' and on the same date the Bill was filed.

"Mr. Betts is very experienced in litigation; he was offered by Mr. Rimmel £1000 for peace, and refused it; and when an attempt at an arrangement was on foot he talked of £20,000 or £30,000 as something solid, something to eat, to be paid by the 'Pharmaceutical body' (how much more from other traders was not stated). Some of the defendants settled with Mr. Betts by paying £20 to £25 each; but it was felt that unless a stand was made Mr. Betts might go through the kingdom in detail, and, with sums of £20 or £25 apiece obtained from chemists, perfumers, wine merchants, grocers and others, fill his money-bags at the expense of legitimate traders, and also that success by Mr. Betts in that operation might encourage other patentees to pursue a similar line, and render business intolerable. Thus, a stand was resolved upon, a committee was formed, and a defence fund raised.

"Under cross-examination Mr. Betts did not recognize his own goods of English manufacture, and admitted having sundry manufactories *abroad;* and when it appeared likely that the capsules on the purchased bottles had been made by his Paris house, he set up a subtle distinction between Betts as a French manufacturer and (the same) Betts as an English patentee, so that the Vice-Chancellor said, 'I must say this seems to me about the most impudent case that ever came into Court. I am shocked at such a mode of making an affidavit. I hope never to see it again.'

"But Mr. Betts, 'the hero of a hundred fights,' will not sit down under the condemnatory judgment of the Vice-Chancellor. He appeals to the Lord Chancellor, and may resort to the House of Lords; and unless he is resolutely met, it is impossible to predict the result. The defence entails expenses which are, and will be, heavy; and we have to appeal, as we do with confidence, to the great body of retail and wholesale dealers to aid the object by a general subscription. Their protection from similar suits has, no doubt, been secured by the defence, as the patent has expired during the four years of litigation.

"It should be understood that the Defence Committee is not identified with, and has no claims upon the Pharmaceutical Society, though many of the leading members of the latter have taken an active interest in the object for which it has been formed.

"Contributions to the Defence Fund, in stamps, P. O. Orders, or cheques, crossed 'London and County Bank, may be paid to the Treasurer, Mr. Lionel Newbery, 44, St. Paul's Churchyard, London, E.C.

"Inclosed is a form for your Subscription, and we ask the favour of your filling it up and remitting it at your earliest convenience.

"For the Defence Committee,
"WILLIAM TEMPLE COOPER, *Chairman.*

"26, *Oxford Street, London, W.*"

The following gentlemen form the Defence Committee, who will furnish any required information:—

BARCLAY, ROBERT, Farringdon Street, E.C.
CARTEIGHE, MICHAEL, 172, New Bond Street, W.
COOPER, WM. TEMPLE, 26, Oxford Street, W.
ELLIS, GEORGE H., 4, Pavement, Finsbury, E.C.
FIELD, GEORGE, 168, Edgware Road, W.
HART, WALTER, 38, Blackman Street, S.E.
HILLS, THOS. HYDE, 338, Oxford Street, W.
HOVENDEN, ROBT., jun., 5, Great Marlborough St., W.
NEWBERY, LIONEL, 44, St. Paul's Churchyard, E.C.
POTTS, ROBERT N., 26, South Audley Street, W.
REDWOOD, THEOPHILUS, 17, Bloomsbury Square, W.C.
SANDFORD, GEORGE WEBB, 47, Piccadilly, W.
SANGER, WM. ALBERT, 150, Oxford Street, W.
SMITH, FRED. WM., 139, Newington Causeway, S.E.
WILLMOTT, WM., 83, High Street, Borough, S.E.

17, *Bloomsbury Square, London.*

"FREE TRADE IN SURGICAL INSTRUMENTS."

Sir,—May we be allowed to say a few words with reference to the article in your Journal of July 30th, in which our names appear?

In sending our catalogue of surgeons' instruments to the profession direct, we most certainly had no intention of injuring in any way our best customers, the chemists and druggists; indeed, apart from any better feeling, our own interest would have prevented our doing this.

We learnt from experience that the surgeons *would* buy their instruments direct, and in endeavouring to transact this branch of our business through the chemists we found we were seriously prejudicing ourselves without really serving them.

With regard to the few sundries included in the surgeons' price-current they were added simply to satisfy the profession without furnishing our general list, and we carefully excluded all articles that we thought could possibly interfere with the *chemists*. As, however, *they* think otherwise, in future we shall confine our surgeons' list strictly to surgeons' instruments and appliances.

We fear, owing to misconception, which we deeply regret, that we have been the subjects of some ill-feeling in certain quarters, but this we feel confident will disappear when our motives become better understood.

In the conduct of our business we have always scrupulously studied the benefits of the trade, even when to our own pecuniary loss.

Apologizing for troubling you on a matter which, although of a personal character, is of no little importance to us,

We are, Sir, yours obediently,
S. MAW, SON AND THOMPSON.

[*** We think it right to remind our readers that the article referred to by Messrs. Maw dealt with the obnoxious mode in which the case had been treated of in a contemporary rather than with the merits of that case, which is somewhat outside the range of this Journal.—ED. PH. J.]

Hospital Dispensing.

Sir,—This morning I was engaged in perusing the article in the Journal containing Mr. Simon's reflections (in his Report to the Lords of the Privy Council) upon the power which is vested in the Pharmaceutical Society to prescribe regulations as to the keeping of poisons not having been exercised by them, when I was interrupted by a female who asked for a seidlitz powder. This was a preliminary to the inquiry how she ought to take a mixture, or whether it was a gargle, that had just been supplied to her at the dispensary of St. Bartholomew's Hospital. She produced about O j of medicine without a label, but in its place a scrap of ungummed paper had been thrust into her hand, upon which was printed

"One teaspoonful every hours."

The medicine was prescribed by one of the officials connected with the hospital, and as far as the prescription could be deciphered from its scrawled and blotted condition, it was this—

"Hj Mist. Cinch. Rosæ c. Acid."
t.

I presume the *t* meant that it was to be taken three times a day, although a teaspoonful dose would be quite homœopathic. I tasted it, and told the patient that undoubtedly the medicine was nothing very potent, especially as it had been compounded at an establishment that did not incur the trifling expense of using adhesive labels.

Coupled with the podophyllin prescription supplied by a correspondent last week, does not this exhibit great laxness on the part of the profession compared with the care and attention displayed in most retail dispensing establishments? Ought not Mr. Simon's strictures in common fairness to be applied rather to the dispensaries for the poor than to the dispensing chemist who, for his own interest, is careful to place explicit directions upon adhesive labels, and attach them to any medicine he dispenses?

I am, Sir, yours, etc.,
Robert Owen Fitch, M.P.S. G.B.

Sir,—I have not had the pleasure of seeing the article in the *Lancet* from which you quoted last week, but, judging from the choice little specimen, feel persuaded that the editor, if not suffering from nervous irritability, must have been inhaling that gas that makes people feel "jolly under difficulties," as did Mark Tapley when reduced to his worst condition in the flourishing estate of Eden.

General practitioners, who are everything in general and nothing in particular, do sometimes assume airs of importance that suffer an eclipse when brought in close proximity with educated pharmacists, whose labours they are not so unwilling to profit by as to acknowledge.

The head and front of their offending is not therefore ignorance so much as being competitors in the healing art. They spoil practice, and many a profitable case is entirely frustrated by the timely dose that *saves* the doctor.

General practitioners must sometimes find their cloth wofully soiled by contact with inferior people at the Polytechnic and elsewhere,—even at church, which does not exclude greasy butchers, dusty millers, musty pawnbrokers or unctuous grocers when properly dressed for the occasion. Above all, these gentlemen have no objection to take pay from the disreputable class who "prescribe (*not*) in the dark," like some shady practitioners of questionable antecedents, in their "hideous dens of iniquity," as designated by the *Times* not many years since.

I hope sufficient spirit will be found among us to assert our claims on public confidence and respect, and that the depletory influence of that very old-fashioned and almost obsolete instrument, the *Lancet*, will not succeed in taking one drop of blood from our body corporate.

I am, Sir, yours faithfully,
Non-Malefactor.

Mr. Coles' Prescription.

Sir,—Respecting Mr. Coles' Prescription in Journal of the 3rd inst., I should have used the *Acid. Nit. Mur.* Dil. in the mixture; and the pills I would have made *into* twelve, knowing, verbally or otherwise, something of the patient; and the *Directions ij p.* r. *n.* Certainly the pills would be powerful, but I should consider perfectly safe.

I am, Sir, yours faithfully,
R. Parkinson.

1, *William Henry Street, Liverpool,*
September 6, 1870.

As Mr. Coles is desirous of an expression of opinion from any member of the Profession as to how the two formulæ he has given ought to be dispensed, I readily offer mine. At first glance, both appear to be unusually strong, while the pill formula is incomplete as to directions for the number of pills intended to be made from the *materiæ* ordered.

In my experience I have frequently met with instances where medical men have given such decided doses of the very same medicines, and I will refer him with pleasure to two who are constantly writing such prescriptions as he has given. From the *adjuvans* ordered in the latter of the formulæ, it appears to have been evidently the intention of the prescribers to exhibit a brisk cathartic to counteract the constipating effect of the acid when given in so large a dose; but then comes the question, how many pills were intended? From that quantity of the materiæ I should have made it into thirty, and directed two to be taken every night.

I can remember a case in my early dispensing days of a man who regularly took one grain of podophyllin combined with colocynth and extract of henbane every night with but little intermission for months, and with apparent ease as well as benefit to his health.

However, if opportunity offered, I should certainly inquire into the case before delivering the medicine to my customers.

Peltatum.

Concentrated Medicine.

A correspondent inquires how to dispense the following:—

R. Ferri Pot. Tart. ʒiij
Amm. Carbonat. ℈iss
Tinct. Aurantii,
Inf. Calumb. Conc. āā ℥iss
Misce.

M. T. (Hampstead) is referred to the Erratum below, and to No. 4, p. 68, where there is a note on the subject.

G. E. C. Brown (Louth) writes to say that he has had several pigeons poisoned by perchloride of mercury, and wishes to be informed in the columns of the Journal whether it would be safe to eat them.

A. B. (Hertford) writes, in reference to the plate licence for smelling-bottles, stating that "silver-capped bottles are exempt if under 5 dwts., gold-capped bottles are exempt if under 2 dwts. of metal." We thank him for this information, which we publish on his authority. It has not been the practice to answer legal questions in this Journal.

September (London) desires to have a formula for Brilliantine. We must refer to the rule as to anonymous letters.

Mr. Francis Bell (Bradford) writes to say that he has forwarded to the German Committee in that town 12 yards of adhesive plaster, 2 lbs. of lint, 6 bottles of Condy's fluid and 1 oz. bottle of Howard's quinine.

H. E. D. (Wallingford) wishes to know whether any better work can be recommended for following in collecting an herbarium than Babington's 'Manual of British Botany' (Van Voorst, 10*s.* 6*d.*) or Hooker's 'Student's Flora' (Macmillan and Co., 10*s.* 6*d.*).

C. W. K. (Thorne).—The exemption is granted to Pharmaceutical Chemists only.

X. Y. Z. asks whether the duty is taken off hops; whether brewers are allowed to substitute any other bitter in making bitter beer and, if so, whether chemists are allowed to sell it to them. We must call our correspondent's attention to the rule given above respecting anonymous communications.

Erratum.—In the answer to *X. Y.*, p. 180, col. 2, line 26 from top, *for* weaker *read* stronger.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

The General Index to the first Fifteen volumes of this Journal may be obtained of the Secretary, 17, Bloomsbury Square, price 2*s.* 8*d.*, post free; bound in cloth, lettered, 3*s.* 8*d.*, post free.

The General Index to the Vols. XVI.–XVIII., Old Series, and Vols. I.–IX., Second Series, may also be obtained of the Secretary, price 3*s.* 3*d.*, post free.

GUARANA.

Paullinia sorbilis, Mart.

BY M. C. COOKE, M.A.

The remarkable product called Guarana has not been many years known in Europe. The tree whence it is obtained belongs to the Order *Sapindaceæ*, and is abundant in the province of Amazonas, along the banks of the Tapajos, Rio Negro, etc., as well as in Guiana and Venezuela. The fruit, scarcely as large as a walnut, contains five or six seeds, which are roasted, then mixed with water, and moulded into a cylindrical form resembling a large sausage, then finally dried in an oven and offered for sale. Guarana is used extensively in Brazil, Guatemala, Costa Rica and other parts of South America, as a nervous stimulant and restorative.

Besides its medicinal properties, this substance has a reputation for affording a refreshing beverage similar in its effects to tea and coffee. It is grated into a powder, very like powdered cacao in appearance. Two spoonfuls of this powder are mixed in a tumbler of water, and this drink is regarded as a stimulant to the nerves, and, like strong tea or coffee, is said to take away the disposition to sleep.

The active chemical principle is an alkaloid first discovered by Dr. Theodore von Martius, and called by him Guaranine, but since shown by Dr. Stenhouse to be identical with Theine. Guarana contains more than double as much of this alkaloid as good black tea, and five times as much as coffee, the proportions being 5·07 per cent. in Guarana, 2·13 per cent. in tea, and 0·80 to 1·00 in coffee.* The same alkaloid is found to the amount of 1·25 per cent. in matè, or Paraguay tea, the produce of several species of *Ilex*.

It is rather a singular coincidence that the same alkaloid should prevail in all the principal substances employed in a a similar manner as beverages in different parts of the world,—in the tea of China and India, the coffee of Arabia, the cacao of Central America, the matè of South America, and the Guarana of Brazil. M. Fournier has found in the last-named substance, besides tannate of caffein, the following principles:—gum, starch, an acrid green fixed oil, a concrete volatile oil, scarcely soluble in water, a peculiar principle not precisely determined, and tannic acid.†

According to the 'Technologist,' there is exported annually from the city of Santarem about 16,000 lbs. of this substance, valued at eightpence or ninepence per pound, and on the Rio Negro it has been sold as low as one penny per pound. Specimens were exhibited in the Brazilian Court of the International Exhibition of 1862, made by the Amazonian Indians, who prepare it for their own use, and for conveyance to Para, Matto Grosso, and Goyaz. Six different preparations made in Vienna from this substance were also shown in the Austrian Court.

When Guarana was first employed in France medicinally, it sold at the rate of from four shillings to twenty shillings per ounce, but has since gone down in price. It is included amongst the non-officinal substances of the 'United States Dispensatory.'

Its effects upon the system are said to be those of a tonic, but they do not appear to have been accurately investigated. It is habitually employed by the Indians of Brazil, either mixed with articles of diet as with cassava or chocolate, or in the form of drink, prepared by scraping it, and suspending the powder in sweetened water. It is considered by them useful in the prevention and cure of bowel complaints. Dr. Gavrelle, who was formerly physician to Dom Pedro in Brazil, called the attention of the profession to it some years since in France. He had found it advantageous in the diarrhœa of phthisis, sick headache, paralysis, tedious convalescence, and generally as a tonic. By Dr. Ritchie, surgeon in the British Navy, it is highly recommended in irritation of the urinary passages.* Dr. Hervé has been in the habit of using it daily for five or six years, and has never failed to derive advantage from it in idiopathic diarrhœa, even in the most obstinate cases.†

It may be given in substance, in the quantity of one or two drachms, scraped into powder, and mixed with sweetened water, but the most convenient form of administration is that of spirituous extract. According to M. Dechastelus, alcohol is the only agent which completely extracts its virtues, ether and water effecting this object but partially. Of the extract eight or ten grains may be given during the day, in the form of pill. It may also be taken along with chocolate as a drink.‡

Another species of *Paullinia* (*P. cupana*) growing on the banks of the Orinoco river, is also said to yield a similar substance. Guarana, or Paullinia, as it is sometimes called, has never obtained general favour in this country.

THE SOURCE OF MUSCULAR POWER.

BY BARON LIEBIG.

Considering muscle as the working apparatus and source of power in the animal body, a knowledge of its chemical composition acquires great interest; but unfortunately we know very much less of this than of its morphological relations.

We distinguish in muscle constituents with definite forms from others that are amorphous; and one-seventh part of the dry material of muscle consists of soluble substances which do not coagulate when heated. These constitute the so-called extractive, that is taken up from disintegrated muscle by cold water.

Urea and uric acid do not exist in healthy muscle; uric acid has only once been met with by Meissner in fowls' flesh, and in very small amount—a few milligrams in nine pounds of flesh.

The mere fact of the invariable presence of creatin or creatinin in the muscular flesh of all the higher classes of animals may be regarded as decisive proof in favour of the opinion that both these substances are necessary for the economy of muscle.

Some physiologists have regarded them as appertaining to excretions, especially because creatinin is frequently present in urine.

Creatin is, in virtue of its chemical characteristics, a substance that is unique; under the influence of very feeble reactions,—such, for instance, as in a fermenting sugar solution,§—it is converted into a

§ Pharm. Journ. 3rd ser. Vol. I. p. 142.

very strong alkaline base, and then again into a neutral substance solely by losing or taking up water, and without the aid of acids when neutralization takes place. A substance possessing such remarkable characters must surely be of some importance for the processes taking place in the force-producing apparatus.

However, there can be no doubt that, in some part, these substances are given off by the system; but I believe it is going too far to infer, from their presence in urine, that they have not taken part in the processes going on in the muscles. The organic alkalies, to which class creatinin belongs, are compounds of a peculiar and very stable kind; and every one would hold it to be inadmissible that quinine should be regarded as without influence in the process of the body, simply because it was present in the urine.

Inosinic acid is, according to the most recent observations of Seekamp, a constant constituent of ox-flesh and probably of all flesh. This is also the case with hypoxanthin.

The uncrystallizable nitrogenous constituents of muscular flesh, which quantitatively preponderate, are almost unknown as regards their chemical nature; among those which are non-nitrogenous there is one substance readily susceptible of conversion into lactic acid, perhaps sugar or inosite, which is present in larger amount in the muscles of the heart.

From what has already been said, it follows that myosin or syntonin, albumen tissues, nerve substance and phosphates do not alone make up muscle, but that the other combustible substances, so remarkable in their chemical nature, must be regarded as equally essential constituents. All together take part in the processes of the working muscle, and they must be considered as conditions of those processes.

There is scarcely an inference, much less a fact, that requires no further foundation; and if the formed muscle constituents be regarded as the parts of the machine, the other mobile constituents of the muscle must serve as the working material.

From this point of view, I believe we obtain a wider conception of the processes of nutrition, which, up to the present, are known only in the most superficial manner; while the difference between these processes in carnivorous and herbivorous animals becomes clearer.

Plants produce the albuminates which the herbivorous animal works up into muscular flesh; while carnivorous animals live upon the flesh of the herbivora; the organism of the carnivorous animal is not incapable of producing albuminates from plants, but, as regards its maintenance and development, it is not adapted for the working up of plant albuminates into flesh.

The organism of the herbivorous animal possesses, in virtue of its peculiar arrangement, the capability of working up its fodder and converting it into part of its body.

The carnivorous animal is wholly destitute of this capacity; its body is not adapted for working up vegetable food, as it is presented naturally.

It is impossible to nourish a carnivorous animal with peas, corn or grass; the animal does not eat these materials, nor can it become used to them; its masticatory apparatus is adapted for tearing and devouring, not for chewing; the meat food the animal is supplied with requires no chewing in order to become assimilable.

By the art of man it is possible to make up for one of these deficiencies, but not for all of them, though some kinds of vegetable food may be made serviceable for carnivorous animals, as, for instance, by converting corn into meal; thus, domesticated carnivorous animals may be nourished with bread or meal in the form of porridge, dumplings, etc., with or without the addition of fat.

The nutrition of carnivora with such prepared vegetable food is always imperfect; the animals consume a large quantity, but their digestive apparatus is not suited for dealing with the large quantity that would be requisite for satisfying the animals' wants within a given time.

The conversion of plant-albuminates into flesh, into the apparatus by which an animal produces its power and heat, and the digestion of starch, subjects its body to working exercise which it is spared when feeding on its usual diet. A greater part of the total of the animal's internal force is expended in the working up of these materials; it loses its wildness, and approximates in character to an herbivorous animal. Therefore a carnivorous animal is scarcely suitable as a subject for experiments intended for the accurate determination of nutrition processes.

On the other hand, the working organs of the herbivora, their chewing apparatus and digestive organs, are not only adapted for the subdivision, but also for receiving large masses of vegetable fodder; in our specially flesh-producing domestic animals nearly the whole of the available force in the body is expended upon this internal work. Besides the carrying and motion of their bodies, these animals do no external work; whatever external work they are compelled to do is lost for their internal work of flesh-production.

Comparing flesh with albuminates the difference between them is immediately evident. Fresh lean muscular flesh (beef) contains:—

Fat and Lactic Acid of Flesh	1·18	24·12
Syntonin, Albumen of Flesh	18·00	
Tissue, Vessels and Nerves	1·50	
Combustible Soluble Material (extractive)	2·64	
Soluble Salts	0·66	
Insoluble Phosphates	0·14	
Water		75·88

The plant-albuminates which serve in the body of an herbivorous animal for the production of its flesh, are chemically identical with the syntonin and albumen of flesh; the tissues and vessels differ far more in their composition from albuminates, and most of all the combustible soluble constituents of muscle.

Hence it is evident that while the conversion of plant-albuminates into flesh-albuminates requires the least expenditure of internal work, the production of the soluble constituents of muscle requires the greatest amount of internal work, and since this is connected with the consumption of material, the animals require for the maintenance or increase of their body-weight a larger amount of albuminates.

In the living organism the laws that obtain in nature generally are also in full force, and thus the character of the fodder has the greatest influence upon the external working capabilities of the animal.

In appreciating and applying these conditions, art is as usual in advance of science, certainly without being able to afford any explanation of the facts they are familiar with, for this is not the province of art.

The feeders of cattle distinguish fodder that produces power from ordinary fodder. Of the former kind are the seeds of cereals and *Leguminosæ*, which are richest in albuminates and starch, the most easly digested vegetable food; they require less internal work, and much less time for digestion in the stomachs of the animals and for their transfer into the circulation, than is required by the nutritive material of grass or hay; and it is well known what a considerable influence is exercised on the vigour of a horse by the addition of oats to hay-fodder, or on the production of flesh in oxen and pigs by beans or peas.

Whatever internal work the animal is relieved of in one direction becomes available in another direction.

Just the same laws obtain for man who combines the peculiarities of both the herbivora and the carnivora.

There are large classes of society, whole nations of people, who live exclusively on vegetable food and possess the full working capacity of working animals, but man, on the whole cannot dispense with meat when engaged in a higher order of work.

This is the case in a special degree for the labour of the brain or intellectual work which the animal has not to perform. This involves as great, and perhaps much greater expenditure of internal force as mechanical work by the limbs. For the maintenance of such work an artificially prepared food is of especial utility to a man, and every one knows that when his digestive organs come into conflict with his food the capacity for either intellectual and bodily work is thereby reduced. The food must be of such a character that the work of digestion and various other kinds of internal work shall not be interfered with. The mere prevention of sleep in consequence of eating indigestible food will, in this respect, produce a difference.

It is also intelligible that for a carnivorous animal a certain weight of albuminates eaten in the form of bread cannot be equal to the same weight of albuminates in its flesh-diet, in which the albuminates are taken, not only in a concentrated form most suitable to the capacity and power of exercise of the digestive organs, but at the same time meat supplies all the constituents of the muscular juices. In the case of a carnivorous animal the food taken requires a minimum of internal work for the reconversion of its constituents into muscular apparatus capable of exertion and for making them serviceable for the other requirements of the body.

The conversion of a part of the plant-albuminate into the soluble constituents of muscle would require in the animal's body a certain amount of work, that it would be relieved of almost entirely when the albuminate was supplied as meat.*

* This will perhaps account for the remarkable fact observed by Bischoff and Voit with the dog as regards the increase of body-weight under meat diet.

A dog that had been reduced by feeding it on bread, and of 34 kilograms weight, was then fed with 1800 grams of meat, and, on the first day, it gained 600 grams. One-third of the meat eaten remained in the dog's body and increased its weight $\frac{1}{58}$th.

On the contrary, in feeding oxen, the rule is that for the increase in body-weight of 1 pound (= 125 grm. dry), from four to six times as much albuminates must be supplied in the food; a tolerably sure indication how much more work and material is expended by the herbivorous animal in producing flesh.

In roasting and boiling meat, the flesh albuminates coagulate, the soluble constituents of muscle pass into the liquid which is retained almost entirely, in the case of roast meat, within it as in a sponge. Physiologists have made the remarkable observation that flesh albuminates, when coagulated by heat and sufficiently subdivided by mastication, are more soluble, or, as this is generally expressed, more digestible than they are in the raw state. Both raw and cooked albuminates are converted in the stomach into one and the same product, peptone, while the most general experience shows that roast meat, as well as boiled meat eaten with the broth in which it has been boiled, possesses the same nutritive value as the raw meat that a carnivorous animal eats. Consequently the soluble constituents of muscle in cooked meat must perform the same duty in the human organism as they do in the organism of the carnivora.

The organs of digestion have the greatest bulk of all the organs of the body; next to the heart and breathing muscles, they have the most severe interior work to perform. A muscular apparatus of considerable development works for hours in order to set in motion the relatively heavy mass of food and to affect the intermixture of all its parts with the secreted juices of the stomach, so that it is easy to understand how the force which those muscles expend must be derived chiefly from the muscles of voluntary motion, and hence it is that rest of the body is one of the conditions of active digestion.*

The influence of indigestible food or of a disturbance of the digestion upon the activity of all the organs in the body, upon the mechanical work of the limbs, the work of the brain and upon sleep is sufficiently well known. It is evident that food which is difficult to digest requires a longer time, while easily-digestible food requires a shorter time for its digestion, and that the time must be proportionate to the work to be performed; the shorter the time of digestion the more force is economized, and of course reserved for other organs. From this point of view, viz. economy of working power, the art of preparing food for men as well as for animals acquires a high significance.

"Soup and porridge," says Hippocrates, "were invented because experience taught men that the food which suits healthy people is not applicable for the sick."

I have already mentioned the remarkable result that is attained by a simple mechanical subdivision of certain kinds of vegetable food in regard to their digestion in the stomach of a carnivorous animal; it spares the animal the work of chewing and enhances the digestibility of the food. Probably by boiling meal to porridge, by the conversion of starch into dextrin and sugar, together with the addition of proper condiments, etc., the nutritive value of the food may be yet further augmented for the animal.

For man especially, the proper selection and preparation of his food are of vast importance for the development and exercise of all his powers.

* The influence of different kinds of working apparatus upon each other is easily intelligible if we think of what takes place in a factory whereby a single steam engine, or by the available power, several machines are kept at work; for example, a hammer and a rolling-mill at the same time. When the rolls are in full work, the hammer does but little, and when the hammer is being worked, only thin plates can be rolled.

Bread such as is commonly eaten, may be in a certain sense compared to the hay with which a horse is fed; but it is known that when a horse is fed with hay alone, all its capabilities are not fully developed.

It is only necessary to compare the performances of German workmen, who consume bread and potatoes chiefly, with those of English and American workmen who eat meat, in order to acquire a clear perception of the degree in which the magnitude, energy and duration of the work done by the latter are augmented by the kind of food they live upon. Again, compare the English statesman who, in expounding his views or maintaining a debate in Parliament delivers a speech lasting five hours or more, who at sixty years of age retains the capability of taking part in field sports, with the German philosopher who at the same age keeps up with difficulty the remains of his powers in order to be capable of work, while he becomes fatigued by a walk of a few hours.

For considerable and long-continued intellectual or bodily exertion it is necessary to have not only good organs of digestion, it is equally necessary that there should be a proper selection of food, which should be of such a character that the smallest possible portion of its available force may be required for the full production of its action in the body, so that there may be the more of that force remaining disposable at the will of the individual.

A knowledge of the conditions most proper for nutrition with a view to the performance of work is therefore most of all requisite in reference to man. We must endeavour to obtain very different means of judging as to these conditions now that we know urea is not either a measure of the work done, or exclusively a measure of the increase or decrease of the body during rest or work, as Dr. Parke's observations show.

WHAT IS ENERGY?

BY BALFOUR STEWART.

III.—THE CONSERVATION OF ENERGY.

It is well known that certain organisms of the animal world do not confine themselves to one state of being or to one order of existence, and the most familiar instance of this roving habit of life is the caterpillar, which passes first into the chrysalis state, and after that into the butterfly. This habit is not, however, peculiar to the organic world, for energy delights in similar transmutations, and we have just seen how the eminently silent and invisible electrical current may occasionally be transmuted into the vivid, instantaneous, awe-inspiring flash of lightning. Nor is this element of change confined to our peculiar corner of the universe, but it extends itself to remote starry systems, in some of which there is a total extinction of luminosity for a while, to be succeeded by a most brilliant luminous outburst, presenting all the appearance of a world on fire.

We shall not enter here into great detail regarding the various changes of energy from one form into another; suffice it to say, that amid all these changes of form, and sometimes of quality, the element of *quantity* remains the same. Those of our readers who are mathematicians know what is meant by variable quantities; for instance, in the equation $x + y + z = A$, if x, y, and z are variable and A constant, you may change x into y and into z, and y into x and into z, and in fact perform any changes you choose upon the left-hand side of your equation, *provided that* you keep their sum always constant and equal to A. It is precisely thus in the world of energy; and the invariability of the sum of all the energies of the universe forms the doctrine known as the "conservation of energy." This doctrine is nothing else than an intelligent and scientific denial of the chimera of perpetual motion.

Recognizing the great importance of work, it was natural enough at an early stage of our knowledge that enthusiasts should endeavour to create energy or the power of doing work, that is to say, endeavour to construct a machine that should go on working for ever without needing to be supplied with fuel in any way, and accordingly inventors became possessed with the idea that some elaborate system of machinery would, no doubt, give us this grand desideratum, and men of science have been continually annoyed with these projects until, in a moment of inspiration, they conceived the doctrine of the conservation of energy.

It flows from this doctrine that a machine is merely an instrument which is supplied with energy in one form, and which converts it into another and more convenient form according to the law of the machine.

We shall now proceed to trace the progress of energy through some of its most important transformations. To begin with that one to which we have already alluded, what becomes of the energy of a falling body after it strikes the earth? This question may be varied in a great number of ways. We may ask, for instance, what becomes of the energy of a railway-train when it is stopped? what becomes of the energy of a hammer after it has struck the anvil? of a cannon-ball after it has struck the target? and so on.

In all these varieties we see that either percussion or friction is at work: thus, it is friction that stops a railway-train, and it is percussion that stops the motion of a falling stone or of a falling hammer, so that our question is, in reality, what becomes of the energy of visible motion when it has been stopped by percussion or friction?

Rumford and Davy were the pioneers in replying to this important question. Rumford found that in the process of boring cannon the heat generated was sometimes so great as to boil water, and he supposed that work was changed into heat in the process of boring. Davy again melted two pieces of ice by causing them to rub against each other, and he likewise concluded that the work spent on this process had been converted into heat.

We see now why by hammering a coin on an anvil we can heat it very greatly, or why on a dark night the sparks are seen to fly out from the break-wheel which stops the motion of the railway-train, or why by rubbing a metal button violently backwards and forwards against a piece of wood we can render it so hot as to scorch our hand, for in all these cases it is the energy of visible motion which is being converted into heat.

But although this was known nearly a century ago, it was reserved for Joule, an English philosopher of the present day, to point out the numerical relation subsisting between that species of energy which we call visible motion and that which we call heat.

The result of his numerous and laborious experiments was, that if a pound of water be dropped from a height of 772 feet under the influence of gravity, and if the velocity which it attains be suddenly stopped and converted into heat, this heat will be sufficient to raise the whole mass 1° F. in temperature.

From this he concluded that when a pound of water is heated 1° F. in temperature, an amount of molecular energy enters into the water which is equivalent to 772 foot-pounds, that is to say, to one pound raised 772 feet high against the influence of gravity, or allowed to fall 772 feet under the same influence.

He found again that if a pound of water were to fall twice this distance, or 1544 feet under gravity, the velocity if stopped would raise its temperature 2° F., and in fact that the rise of temperature under such circumstances is proportional to the height from which the pound of water is supposed to fall. By this means an exact relation is established between heat and work. Grove was the first to point out the probability of a connection between the various species of molecular energy; and the researches of Joule, Thomson, and others have established these relations with numerical accuracy. No better example of the correlation of the various kinds of energy can be given than what takes place in a galvanic battery. Let us suppose that zinc is the metal used. Here the source of energy is the burning or chemical combination of the zinc with oxygen, etc., in order to form a salt of zinc. The source of energy is, in fact, much the same as when coal is burned; it is the energy produced by chemical combination. Now, as we have said, the zinc combines with the oxygen and sulphate of zinc is produced, but the result of this combination does not at first exhibit itself in the form of heat, but rather in that of an electric current. No doubt a great portion of the energy of this electric current is ultimately spent in heat, but we may, if we choose, spend part in promoting chemical decomposition; for instance, we may decompose water. In this case part of the energy of the battery, derived, as has been stated, from the burning of the zinc, is spent in heat and part in decomposing the water, and hence we shall have less heat than if there were no water to decompose. But if, when we have decomposed the water, we mix together the two gases hydrogen and oxygen which are the results of this decomposition and explode them, we shall recover the precise deficiency of heat. Without the decomposition, let us say that the burning in the battery of a certain weight of zinc gives us heat equal to 100, but with the decomposition only 80, twenty units of energy have therefore become spent in the decomposition; but if we explode the mixture of gases procured from the decomposition, we shall get back heat equal to 20, and thus make the whole result of the burning of the zinc 100 units of energy as before.

In like manner, if our electric battery is made to do work, thus forming a kind of engine, we shall have the heat produced by the current diminished by the exact equivalent of the mechanical effect which we have obtained from this engine.

There is nothing for nothing in the universe of energy.

CONDY'S PATENT FLUIDS.

The extremely powerful oxidizing properties possessed by the manganates and permanganates have been well known, and have frequently been made use of in the laboratory of the chemist for a considerable time past. The merit, however, of introducing these salts to the general public as most valuable deodorizers and purifiers belongs, we believe, to Mr. Condy. But though the initiative in establishing their manufacture on a large scale thus belongs to Mr. Condy, he seems to have allowed himself to be outstripped in their economical production. In the following table will be found the strength of three kinds of Condy's patent fluids as sold in London, measured by their oxidizing power in comparison to pure permanganate of potash.

For a due appreciation of the table, it is necessary to bear in mind that the crystallized permanganate used for comparison is a chemically pure article, while Condy's fluids Nos. I. and II. are solutions of the impure crude article, and that even the ozonized water does not contain the absolutely pure salt. With these explanations the table will speak for itself.

1	2	3	4	5	6
Description of Article.	Price retail in London.	Total solid contents in 100 parts.	Amount of Permanganate of Potash equal in oxidizing power to 100 parts.	Quantity equal in oxidizing power to one ounce Permanganate.	Price of the quantity given in column 5 as equivalent to one ounce Permanganate of Potash.
					£. s. d.
No. I.—Green Fluid	5*d.* per 7½℥	13·76	1·781	56·14℥	0 3 7
	5*s.* per gall.	13·76	1·781	56·14	0 1 9
No. II.—Red Fluid	11*d.* per 7½℥	8·40	1·786	55·99	0 6 10
	10*s.* per gall.	8·40	1·786	55·99	0 3 6
No. III.—Ozonized Water . .	1*s.* 8*d.* per 4℥	0·245	0·224	447·4	9 6 5
	3*s.* per 8℥	0·245	0·224	447·4	8 7 9
Pure crystallized Permanganate of Potassium	2*s.* per 1℥	100	100	1℥	0 2 0

Particulars of Samples Analysed.

No. I. *Condy's Patent Fluid* (*green solution*).—Contained in a glass bottle holding 7½℥; sold retail at 6*d.* per bottle, being about 5*d.* per 7½℥ contents. The bottle was wrapped in pale buff-coloured paper, nearly covered by two large labels with green print. The cork was secured by a strip of label, on which was printed "Condy's Patent Fluid. For destroying all offensive odours. Will not stain when diluted."

No. II. *Condy's Patent Fluid* (*red solution*).—In a glass bottle holding 7½℥; sold retail at 1*s.* per bottle, being about 11*d.* for the contents. The wrapper was buff-coloured, nearly covered by two labels with red print. The cork was secured by a strip of label, on which was printed the trade mark (a triangle enclosing a Θ surrounded by "Trade Mark—Condy"); the French and English prize medals; and in two circular spaces on one side, "Condy's Fluid. Does not stain when diluted;" on the other side, "Natural Disinfectant. N.B. The cork in each bottle of Condy's fluid is secured by a strip identical with this."

No. III. *Condy's Patent Ozonized Water for Toilet Purposes.*—In a small stoppered bottle holding 4℥, retail price 2*s.*, leaving about 1*s.* 8*d.* as the price of the contents. The bottle is nearly half covered by a label, on which are printed directions for use, prize medals, etc.; nearly the whole label being covered by trade marks arranged in a pattern as a groundwork.

The active agent in No. I. is chiefly the manganate of soda, though in the table its effect is measured against its equivalent of permanganate. In Nos. II. and III. the active agent is chiefly the permanganate of soda, though they contain also some potash. They have also been compared to permanganate of potash.

The crystallized permanganate of potash used for comparison was bought retail for 2*s.* the ounce. It was in fine crystals, contained no soda, and its oxidizing power, as measured by pure oxalic acid, was exactly equal to 100 per cent. of permanganate of potash. It was, therefore, chemically pure.

PAYTINE.

Hesse gives this name to an alkaloid he has obtained from the white cinchona of Payta. The powdered bark is first extracted with alcohol; the residue left after distilling off the alcohol is mixed with caustic soda and shaken with ether. To the ether solution dilute sulphuric acid is added, and, after neutralizing the excess of acid with ammonia, the base is precipitated by iodide of potassium. The iodide of paytine is again decomposed by soda, and the liquid, shaken with ether, gives a solution which, on evaporation, deposits fine crystals of paytine. The composition of this base is represented by the formula $C_{21}H_{24}N_2O + H_2O$. It is soluble in benzol, ether, chloroform, petroleum and alcohol; slightly soluble in water; it melts at 156° C.

The hydrochlorate, $C_{21}H_{24}N_2OHCl$, forms colourless prisms soluble in 16·6 parts of water at 15° C. It has a very bitter taste, and does appear to be poisonous. The chloroplatinate is a yellow amorphous precipitate.

When distilled with lime, paytine yields a non-nitrogenous product, which the author calls paytone, as colourless plates or needles soluble in ether and alcohol. It does not combine with acids or bases.—*German Chemical Society.*

GINGILIE OIL.

The gingilie (*Sesamum Indicum*) is said to be an African plant, and is supposed to have been introduced to the West Indies by the negroes. It is now pretty generally distributed, and in this country it thrives admirably in the Newera Kalawyia district. The plant is cultivated for the seed, which yields a fixed oil. The method adopted in Ceylon of expressing the oil is rather primitive, and consequently it possesses an unpleasant flavour and a brown muddy colour. If properly prepared, the oil would form a very good substitute for sweet oil. The best method of preparing the oil is as follows.—First steep the seeds repeatedly in cold water, or boil them for a short time, till they are divested of the reddish-brown colouring matter contained in the epidermis of the seeds, then, when the seeds have become perfectly white, dry them in the sun, and express the oil in the ordinary way. The seed yields from 40 to 44 per cent. of a pale straw-coloured oil. When thus prepared, the oil is perfectly devoid of smell and may be used for extracting the perfume of the jasmine, tuberose, camomile and yellow rose. To effect this, one weight of the flowers should be added to three weights of the oil in a bottle, which should be corked and left in the sun for forty days, when the oil will be impregnated with the perfume of the flowers. The gingilie oil is soluble in alcohol, saponifies with alkalies, solidifies by nitric acid, and combines with the oxide of lead. The gingilie oil is highly esteemed by Egyptian belles for its properties of cleansing the skin and of imparting to it a bloom and lustre, and also of preserving the beauty and gloss of the hair. In Ceylon it is used for similar purposes. The negroes also use the seeds for making a sort of beverage something like coffee, by roasting the seeds and infusing them in water. The commercial value of the oil in England is £40 per ton.—*Jaffna News.*

A Gigantic African Mushroom.—Dr. Welwitsch, in his travels in Africa, met with a number of cryptogamic plants; among them a gigantic agaric, distinguished by the immense size of its head, sometimes measuring more than three feet in circumference, as well as by the delicate flavour of its flesh. It appears that on a botanical expedition in a district called Calungembo, near Pungo-Andongo, his provisions began to run short, and towards the close of a day's ramble he came upon some of his men carrying one of these enormous mushrooms home to camp for supper. He had not himself previously met with it, but the natives had; and the short commons on which they found themselves had sharpened their eyes and led to their picking it up. Some idea of the size of this specimen may be formed from the fact that that single mushroom made soup sufficient to feed his party of twenty. It was as large as an umbrella. Subsequently he met with it repeatedly, and also found that it was familiar to all the inhabitants, a few being regularly, or rather irregularly, brought to market during the season, at the Præsidium of Pongo-Andongo, where they were sold at 1*d.* to 3*d.* apiece, according to size. The natives usually brought them, one or two hanging at each end of a stick, carried Chinese fashion over the shoulder. It is a true agaric, as yet undescribed.—*The Food Journal.*

The Food of Infants.—Dr. C. A. Coudereau expresses himself in opposition to the generally received opinion that the milk of a wet-nurse is the best substitute for that of the mother when the latter cannot be obtained. He has found in the milk of many wet-nurses, dependent on their want of cleanliness, a peculiar fungus, which will develop under favourable circumstances in every other kind of milk, giving to such milk a peculiar odour, and discoverable in the evacuations of the child. In regard to artificial food, he rejects also beef-tea, as well as Liebig's extract of meat, but recommends a fluid into the composition of which eggs enter largely. He considers that a very nourishing and wholesome kind of drink can be obtained from eight eggs, white and yolk together, beaten up with about two ounces of sugar and enough water to make a pint and a half of fluid. To this he adds a small quantity of lime-water, sulphate of potash and chloride of sodium. With a fluid so composed he has obtained excellent results.—*Wiener Medizinischen Wochenschrift.*

Chilblains.—M. W. E. Schaller says that the fluid concentrated chloride of iron is an unfailing remedy for chilblains, its application to them for a single day effecting a cure. It may also be used with advantage for frost-bites.—*Wiener Medizinischen Wochenschrift.*

Gastric Juice.—Signor Arturo Menzel has published a considerable number of cases where gastric juice has been employed with advantage in cancerous tumours.—*Gazetta Medica Italiana Lombarda.*

The Pharmaceutical Journal.

SATURDAY, SEPTEMBER 17, 1870.

THE BRITISH PHARMACEUTICAL CONFERENCE.

The Seventh Annual Meeting has been a great success in every respect. After the PRESIDENT had delivered the admirable address published in another column, the reading of papers was continued until 4 o'clock, when the members adjourned to the Exhibition, where a number of objects interesting to pharmaceutists were collected and arranged in a manner that afforded great facilities for examination. We shall refer more particularly to some of these hereafter, but cannot now omit to mention the very excellent exhibits of Messrs. HOPKIN and WILLIAMS, Messrs. SOUTHALL, DYMOND and Co., and Messrs. MACFARLANE, comprising the new compounds of chloral, Indian drugs and alkaloids.

The dinner was well attended, and the presence of the PRESIDENT of the Society was heartily appreciated. One of the most interesting points was the transmission by telegraph of a message of greeting from the Conference to the Pharmaceutical Association now meeting at Baltimore, a reply being received from America the following morning.

At the meeting of the second day the discussion of the Education question was one of the main features of interest. Many members spoke, and though the discussion did not result in any practical suggestion, it was evident that much attention had been given to the subject.

It augured well for progress in British Pharmacy to hear the statement boldly put forward, and apparently assented to, that many druggists who take apprentices are either incompetent to give instruction requisite, or if they were competent to do so, did not take the trouble. At the same time great difference of opinion was expressed as to the way in which aid could best be given to promote the education of apprentices and assistants. In many cases, it was urged that the previous education, or want of education, rendered apprentices unfit for acquiring a knowledge of chemistry and other sciences, or availing themselves of the advantages within their reach. The most practical feature of the discussion was the reference to the Preliminary examination of the Society, and the proposal that the passing of this examination should invariably be required of all apprentices before they are received.

If this measure were generally adopted, no doubt a great advance would be made towards raising the future status of pharmacists.

Another suggestion, tending in the same direction, had reference to the propagation of the scientific training now given at the School of Pharmacy, by enabling the successful students of that School to employ themselves in teaching throughout the country. If this could be effected, there is reason to believe that the results would far surpass those attainable by any other means in many instance. At places where there are medical schools in existence, this might be superfluous if a course of pharmacy were given in connection with those schools, as at the University of Durham and at Newcastle. One main thing necessary in any step of this kind, is the suppression of cramming.

It was a matter of general regret that Mr. SCHACHT, who has taken so much interest in the subject of provincial education, was not present at the Conference; but, to judge from the general spirit evinced by those present, there is reason to hope that his efforts will find numerous supporters, and we trust that those who are able to put forward suggestions as to the means of promoting pharmaceutical education in the provinces will not fail to do so in the columns of this Journal. The means of aiding in this work may be more in the hands of the individual members of the trade than is generally believed. The judicious introduction of science into the educational training of the young is a measure that we hope to see realized before long, and if that be done in such a way as to substitute for mere teaching the education in scientific habits of thought, which would develope not only a capacity for appreciating natural facts but also a taste for scientific knowledge, it would be of vast benefit to the country at large and especially conducive to the elevation of Pharmacy, notwithstanding its frequent necessary connection with the trade element prevailing in the business of country places.

HOSPITAL DISPENSING.

Since we last referred to this subject in a few remarks which have attracted the attention of two of our medical contemporaries, another and a somewhat singular instance of accidental poisoning has occurred. An old woman, starting on a long railway journey, provided herself, as she thought, with her gin bottle, and, by way of being polite to her fellow-travellers, offered them a little alcoholic refreshment, which was accepted by two females, who, being strangers, of course, drank first. It was not until after they had each swallowed their dose that the liberal old lady, in taking her turn and applying a more appreciative palate, discovered that her new acquaintances had swallowed unknowingly a wine-glassful of a lotion meant for external use only. Their quiet absorption of this liquid speaks volumes for their politeness, and something also for the patient endurance with which the poor swallow very vile liquor, indeed with the hope of deriving some consolation from the consequent alcoholic exhilaration. Fortunately the train just then reached Slough, where, amid what is described as a scene of great excitement, salt and water emetics were successfully administered, so that no great harm seems to have been done.

The *British Medical Journal*, in commenting upon the case, and referring to our recent note on the subject, adds, "The accident gives room for thought. If the Pharmaceutical Society, whose function it is by Act of Parliament to devise rules for storing and dispensing substances, can offer any suggestion to our hospital authorities, they will certainly be favourably received, and carefully considered. There is in many instances much room for improvement."

The *Lancet*, however, in an article which not even the advent of the "silly season" can justify, appears to object to our statement as to "carelessness about bottles and labels too, at a great many hospitals," and adds, apparently in the way of refuting our remarks, that even the out-patient section of the imperfect work of the hospital system is an immense boon "to the sick and diseased poor." This certainly never was doubted; but it need not be balanced by unnecessary accidental poisoning of the class benefited, if that result can anyhow be prevented. The writer of this article also thinks our remarks "came with exceedingly bad grace from such a source," and he concludes by intimating in his not very exquisite language that the class of pharmaceutists are "malefactors." To reasoning so conclusive, and language so refined, we can only render the homage of silence. This is not the customary language of the profession to which a writer in the *Lancet* may be presumed to belong, and in the name of which he assumes to speak.

The general moral of the whole affair is to indicate, not only the desirability of poison regulations or precautions, but also to point out the difficulties which environ the subject, since precautions are subject to the disturbing influence of such extreme negligence and stupidity as are displayed in these latest examples of accidental poisoning. However, it is not against those disturbing influences that we can hope to prevail. They will baffle all precautions; but that is of course no reason why an attempt should not be made to afford as much security as possible, and to decide whether any mechanical precaution or any set of regulations are at all likely to meet the desired object.

THE draft of a Bill has lately been laid before the French Senate, containing provisions for medicinal and pharmaceutical education, the details of which we propose to notice in a future number. Its consideration has been deferred by the occupation of the Senate and Corps Législatif; but it is evident that the subject has been thoroughly examined, and it may be assumed that the Bill shadows forth the reforms which are about to be made in France, in the important subject of superior education and professional degrees.

REPORTS ON THE EXAMINATIONS OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

In an Appendix to the Twelfth Report of the Medical Officer of the Privy Council are printed two lengthy reports from Professor Christison and Dr. Greenhow, the official Assessors of the Privy Council, in which they describe the objects and methods of the Major and Minor Examinations, and state their conclusions as the sufficiency of these Examinations. The greater part of these reports is occupied by the details of Examinations, with which our readers are well acquainted. The following are the more important of their comments. Dr. Greenhow says:—

"The technical examinations are made as practical as possible. The prescriptions submitted to the candidates are very various in character, and have all been actually written for patients and dispensed in chemists' shops. The ability to read prescriptions is obviously one of the most necessary qualifications for chemists and druggists, and a large proportion of marks has therefore been very properly allotted to this subject in both the Modified and Minor examinations. When present I have observed that although most of the candidates can read ordinary prescriptions correctly enough to ensure their being able to dispense from them with safety, comparatively few are sufficiently conversant with Latin to read with accuracy prescriptions couched in somewhat unusual terms, or having appended to them minute directions for use in the Latin language. The already-recited regulations sufficiently show the scope of the several examinations in the other subjects, and I may add, that the selection of specimens submitted to candidates for recognition is well calculated to test their practical knowledge.

"I have closely observed the mode of conducting the several technical examinations by the appointed examiners, and can bear testimony to the zealous and conscientious manner in which these gentlemen discharge their duty. On some occasions I have followed the same candidates through their examination in all the successive subjects, making my own estimate of the number of marks which they had earned in each subject, and then comparing this estimate with the number of marks assigned to them by the examiners, which has seldom shown any considerable discrepancy. On other occasions I have remained for a considerable time watching the examinations of successive candidates in the same subject, and have satisfied myself of their being conducted with perfect fairness and impartiality as between one candidate and another.

"I am informed that it is intended gradually to raise the standard of the examinations, and particularly of the First or Preliminary examination; but it would have been manifestly unfair to have passed suddenly from the degree of laxity which, before the passing of the Pharmacy Act, allowed persons to act as chemists and druggists without any examination at all, and to have begun at once to exercise a degree of severity in the examinations, which would exclude from the privileges of registration under the Act many fairly qualified candidates whose education had commenced before the Act was passed.

"The regulations have now, however, been in force for some time, and young men who may hereafter intend to become Chemists and Druggists, or Pharmaceutical Chemists, will have no reason to complain if, after a reasonable period has elapsed from the passing of the Act, they should be required to give proof of still higher qualifications before being admitted to registration.

"The fact of the rejection of so large a proportion of the candidates at every examination, would seem to show conclusively that the standard of the Board of Examiners is as high, and their mode of examination as stringent, as can be practically enforced at the present moment; and, even though the present standard only were maintained in future, the gain to the public would be very great, as they would thereby obtain security for a degree of competency in all the chemists and druggists throughout the country, such as was previously unknown, excepting among the best chemists in large towns.

"I have, in conclusion, only to repeat what has already been implied in my report, that, in my opinion, the examinations of the Pharmaceutical Society are of such sort, and are conducted in such manner, as to constitute a sufficient guarantee to the public with regard to the qualifications of persons admitted to register under the Pharmacy Act, 1868."

Professor Christison's most important comments and criticisms run thus:—

"The only remark I have to make on the Preliminary examination is, that while the examination on English and arithmetic was such as to prove a thorough knowledge on the part of candidates, the test of Latinity is at present pitched somewhat low. I am satisfied, however, that it would be unsafe to attempt to establish a higher standard on that subject for some time; for I am aware that for about thirty years past, in the class of society from which the candidates at the pharmaceutical examinations are derived, the acquisition of classical knowledge has been discouraged in Scotland through the activity of the utilitarian sect of educational enthusiasts, and that the quality of the teaching in many of the primary, and even some of the secondary, schools of the country has in consequence been thought to have undergone deterioration. The Edinburgh members of the Pharmaceutical Society, however, have expressed their desire to raise their standard of Latinity by degrees, and it is hoped that a thorough Education Act for Scotland will in no long time facilitate the attainment of that object.

"The Professional examination has, in my opinion, been conveniently subdivided by the Council of the Society; and the extent of examination under each head has been skilfully limited in its range to the topics which it is practically important for the pharmaceutic chemist to know.

"I witnessed several times an examination on every subject, except the fifth or botanical examination, and I have been gratified by the ability, fairness, patience, and kindliness of the examiners. I have also attended the decisions of the assembled examiners, both on preliminary and professional matters, and I concurred in the determination come to in regard to those candidates—some of them failures—whose examination I had witnessed, or whose examination papers I had read.

"The examiners being comparatively new to their duty, it is natural that they should now and then discover defects, and remedy methods of examination. A little more experience on my part may enable me to suggest improvements. At present I have but one suggestion to make. Most examining boards have found advantage in their candidates being examined on each subject of examination before two examiners, each duly qualified in the same subject. It is needless to point out how this system tends to secure fullness and fairness of examination—to satisfy the public—and also to promote the comfort of the examiners themselves, and their confidence in their own decisions. It is probable, therefore, that this measure may be found advisable in the practice of the Pharmaceutical Society also.

"The examination-books were put before me, and from these I find that, between January 1st and December 1st, 1869, a board for examination was held on eleven days; that 41 candidates were examined on preliminary education, of whom only 1 failed; and that the Minor, Major, or Modified examination on professional matters was undergone by 112 candidates in all, of whom 21 failed to pass.

"As I have seen no reason to doubt either the stringency of the examination or the fidelity of the decision of the examiners on preliminary education, the very limited amount of failure in this department may be taken as proof sufficient that the standard of examination may be raised when it may be thought advisable to do so. But for various reasons, which it is perhaps scarcely necessary for me to enter into here, I think the Society have done right in not fixing the standard higher at first.

"The results of the professional examination seem to me satisfactory in every point of view. First, the number of candidates who have come forward last year is considerable. Secondly, the rejections, amounting to nearly a fifth of the whole, testify that the duty of the examiners has been faithfully discharged. Thirdly, it is creditable to the candidates that the number of failures has not been larger; for in other professions about a fifth of failures seems the usual average when examining boards are well organized and faithful, and the generality of their candidates are well prepared."

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

The following communication has been received by the Treasurer, and gives gratifying evidence of the appreciation by the "Society for Aid to the Sick and Wounded" of the efforts made in its behalf by British Pharmacists.

"2, *St. Martin's Place, London, W.C.*
"*September 6th.*

"The Secretary of the National Society for Aid to the Sick and Wounded in War, and the Ladies' Committee, desire to thank the Chemists and Druggists of Great Britain for their Subscriptions, and for the very valuable medicines they have contributed, which were most grievously needed. They are immediately sent off to the Continent with no delay, as it has not been necessary to unpack them.

"*Elias Bremridge, Esq.*"

The following contributions have been received since last week:—

	£.	*s.*	*d.*
W. H. Allen, The Grove, Stratford	1	1	0
J. Bowes and Co., Whitehaven	1	1	0
John Broad, Hornsey Rise	1	1	0
T. Crowther, Tickhill	0	2	6
C. Emerson, 8, Church St., West Hartlepool	0	10	6
John Ingham, Upper Tooting	0	2	6
J. N., Assistant, Turnham Green	0	2	6
W. Parsons, St. Mary Street, Portsmouth	0	5	0
John Pepper, 207, Tottenham Court Road	1	1	0
R. O. Rippon, Great Berkhampstead	0	5	0
J. G. Rollin, 3, South Street, Durham	0	10	0
John Stevens, High Street, Broseley	0	10	6
Wilson and Kitchin, 30, King St., Whitehaven	1	1	0

Collections per W. Moss, Local Secretary, Carlisle:—

	£.	*s.*	*d.*
J. Daniel	0	5	0
J. Hallaway	0	10	0
J. P. Harrison	0	10	0
W. Moss	0	5	0
James Sawyer	0	5	0

	£3	2	6

Per Mr. Wilkinson, Manchester, T. S. Johnson	0	5	0

Ferdinand Coles, 248, King's Road, S.W.,
2000 ¼ gr. morphia pills in boxes of 50 each.
4 lbs. lint.

W. E. Jameson, Reading,
6 1lb. stoppered bottles chloroform.

Per A. W. Postans, 35, Baker St., W. :— £. s. d.
Rev. Dr. Anderdon........................ 0 5 0
From a Lady,
Quantity of lint and linen.

Walter Lacey, Cotham, Bristol,
Box of Natal arrowroot.
1 oz. of quinine.
Bottle of pure chloroform.
„ „ methylated do.
Quantity of sponges.
2-, 3- and 4-inch bandages in 3, 4, 5, 6, and 12 yard lengths.

Per T. K. Williams, Welshpool:—
T. K. Williams,
1 oz. sulph. quinine.
Bottle of chlorodyne.
2 oz. hydrate of chloral.
G. W. Benson, Welshpool,
2 yds. waterproof sheeting.
3 2 oz. bottles of laudanum.
3 bottles 1 gr. opium pills, 4 doz. in each.
4 oz. cotton wool.
Thomas Griffiths,
1 lb. lint.

A. Yeatman, 141, Kentish Town Road,
1 gross 2 gr. quinine pills.
1 gross ¼ gr. morphia pills.
Quantity of lint and bandages.

Erratum.—The contribution announced in our last number from Messrs. Hearon, Squire, and Francis, 5, Coleman Street, should have been acknowledged as from Mr. Silvester, of Knutsford, per Messrs. Hearon, Squire, and Francis.

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL,

September 7th, 1870.

MR. HASELDEN, VICE-PRESIDENT, IN THE CHAIR.

Present—Messrs. Bottle, Deane, Dymond, Evans, Hills, Reynolds, and Savage.

The minutes of the last meeting were read and confirmed.

The Report of the Finance Committee was presented, showing, on the General Fund Account, a balance in the Treasurer's hands of . . . . £342. 19*s*. 3*d*.
And submitting for payment accounts, amounting to . . . . £337. 11*s*. 7*d*.
On the Benevolent Fund Account a balance of . . . . £603. 17*s*. 11*d*.

Resolved—That the Report be received, and payments made.

Resolved—That the Report and Recommendations of the House Committee be received and adopted.

Resolved—That the Report and Recommendations of the Library, Museum, and Laboratory Committee be received and adopted.

Resolved—That the Pereira Medal be awarded to Frederick Hamilton Peck.

The Secretary presented the names of two members who had paid their subscriptions since the 30th April.

Resolved—That they be severally restored to their former *status* on payment of a fine of one shilling.

Resolved—That John Becket Hurst, of Louth, and Jonathan Sparke Walton, of Haydon Bridge, be and are hereby elected members of the Society.

Resolved—That the following, having passed the Minor Examination, be elected

ASSOCIATES IN BUSINESS.

Alford, Thomas ....Stonehouse.
Michell, Frederick John C. ......Falmouth.

Resolved—That the following, having passed their respective Examinations, be elected

ASSOCIATES OF THE SOCIETY.

Minor.

Broad, John Morris ....Hornsey Rise.
Sherburn, Thomas ....Harrogate.

Modified.

Baynes, James, jun. ....Hull.
Burn, Thomas................Hartlepool.
Gibson, William H. ....Brighton.
Hartley, Stephen ....Ulverstone.
Holmes, Frederick George ....Brill.
Jones, George Coverdale ......Bournemouth.
King, Abraham ....Bristol.
Metcalfe, Alfred ....East Retford.
Oldham, Gervase ....Stockport.
Siminson, Henry ....Kidderminster.
Tupholme, Edward H. ....London.

Resolved—That the following registered Chemists and Druggists be elected

MEMBERS OF THE SOCIETY.

Bray, William ....Buntingford.
Hickin, Henry ....Shrewsbury.
Iberson, John ....Barnsley.
Jackson, Christopher ....Acton.
Morris, Thomas Henry ......Rhyl.
Preston, W. L. ....Dalton-in-Furness.
Sowerby, Joseph............Carlisle.
Taylor, William............Saltburn-by-the-Sea.
Watkins, William Henry ....Blackwood.

Resolved—That a copy of the following resolution of the Provincial Education Committee be forwarded to the General Secretaries of the British Pharmaceutical Conference:—"This Committee recommend that the Council invite the British Pharmaceutical Conference to bring forward the question of Provincial Education for discussion at its meeting in Liverpool in September, which would give an opportunity for the interchange of opinion amongst those best acquainted with the question."

Resolved—That the schedules issued to Provincial Chemists' Associations having now been returned to the Council, an abstract of the same be prepared and printed, proofs of the same being issued, but that its insertion in the Journal be deferred until after the next Council meeting.

Opium.—Mr. Richardson, the Opium Agent at Benares, has conceived and carried out a judicious redistribution of establishments, which will result in a great extension of opium cultivation without entailing additional expense on the Government.—*Indian Daily News.*

Fly Poison.—A singular fatality is recorded by the *Times* as having occurred at Newmarket. A woman named Cooper, housekeeper to Mr. W. Boyce, was sitting near a table on which some poisoned papers had been placed for the purpose of killing flies. A fly was seen to leave one of these papers and alight on the woman's nose, which was slightly scratched. The wound speedily became inflamed; in a short time her whole system became affected, and she died in about twenty-four hours.

Proceedings of Scientific Societies.

BRITISH PHARMACEUTICAL CONFERENCE.

Meeting at Liverpool.

The British Pharmaceutical Conference commenced its seventh Annual Meeting on Tuesday morning last, in the Lecture Theatre of the Royal Institution, Colquitt Street, Liverpool, under the Presidency of Mr. W. W. Stoddart, F.C.S., F.G.S. The Conference assembled shortly after 10 o'clock, when the business was commenced by the reading of a very long list of candidates for membership by one of the Honorary General Secretaries. The candidates reside in all parts of the United Kingdom, and one of them in Kentucky, United States; they numbered about 920, and were duly elected by ballot.

The President acknowledged the presence of Mr. Sandford, the President of the Pharmaceutical Society, an announcement which was received with applause.

Professor Attfield then read the

Report of the Executive Committee.

During the past year your Committee has been actively engaged in three important matters:—First, the organization of means whereby to produce such a Year-book of Pharmacy for 1870 as the meeting at Exeter decided should be issued. Secondly, the conduct and completion of a system of canvassing for members amongst the Pharmacists of England, with the double object of advancing the general aims of the Conference and securing a sum of money which would admit of the production of such a Year-book without interruption. Thirdly, the appropriate disposal of the Bell and Hills' Library Fund—a sum of fifty guineas, generously given to the Conference by Mr. Thomas Hyde Hills, with the suggestion that it should be employed in further stimulating pharmaceutical education.

The Year-Book.—In accordance with your instructions at the last Annual Meeting, your Committee proceeded to obtain the services of an editor, and to arrange for the publication of the yearly volume.

The salary of the editor was fixed at £100, this sum to cover the expenses incidental to the literary part of the work. In answer to the advertisement, four applications for the office of editor were received. After due consideration of the claims of the respective candidates, your Committee elected Mr. John Cargill Brough. A sub-committee of publication was then formed, consisting of Daniel Hanbury, F.R.S., W. W. Stoddart, F.G.S., Joseph Ince, F.L.S., Michael Carteighe, F.C.S., and T. B. Groves, F.C.S., with Prof. Attfield as Secretary. These gentlemen have reported as follows:—First, that they have accepted the estimate of Messrs. Butler and Tanner, of Frome, to supply the Year-book on good paper, bound, and otherwise complete, on terms within the means at the disposal of the Conference for the purpose. Secondly, that they have accepted the offer of Messrs. Churchill and Sons, of London, to undertake all matters connected with the advertisements on eligible conditions; to prepare the Year-book for delivery to members, and to place on the title-page the name and address of their firm as publishers.

Your Committee has instructed the sub-committee to make such arrangements as shall ensure the issue of the Year-book not later than December 1st. They can, however, hardly dismiss this subject without an expression of deep sympathy with the editor under the trying circumstances which have contributed to cause some delay in the fulfilment of his arduous and responsible duties, and an expression of their earnest hope for his speedy restoration to health and strength.

New Members.—In July of the present year, the secretaries drew up a circular of invitation to membership, and sent a copy, with specimen pages of the Year-book, to every pharmacist in England not already a member of the Conference. This course, supplemented by the active exertions of the local treasurers and other working members, has produced the gratifying result of swelling our numbers from about 600 to about 1500, and even this high number may, in the opinion of your Committee, be even further increased when the Year-book has been distributed, and opportunity been afforded for the recognition of its value.

The Bell and Hills' Fund.—Very soon after the last Annual Meeting of the Conference, the following letter was received from Mr. Hills by the Treasurer:—

"Herewith I have much pleasure in redeeming my promise made at Exeter, and enclose a cheque for fifty guineas. Twenty-five guineas I give in memory of my good friend Jacob Bell, who, I feel, would have been pleased with what the British Pharmaceutical Conference has done and is doing, and twenty-five guineas in my own name. I give the money to the Council of the Conference to do what they in their wisdom think will best promote a good feeling amongst pharmaceutists and assist the education and well-being of assistants and apprentices. I give it without conditions. You will remember I suggested that ten guineas' worth of books should be presented to the pharmaceutical chemists and chemists and druggists of the cities and towns in which the Members of the Conference may meet, as an addition to, or nucleus for, the formation of a library, where the assistants or apprentices may assemble for the purposes of study and mutual improvement. I think the Conference is a great success, and will do much good. The generous exhibition of good feeling of the chemists of Exeter and Torquay is worthy of imitation everywhere, London not excepted. The 19th and 20th of August will be red-letter days in my pharmaceutical calendar and green spots in my pharmaceutical life. The meetings bring forth kind sentiments and friendly feelings between men interested in the same business and obliterate imaginary jealousies. With best wishes for the success of the British Pharmaceutical Conference, believe me,

"Always yours faithfully,

"Thomas Hyde Hills.

"P.S.—The five artists' proofs of my good friend Jacob Bell which I promised to your Committee, I will have framed, to save the Conference trouble and expense."

The Committee accepted in trust this handsome donation of Mr. Hills, and returned him the warmest thanks of the Conference. A separate statement concerning this fund will be presented annually by the Treasurer. To the Library of the Exeter Branch Pharmaceutical Society, after appropriate inquiries and arrangements, your Committee granted ten guineas' worth of such scientific books as were most required by the local committee.

Railway Arrangements in connection with the Meetings of the Conference.—The privilege accorded by the railway companies to the British Association, namely, that of extending the time during which a return ticket is available, so as to include the whole period of the meetings, has often been desired by the members of the Conference. The number of those travelling to the Annual Meeting hitherto has not been, however, sufficiently great to take the trouble this arrangement would involve. But it was thought that perhaps the companies might allow the time covered by the return ticket to include the first Monday instead of, as usual, the first Tuesday of the Association week, and at Exeter last year, the President of the Conference addressed the President of the British Association on the matter. The answer was that the officers of the British Association had repeatedly attempted, but in vain, to obtain from the railway companies the extension mentioned.

In conclusion, your Committee desires to testify to the untiring efforts the Liverpool local committee has made to secure the success of the present meeting. The exhibition of objects connected with Pharmacy has been entirely organized by the resident members. The thanks of the meeting will doubtless be fully expressed to the Local Committee when, at the close of the sittings, the members will have had opportunities of noticing the extent to which the desire for their comfort and pleasure have been thoughtfully and completely anticipated.

On the motion of Mr. Sumner, seconded by Mr. J. Shaw, the Report and an accompanying Balance Sheet were adopted.

The following gentlemen were in attendance as delegates from various societies:—

Bristol Pharmaceutical Association.—The President, Mr. Stoddart.

Nottingham and Notts Chemists' Association.—Messrs. J. H. Atherton, J. Rayner.

Edinburgh Branch of the Pharmaceutical Society.—Messrs. H. C. Baildon, George Blanshard, D. Brown, jun., and J. Mackay.

Manchester Chemists and Druggists' Association.—Messrs. W. J. Brown, W. J. Halliday, J. T. Slugg, F. B. Benger and R. Hampson; Members of Council who may be present.

London Chemists' Association.—Mr. W. Martindale.

Ashton and Dukinfield Chemists' Association.—Messrs. Jabez Waterhouse and W. Bostock.

Scarborough Chemists' Association.—Mr. J. Whitfield.

Leeds Chemists' Association.—Messrs. R. M. Atkinson and R. Reynolds.

Bradford Chemists' Association.—Dr. Parkinson, Ph.D.

Sunderland Chemists' Association.—The Hon. Sec., Mr. J. J. Nicholson.

Bath Chemists' Association.—The Treasurer and Mr. C. Ekin.

Brighton Chemists' Association.—Mr. Savage.

Newcastle-on-Tyne Chemical Society.—Mr. H. B. Brady.

On the motion of Mr. Baildon, seconded by Mr. Evans, the following foreign members of the Conference were elected:—Mr. Carlos Murray, of Buenos Ayres: Senhor Joaquim Correa de Méllo, of Campinas, Brazil; and Professor Soubeiran, of Paris. The number of foreign members, which by the rules of the Conference, is limited to twenty, is now ten.

The President then delivered the following

Introductory Address.

Gentlemen,—It has now become an annual custom to commence our Conference meetings with an introductory address, the principal object of which is to briefly recall to our memories some of the most prominent observations or discoveries that have taken place during the previous year. Nor is the custom less instructive than interesting, for all who are in the habit of reading from month to month the labours of others know full well the value of such occasional reviews.

The prosperous career of the Pharmaceutical Conference is fully apparent in this our seventh meeting, which promises to fairly rival any of the former ones, both in number of visitors and interest of papers.

The number of new members is so unprecedented as to call for special notice as a great subject for congratulation. No fewer than 900 having been added to our list since the last meeting is a plain and unmistakable proof that the institution of the Society has not been in vain. Indeed, if any evidence were necessary to prove the appreciation of our annual gatherings, it would be most abundantly afforded by the good people of Liverpool, who have left nothing undone to make our visit successful, and ourselves at home.

I feel assured that it is not only the wish of your Council, but of all the members, that our various visits throughout the kingdom should be productive of good, by planting a seed or two of the tree of knowledge, which by a little careful training and judicious culture after our departure, may in after years yield the fruit of increased intelligence.

It appears to me that the fundamental idea of the Conference is the furtherance of Pharmacy proper, by directing attention to the proper means of scientific education, or judicious training, and the advancement of our status as a profession.

Nowhere in the kingdom is there a better spirit for improvement or stronger ambition for advance shown, than by the inhabitants of this part of her Majesty's dominions. I would therefore appeal to their experience whether or no the cultivation of the mind in scientific pursuits be not an exquisite source of pleasurable enjoyment and actual profit. It may be some curious reaction to be unravelled, some puzzling phenomenon to be explained, or the most profitable method of conducting an operation to be found, which, to the intelligent mind, furnishes a zest for exploration that must be felt to be properly understood.

What pleasure is there so innocent or so enthusiastic as the mutual examination of perhaps a common object under the microscope, or unfolding the nature of a substance with the subtle art of chemistry?

I do not for one moment believe that such works are only for the anchoret or the recluse; nay, a spirit of enduring and cordial fellowship is created, by the glorious relish of meeting a kindred spirit, to whom you can show a treasure, or with whom you can have an hour's chat.

In every age the pursuit of knowledge has been the theme of song and verse. The very nature of a man possessing a "mens sana in corpore sano" forces him to appreciate all that is beautiful, and fills him with an insatiable desire to discover the cause of the many wonders that are continually taking place around him.

> "Not a tree,
> A plant, or leaf, or blossom, but contain
> A folio volume. We may read, and read,
> And read again, and still find something new,—
> Something to please, and something to instruct."

That horrid, but perhaps necessary cry, *cui bono?* must sometimes be met, and surely past experience can satisfy the most mercenary spirit, and show that the so-called hobby of a philosopher, foolish as it may seem, frequently gives birth to results that must startle the most cold-hearted utilitarian.

I cannot endorse the assertion of Adam Smith that a philosopher is a person "whose trade is to do nothing and speculate in everything." Where would be our telegraph if Faraday and Oersted had not studied the properties of an electrified wire? Or the wonderful calculations of astronomy if Newton had let the fall of an apple pass by unheeded? To the student nothing should be considered too trifling or unimportant.

But it is to the improvement of our own particular profession of pharmacy that I wish to call your attention, hoping, as I do most sincerely, to enlist your interest.

We live and have our being in complete subjection to Nature's laws. How foolish, then, to remain without learning what those laws require, so that we may have them with us and not against us!

Pharmacy, of all pursuits, is the one most dependent on the proper use of these laws. The pharmaceutist must make the most he can of the numerous animal, vegetable and mineral substances with which he has to do, and to carry on his operations with the view of producing the best results. I am convinced that the most prosperous and happy of our body are those that bear these things in mind, and who look upon mental cultivation as a delight, and not as a necessary but disagreeable task.

Probably of all occupations for procuring the means of subsistence none surpasses our own in the small return for the large amount of work done. Truly the pharmaceutical motto ought to have been, "Nihil est aliud magnum quam multa minuta."

Thirty years ago the pharmaceutist was a literal tradesman, and for thirty years we lived in a theoretical anticipation of our character and status being raised to a higher standard. Our ever-to-be-remembered Jacob Bell and William Allen, with others of advanced views, steadily persevered in the attainment of this object, and hoped on in the face of strenuous opposition to see the things that we see.

Two years ago we obtained the long-wished for Pharmacy Act, but at our last meeting we had no practical experience of its working. All was in embryo. Since that time a twelvemonth has elapsed; and, though too short a time perhaps for a conclusive verdict, yet I venture to say that it has worked well, and now more than ever its expected benefits loom more decidedly in the future.

Let us always beware, however, of infusing a mercenary spirit into the conduction of our Pharmaceutical Society. Its main object is, and ever must be, the upraising of our Pharmaceutical education, and not the lowering it into a trades' union, a spirit which I am bold to say would prove its ruin.

We must not be too impatient of a little more nursing by the valued hands of the older members of the Pharmaceutical Society.

Chemistry, botany and physics are to us only secondary in importance to a well-grounded general education.

The study of botany is peculiarly a necessity, since we derive so many of our preparations from various plants; but its demands have been so well put before you on former occasions by our esteemed Professor Bentley that I must not take up your time by dwelling on them now.

Our younger members will need no reminder from me that great changes have within the last few years taken place in chemical philosophy. Chemistry now, more than ever, claims to be an exact science; and, although I fear many of us have bemoaned the change in notation and the attendant difficulty of unlearning an old system, yet the more simple explanation of puzzling organic metamorphoses will amply repay any trouble taken by the persevering student.

Nearly twenty years ago, our countryman, Professor Williamson, introduced to public notice the modern view of chemical types. Three years afterwards Gerhardt added to the Professor's water-type two others, the hydrochloric acid and ammonia.

From these views we have a more complete classification of the elements and their combinations than we ever had before. Ere many more years have elapsed, works on chemistry must be arranged on quite a different plan, especially with regard to the terms inorganic and organic.

In our older books the compounds included under these heads were supposed to be as distinct as if they belonged to the animal and mineral kingdoms. The term "organic" then denoted those compounds which were thought only producible in the bodies of plants and animals, and that their production was due to a supposed "vital force." Of course I here allude to organic and not *organized* bodies.

In later years many of these have been, and probably all will be formed by the chemical transformation of inorganic elements or molecules; as cases in point, I would mention the artificial production of alcohol, sugar, acetic acid, etc. etc.

Perhaps the best definition of an organic substance is, that it is a carbon compound, and that carbon in chemistry is analogous to desmids and diatoms in microscopy. The latter seems to be debatable ground between the animal and vegetable kingdoms, as carbon is between inorganic and organic chemistry.

Oxalic acid was once considered to be only found in the juices of plants. Now it has been prepared from purely inorganic elements. By the decomposition of a piece of chalk we produce the well-known gas carbonic anhydride or carbonic acid. Then by passing this gas over sodium and sand we have oxalic acid, identical in every respect with that found in the *Rumex* and *Oxalis*.

$$\underset{\text{Carbonic acid.}}{2CO_2} + 2K = \underset{\text{Oxalate of potassium.}}{K_2C_2O_4}$$

Our well-known alcohol is another instance of the artificial production from inorganic ingredients of what was formerly supposed to be formed only by the fermentation of starch or sugar.

By passing the vapour of that commonest of all minerals—sulphur—over the surface of red-hot charcoal, we have carbon disulphide, the disagreeable liquid so often used for dissolving india-rubber. Then, again, if we mix this with hydro-sulphuric acid gas, and pass the mixture over red-hot copper, or with carbonic oxide over iron, we may, as proved by the experiments of Mr. Berthelot, produce olefiant gas, or, as it is now called, ethylene (C_2H_4).

$$\underset{\text{Carb. disulph.}}{2CS_2} + \underset{\text{Hydro-sulph. acid.}}{2H_2S} + 6Cu = \underset{\text{Ethylene.}}{C_2H_4} + \underset{\text{Cupric sulphide.}}{3Cu_2S}.$$

Lastly, if we dissolve the ethylene in strong sulphuric acid, dilute with water and distil, we shall have as the result alcohol, similar in every way to that prepared by the distillation of grain—

$$\underset{\text{Ethylene.}}{C_2H_4} + \underset{\text{Sulph. acid.}}{H_2SO_4} + H_2O = \underset{\text{Alcohol.}}{C_2H_6O} + \underset{\text{Sulph. acid.}}{H_2SO_4}.$$

We might, in like manner, follow the synthetical formation of acetic acid from the same inorganic materials, carbon and sulphur.

The vegetable alkaloids, it is true, have not yet been artificially produced; but so great an advance is being made in the formation of organic compounds by artificial means, that I think it is not too chimerical an idea to expect a pharmaceutical solution of the philosopher's stone problem, and to manufacture quinia and morphia on the large scale. We should then be entirely independent of the *Cinchonaceæ* and *Papaveraceæ*, on which we now entirely rely for these invaluable medicines.

In the January number of the *Journal de Pharmacie et de Chimie* is an article by M. Bourgoin on the electrolysis of the vegetable alkaloids,—an interesting subject that has not hitherto received the attention it deserves.

It has for some time been known that the salts of vegetable alkaloids, when subjected to galvanic action, obey the usual law of metallic bases and acids, for the alkaloid appears at the negative and the acid at the positive pole.

The author states that the sulphates of atropia, brucia, strychnia, codeia, and quinia, when acted upon by the galvanic current, behave exactly like ammonium sulphate—

$$NH_4SO_4 = \underset{+}{SO_4} + \underset{-}{NH_4}.$$

But, more than this, he goes on to say, that when an *acid* solution of either alkaloid was used, and the conductibility of the liquid thereby rendered more perfect, the electrolytic action was much more violent. The solution became coloured round the positive electrode, and evolved oxygen, carbonic acid and carbonic oxide gases.

The most remarkable result of the experiment was that, in each case, *the colour produced was identical with that seen when the alkaloid was acted upon by strong nitric acid*. Thus, atropia and strychnia gave a yellow, brucia a blood-red, and codeia an orange colour.

This effect was the result of true oxidation, and not from the formation of nitric acid.

The experiment appears to strengthen the idea of Liebig, that the nitrogenous alkaloids are substitution compounds containing amidogen, NH_2; in other words, that they may be derivatives of ammonia, NH_3, in which one atom of hydrogen has been displaced by an organic molecule.

Having alluded to botany and chemistry, allow me to take up a little more of your time by giving an illustration of the advantage of a knowledge of natural physics, because many of the most beautiful phenomena pass under the dispenser's notice every day.

At our last meeting I had the honour of alluding to some experiments, showing the practical application of spectrum analysis to several of our fluid preparations. By means of the spectroscope many elements have since then been detected in articles of the Materia Medica, which, a few years ago, were considered great rarities.

On the table are the ashes of many pharmacopœial substances which contain the metals rubidium, lithium and strontium.

Lithium has been noticed in creta præparata, potassæ tartras acida, radix taraxaci, radix rhei, *Gentiana lutea*, *Atropa Belladonna*, *Nicotiana Tabacum*, *Triticum vulgare*, commercial pearlash, raisins, carbo animalis, carragheen and kaolin.

Strontium exists in many specimens of taraxacum, creta præparata, calamine, etc.

Rubidium has been detected in syrup made from loaf sugar which most probably had been manufactured from Austrian beetroot, also in oak-bark, from trees growing on beds of lias in the neighbourhood of Bristol, and in tea, coffee and cream of tartar.

Many samples of bismuthum album show the green line of thallium very distinctly, while oxide of zinc will sometimes indicate the presence of indium.

By some authors it has been denied that plants absorb from the earth such metals as are not absolutely essential to their nutrition. Experiments, however, afford strong evidence to the contrary.

Mr. R. Warington (*Journ. Chem. Soc.* 1865) found in the ashes of the beech and birch ·193 per cent. of manganese. In a case of cattle poisoning at Wells Assizes, the animals were proved to have been killed by eating plants containing lead derived from the soil on which they grew. Analysis showed that grass, weeds, fungi, thistles and shrubs contained a poisonous quantity of lead, although totally unaffected in their growth.

The triassic marls of Cotham, near Bristol, are celebrated for an abundance of celestine, or sulphate of strontium. An examination of the ashes of plants and shrubs growing on these strata nearly always shows the presence of strontium in small quantity. I have detected this metal in *Taraxacum*, *Arabis*, *Senecio*, *Capsella*, *Poa*, *Senebiera* and *Scoparium*.

In a communication to the Royal Society (*Proc. Roy. Soc.* 18, 546) Mr. Huggins says he has found traces of lime in every specimen of magnesia he has examined, even in what was sold as pure magnesium oxide and magnesium chloride.

When magnesium oxide was examined, the heat of the oxyhydrogen flame was necessary to bring out the calcium lines distinctly. He noticed that it was always most satisfactory to employ a minimum quantity of oxygen, for when too much was used they were not so distinctly visible. Dr. Emerson Reynolds, whose experiments were recorded in the same paper, gives the same results.

But perhaps of all the phenomena observed in pharmaceutical optics, that termed fluorescence is the most striking and beautiful. It is the ghostlike appearance which we see every time we dispense a bottle of mixture containing quinine, or syrup of red poppies. By very delicate methods of observation the singular fluorescent property may actually be seen on the white demy in which we wrap our bottles before sending them out.

It was formerly supposed to be occasioned by the reflection of light from an irregular surface, or from particles mechanically suspended in a solution, as when tincture of arnica is added to distilled water. In such mixtures, the effect to the eye very much resembles fluorescence, yet is of a very different character, and may be distinguished by the rays of light being polarized, which is never the case with the true diffusion of fluorescence.

The most convenient way of viewing these phenomena is by looking at the solution under examination through a prism, or by the actinic light of burning magnesium, or by passing the spark of an induction coil through a central vacuum tube.

Fluorescence may thus be observed in many substances of the Pharmacopœia, such as guaiacum, sulphate of quinine, *Hyoscyamus*, *Stramonium*, *Curcuma*, *Cannabis indica*, *Digitalis*, *Lobelia*, litmus, orchil, madder and *Papaver Rhœas*.

For some time the phenomena were explained by Sir J. Herschel, under the term epipolism, and afterwards by Sir D. Brewster as internal dispersion. It however remained for the President of the British Association, Professor Stokes, to discover the true explanation, viz. that the effects were caused by a change of refrangibility in the rays of light. The index of refraction is always *diminished*, because the length of the light wave is increased and the velocity lessened.

For instance, the invisible actinic rays which lie beyond the violet, are shown by quinine in the blue, by stramonium and curcuma in the yellow, and by chlorophyll in the red. In every case the change is towards the red end of the spectrum.

It sometimes happens that fluorescence is observed to commence in two parts of the spectrum, and would indicate that the solution under examination contained two distinct chemical compounds.

The bark of the horse-chestnut (*Æsculus Hippocastanum*) is a remarkable example of this. Its beautiful green fluorescence was formerly supposed to originate from a crystalline substance called æsculin. A more accurate series of experiments by Mr. Stokes has shown that two parts of the spectrum were simultaneously affected.

This fact aroused the professor's suspicion, which a chemical analysis afterwards proved to be well grounded. Two glucosides were produced, viz. æsculin ($C_{21}H_{24}O_{13}$), which gives a sky-blue light, and paviin ($C_{27}H_{30}O_{13}$), which gives a bluish-green. When an aqueous mixture of both these principles is submitted to examination, a light is perceived in every particular identical with that from an infusion of the original bark.

Thus it is that we often observe the different branches of natural philosophy dovetailing as it were into each other, and hastening to complete the chain of evidence required for the elucidation of some interesting problem.

The past year has been prolific in so many new and important discoveries that it becomes difficult to point out one or two only for consideration.

At our last meeting Mr. Hanbury brought before our notice a new hypnotic, the chloral hydrate. Then it was an expensive curiosity, now it is in every one's pharmacy and manufactured in enormous quantities. The general impression is, that it will prove a very efficient remedy, especially where opiates are inadmissible. It is, however, much to be regretted, that already another preparation has been introduced into the market, which only contains 70 instead of 90 per cent. of chloral, and which is declared by Dr. Liebreich to be devoid of any therapeutic power. The chloral alcoholate, as it is called, is not so deliquescent as the hydrate, and has a boiling point of 113·5° Cent. and a sp. gr. 1·34, while the true hydrate boils at 97° Cent., and has a sp. gr. of 1·57.

A very simple method of detecting the imposition by the use of ammonia is described by Mr. Umney. (PHARM. JOURN., Aug. 6, 1870.)

Sulpho-carbolic acid is another preparation that has recently been brought into use. It is made by combining sulphuric and carbolic acids in their molecular weights (49 to 94) at a temperature of 290° F.

That true chemical union occurs is evident from the fact that sulpho-carbolic acid gives no precipitate with chloride of barium or nitrate of lead. It produces a characteristic purple colour with perchloride or pernitrate of iron.

Many physicians affirm that it is a more powerful disinfectant than plain carbolic acid. The salts most commonly used are the sulpho-carbolates of soda and zinc.

Last year Mr. Hanbury alluded to the madder plant, a species of the *Rubiaceæ,* which, although not in our Materia Medica, yet is employed as a medicinal agent in manufacturing districts, and will, therefore, be my excuse for again alluding to it.

Its principal consumption, as you know, is for tinctorial purposes, and its value may be easily conceived when no less a sum than £1,000,000 is annually paid by us for foreign madder.

It owes its colouring matter to alizarine, which, singularly enough, does not exist in the living plant, but is produced by a kind of fermentation.

A few months ago two Germans succeeded in artificially making alizarine in quantity by the destructive distillation of coal-tar, like the well-known aniline dyes, alizarine being a product from anthracine as aniline is from benzol.

During the past twelve months our London and provincial brethren have not been idle at their evening meetings, for subjects of the highest importance have been discussed.

In London Professor Redwood, with his usual aptitude, has given a series of most useful notes on the Pharmacopœia, which have in their turn elicited practical remarks from our ever-ready friend, Dr. Attfield, and other members. Abstracts of these have appeared in the Journal, to which periodical I must also refer you for an amount of work done in the provinces, and which I think will thoroughly stand the test of criticism. Nor must I forget our Transatlantic *confrères*, who have been prosecuting pharmaceutical researches with great diligence. Their transactions are well worth an attentive perusal.

Since our last meeting at Exeter an International Congress of Pharmacists has been held at Vienna, and I trust we may have the pleasure of reciprocating the friendly feeling evinced on that occasion by a cordial invitation to our own shores.

In conclusion, I trust I shall be forgiven if I impress on every one present the importance of sinking petty differences of opinion, and uniting together in advancing the object for which we have met here to-day, viz. the promotion of pharmacy. We certainly have the opportunity, and we ought to take the greatest care not to let it pass unheeded or unimproved.

Government shows a disposition to help us in every way, and will give a decided preference to those who pass our examinations. For instance, they will admit no candidate for the office of naval dispenser until he has a satisfactory diploma from the Pharmaceutical Society. In return we are in duty bound to see that we fulfil our trust, and discharge the moral obligations that they have entrusted to our care.

We are pharmaceutists, that is, professed preparers of compounds containing the active principles of articles in an acknowledged materia medica, and such, in my opinion, ought to be our chief business, and the object of thoughtful study.

If my view be correct, our proper and legitimate aim ought to be attaining a knowledge of the best method of making those preparations.

I am well aware that in order to make both ends meet, a great number of our body combine a multitude of heterogeneous goods in their common stock. Nevertheless, I submit that it does not alter my idea of the desirability of a pure and simple pharmacy.

The general tendency of the medical profession of the present day is to leave to us dispensing of prescriptions which they prescribe. It is then plainly our duty to lose no time in rendering ourselves competent to undertake that office in the best possible manner.

At a late address Professor Huxley spoke very strongly on this point. He said, when speaking of the curriculum of study, "I would abolish Materia Medica altogether. . . . I cannot understand the arguments for obliging a medical man to know all about drugs and where they came from. Why not make him learn about cutlery, because he uses knives?"

I quote this as a very significant expression and sign of the times. I must confess I cannot go quite so far as the Professor, for the dispenser well knows the difficulty in dispensing that often arises from a want of knowledge in the properties and peculiarities of the drugs with which the prescriber has to do.

No one, I presume, would call the medical profession a trade, because in some out-of-the-way spot in the country, and many miles from a pharmaceutist, a medical practitioner dispensed his medicine or even the prescription of another. Then why should we be prevented from raising our status and entering the professional ranks, because some of our brethren in the country find it necessary to amplify their already small income by the sale of more general accessories?

It must be borne in mind, too, that the present time is an anomalous one, and one that will gradually pass away, like the old apothecary.

Let us then accept the challenge that is now virtually thrown at our feet, and do the best we can under the circumstances. In future years our children and successors will give us credit for, and enjoy the advantages which will have arisen from our present endeavours in their behalf. It may be that all the thanks the founders of Pharmacy will ever obtain, will be given by them long after we have passed away.

Nevertheless *we* should err if *we* forgot the long-tried, steady and faithful work done by such men as Squire, Morson, Deane, and many others whose names need only be mentioned.

Why should we not then unite hand in hand, and with the unselfish and free spirit of true science, proceed steadily onwards, surmounting every obstacle, and letting the motto on our banner be "Excelsior!" for

> "All the means of action,
> The shapeless masses—the materials—
> Lie everywhere around us. What we need
> Is the celestial fire to change the flint
> Into transparent crystal, bright and clear."

I cannot conclude without alluding to the great exertions of Messrs. Attfield, Brady and Reynolds on behalf of this Conference. I do not hesitate to say that to them we are in a great measure indebted for our successful progress. Few know the immense amount of work that has been willingly gone through by their untiring exertions.

Long may *we deserve* and appreciate their self-denial, and long, very long, may we enjoy the privilege of having them as our official guardians.

In a society like the present, money matters necessitate delicate, firm and careful management, and this we have in our esteemed Treasurer, Mr. H. B. Brady, who, though always considerate, is ever watchful for our interests; I sincerely hope, therefore, that we may hail him for many more years as Honorary Treasurer to "The British Pharmaceutical Conference."

On the motion of Mr. MACKAY (Edinburgh), seconded by Mr. WILLIAMS (London), a vote of thanks was accorded to the President for his excellent address; which compliment he briefly acknowledged.

The reading of Papers was then commenced, and was carried on till shortly after 4 o'clock, when the Conference adjourned to the Exhibition of Pharmaceutical Products, Apparatus, etc., which is held in a room over the Savings Bank in Bold Street.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Meeting at Liverpool.

The Fortieth Annual Meeting of the British Association commenced on Wednesday. It is the third visit the Association has made to Liverpool, and promises to be very successful. The first general meeting was held in the Philharmonic Hall. The retiring President, Professor Stokes, having vacated the chair, Professor Huxley, the President for the year, proceeded to deliver the customary address, the subject chosen by him being Spontaneous Generation.

The business of the several sections commenced on Thursday morning. Among the events of interest announced to take place during the meeting may be mentioned the discourse of Professor Tyndall, on Friday, upon the Scientific Uses of the Imagination; and the Lecture of Sir John Lubbock to working men, on Saturday, upon "Savages." The Mayor of Liverpool gives two *soirées* during the week. A *soirée* will also be given by Mr. Bickersteth, for which one thousand invitations have been issued. The excursions, seven in number, are fixed to take place after the close of the business of the Association.

SHEFFIELD SCHOOL OF MEDICINE.

The winter session of the Sheffield School of Medicine will commence on October 1st, when the Introductory Address will be delivered by the Rev. J. Lettis Short, and the Prizes distributed in the Anatomical Theatre at 4 P.M.

SOCIETY OF ARTS.

On Fermentation.

BY PROFESSOR A. W. WILLIAMSON, F.R.S.

Lecture II.—continued.

There is one other remarkable instance which I must give you, to show the difficulty in some cases of analysing these phenomena. It is the case of the metal platinum, which I can hardly describe better in general terms, as regards its properties, than by comparing it to gold. It is what is termed a noble metal; it does not dissolve in any ordinary acid; you might boil platinum in nitric acid for any length of time and it would not dissolve. On the other hand, silver is a metal which dissolves readily in this acid, and if you melt silver and put platinum into it, it will also melt, and you obtain a compound of the two metals mixed pretty uniformly together. It was noticed that when such a button of platinum and silver is put into nitric acid, not only does the silver itself dissolve, as you would expect, but some of the platinum also dissolves with it; not the whole, but a portion. That seems, at first sight, favourable to the theory of contagion; it seems natural to suppose that the silver in dissolving has communicated the same tendency to the platinum, and made some of it dissolve. But that explanation will not do, and for this reason. When platinum is combined with anything else, I care not what, its properties are not the same as when uncombined. The very essence of chemical combination is that the particles which are in intimate contact unite, and that the compound possesses different properties from the original elements. We know that metals combine with one another; there are many cases known to us of the forcible union of metals, and we have no right to suppose in any case, unless we have actual proof of it, that a metal is present in such a compound with its ordinary properties. Therefore, it is not free platinum, but a compound of platinum and silver which dissolves, and there are some compounds of platinum which dissolve in water, and others which dissolve in nitric acid, so that this process has really nothing to do with contagious action.

In the composition of alcoholic ferments there are several substances of which we know very little at present, I am sorry to say, but the want of this knowledge is so great that I have no doubt it will be soon supplied; certainly, this is a most important field for the investigation of naturalists who possess an accurate knowledge of chemical manipulation. I mean the simplest and lowest organisms, whose functions are of such importance in these changes, and certainly claim much careful investigation. But some of the things which we do know about the yeast-cells, I must now state, with relation to the facts and ideas which we have just had before us. In the first place, with regard to their growth. It is very common, in the process of brewing, to feed the yeast-cells with a substance which is formed in the germination of barley. When barley is left in a moist state, at a suitable temperature, it begins to sprout, and during that process there is a change in two of its constituents, which I showed you the other day. One is gluten, a body containing nitrogen, which I compared, for the sake of convenience, to muscular fibre, being in reality very closely allied thereto in chemical composition, and during the germination of the seed this substance passes over into some product or products—I had better speak quite generally—known by the name of diastase. In the yeast-cells there is a substance very nearly resembling in composition this gluten, and it cannot be doubted that this gluten, or albuminous body as it is frequently called, is capable of undergoing a similar transformation into diastase, and of all foods the yeast-cell enjoys most those which contain diastase. I have a good many yeast-cells growing in a suitably heated chamber, and those which seem to thrive most are some which were put into an infusion of malt to which sugar was added. It is common, in the process of fermentation, to put in yeast in tolerable quantity, but the extent to which it grows depends upon the time for which it is left in contact in the material. I am told that the common proportion is about one-twentieth of the quantity of yeast required. For instance, if 20 lbs. of yeast are wanted to effect a given fermentation, you put into the liquid which has been fermented 1 lb. of yeast calculated in the dry state, and give it this diastase to feed upon. At the same time, there is sugar present in the liquid, and during the process of fermentation this pound weight of yeast increases more and more, by a process of true germination and growth. Professor Mitscherlich actually saw, under the microscope, some little cells of yeast sprout and put out, from the side of the parent cell, small cells, which gradually increased in size. The actual process, however, has not been seen by many observers. And not only does the yeast-cell in that way feed upon these albuminous bodies, which are grouped together by the name of diastase, but it also takes part of the sugar; and these are the two prominent facts which we know with regard to its food—that it feeds upon substances of those two classes; sugar, which contains no nitrogen, and also nitrogenous substances, which are formed by the partial breaking up of the gluten. On the other hand, its decomposition—I mean during its life; I am not speaking of any decomposition which its materials may undergo if it is killed—gives off alcohol, carbonic acid, succinic acid and glycerine; in fact, the four chief products of ordinary alcoholic fermentation, which I enumerated to you the other day. And while these products are being given off, there is at the same time a considerable quantity of nitrogenous substances being given off. The albuminous matter in the yeast-cells is undergoing decomposition, and is giving off nitrogenous substances. There is not any well-authenticated case of the yeast-cell forming, during its active functions, products of complete breaking up or putrefactive decomposition; all the products which we know best are substances of considerable complexity—less complex than the materials of the plant, but of great complexity; and, accordingly, the notion which Liebig had that the yeast-cell is active in the proportion as its materials are undergoing complete analyses or breakings up, and forming ammonia and carbonic acid, is not now entertained by that distinguished philosopher.

Some time ago, an exceedingly important experiment was made by M. Pasteur, with a view of testing the vital functions of the yeast-cells in a definite way. The statements which I have made to you contain a good many terms which are exceedingly general, as, for instance, the allusions to diastase. We really do not know what that is. We know about what sort of a thing it is made from, but not definitely. And the same with the nitrogenous products which are given off by the yeast-cells; we know something about them, but only a little. Pasteur put into a solution of sugar, in which some yeast-particles were present, some ammonia combined with an acid, and at the same time he put some of the ashes of other yeast-cells. He took a certain quantity of yeast and burnt it, so as to remove by oxidation the carbon, hydrogen and nitrogen of the substance, and the earth substances which remained, which are essential to the formation of a new yeast-cell, he put into some fermenting liquid, together with some salt of ammonia. When he did that, he really was treating the yeast-cells very much in the same way as a good farmer treats the wheat plant. If you want a wheat plant to increase rapidly, you must, in the first place, take care to supply to it all that the wheat plant takes up in the shape of mineral matter from the soil, and the best way to find that out is to burn some wheat, and see what is left. Then you must supply plenty of ammonia, and the more ammonia you supply up to a certain extent, the more rapidly does the wheat grow, by building up various simple substances into the complex substance, gluten, which I was speaking of just now. Pasteur put into such a mixture a few little cells of the yeast, and they did not thrive. They did transform some sugar into alcohol and carbonic acid, but they evidently were not at home, and at the end of a certain time, I forget how long, he found there was actually a smaller weight of yeast present than he had put in. That was a very different result from what happens when nitrogen is supplied to the yeast-plant in the form which I mentioned just now as the usual one; and I think the fact is most instructive, and serves to show us what kind of a being the yeast-cell really is,—I mean whether it should be classed among animal or vegetable beings. I need hardly say that absolute distinctions amongst beings which we find in nature are out of the question; we do not generally get any absolute line of demarcation, for one class flows over into the other; but still the ideas which serve us to classify organic and other beings are exceedingly important, and in a case like this it is certainly of considerable interest to have some leading idea, by which one may see whether there is a reason for placing these beings amongst vegetable or animal organisms, and we cannot help giving special weight in that respect to the kind of process which the respective classes of beings carry out in their organisms. Plants build up complex substances from simple. All the most complex substances that we can get are made in the organisms of plants. They may have been taken over by animals from plants, but they are formed in the main by plants. And the chief chemical activity of animals is precisely opposite; they take those complex substances, and break them down, by means of their vital functions, to the simple products which are exhaled and given off in the processes of animal life. Therefore, the question whether the process which the yeast carries on is a synthetical process, a building up, or whether it is in the main an analytical process, is certainly one of the most important which can guide us. Now, I think what I have said must appear to you all most conclusive in that respect,—that what we know best regarding the nature of the yeast-cells, the food which we know they take in large quantities, and upon which they live, is certainly exceedingly complex, and what the yeast-cells take up in preference is certainly sugar, and the very complex nitrogenous substances which are present in solution in the malt, and the products which they give off, are exceedingly simple in comparison. Their functions are in the main (those which we know best, at any rate) analogous to those which take place in animal organisms, and are most remote from those which take place in vegetable organisms.

In a paper which he has recently written on the subject of fermentation, Liebig has drawn attention, amongst other things, to the circumstance that the common alcoholic ferment can be made to eat tartaric acid. If you were to neutralize a solution of some of these crystals in water, and put with the solution some yeast-cells, at the same time supplying some nitrogenous material, the yeast-plants would grow, and transform that into other substances. In the same way, if you were to put in some of this malic acid (which got its name from the circumstance that it is present in sour apples), the yeast-cells would also transform that; and the same in other cases. One of the most remarkable decompositions is that of nitric acid, which, by the action of the yeast-cells, is deprived of some of its oxygen, and converted into nitrous acid, so that it would appear that the plant can actually assimilate or eat the nitrates, forming these simpler derivatives from them.

There is one case which I should like to show you, of an inorganic action, one in which there is no vital process concerned, but it bears a sort of general resemblance to what I conceive to be the principle of those which I have been speaking of. I have here a piece of platinum in a peculiar state, which is well described by the term "spongy." If I hold it in the flame of common coal-gas mixed with air, from a Bunsen burner, the spongy platinum eats the air or the oxygen contained in it and the gas. The word "eat" is not really so inappropriate as it may seem. If I were to put this spongy platinum into oxygen, I should find that it would combine a quantity of oxygen into its substance, and make it part of itself, and the same with regard to the coal-gas. So that here you see, from the heat which was given off, the substance is really effecting a chemical change upon the materials which it absorbs, and it effects that change in its own substance. It is admitted that, in some way or other, the yeast organisms—I will not again call them plants—actually assimilate and make part of themselves the sugar, or tartaric acid, or whatever it may be which they decompose; but they do not give off that substance which they have eaten in the same form. They give off its elements, after they have undergone a rearrangement in other ways. At our next meeting I propose to bring before you some different considerations regarding the vital functions of these organisms, and some points which bear upon questions of sanitary importance.

AMERICAN PHARMACEUTICAL ASSOCIATION.

From a circular issued by the Permanent Secretary, Mr. John M. Maisch, we learn that the Eighteenth Annual Meeting of the American Pharmaceutical Association was to be held on Tuesday the 13th of September, in the building of the University of Maryland, in the city of Baltimore. Ample accommodation has been secured in the same building for the exhibition of drugs, preparations, apparatus, models, and specimens interesting to and connected with the business of the pharmacist. The central position of Baltimore, and the important subjects to be reported and acted upon, are expected to render this meeting a very interesting one.

Obituary.

THE LATE BENJAMIN BROGDEN ORRIDGE.

"On the 17th July, at his residence, 33, St. John's Wood Park, Benjamin Brogden Orridge, Esq., F.G.S., in the 57th year of his age."

This brief announcement, which appeared in our columns a few weeks ago, probably conveyed to most of our readers little beyond the fact that a man active in business and without reproach in his conduct of transactions involving no ordinary responsibility and delicacy, had passed from our midst. To some, it is true, the words might have a deeper meaning, but the life they referred to had been so unostentatious that, even to colleagues in various engagements of a public character, it seemed to be associated with the single sphere of work they had in common. Of a many-sided existence, even his fellow-labourers saw but that which reflected the object they were mutually engaged upon, or at most it showed but a glimpse of its other phases. Hence a few details, meagre though they be, and gathered not without difficulty for this very reason, may have an interest alike for some who enjoyed his personal friendship, and others who knew him but by name or in connection with the Council of our Society.

Mr. Orridge was born at Malta in the year 1814. His father then held an official position in the island, which he resigned about the year 1820, and returning to England, settled at Oakham, in Rutlandshire, as Governor of the county jail. Here the boyhood of his son, the subject of our memoir, was spent, and during his education at the Oakham Grammar School, under the late Dr. Dancaster, he had for schoolfellows Noble and Pratt and others who have since become famous. In 1827, whilst still a lad, he lost his mother, and a year or two later we are told that he was apprenticed to his uncle, a chemist at Colchester. Beyond this we have no particulars of his early life.

Arrived at manhood he removed to London, and we hear of him shortly afterwards as Dispenser to the Marylebone Infirmary. He entered the Pharmaceutical Society as one of its founders, and, at a later period, settled in the City as a confidential agent in the transfer of pharmaceutical businesses and medical practices, acquiring eventually a high reputation for probity and skill in such negotiations.

Separated by the nature of the occupation he had chosen from the actual practice of pharmacy, he still found an ample sphere of usefulness to his fellow-members, giving his attention to such objects as the scrutiny of measures of general or local legislation likely to affect the interests of pharmaceutists. But the subject he laid to heart above all was the Benevolent Fund, its condition and prospects; and chiefly with a view to effecting some alterations in its administration, he allowed himself to be nominated for the Council in 1864, when his well-known name secured his immediate election.

It is needless to recount his various efforts in respect to the Fund, he was not less zealous in its augmentation than urgent in its liberal distribution; nor is it too much to say that to Mr. Orridge more than to any other single member, its present noble dimensions are attributable. Others worked with him and heartily, but to his clear judgment and appreciation of its proper scope we owe the wider basis on which it at present rests, and many may bless him for the provision it now affords to enfeebled age and desolate widowhood.

Such is the simple chronicle of his life so far as immediately concerns us; he had done his work, and only resigned his seat in our Council a few months before his death.

This, however, is but one sphere in which his active mind courted usefulness. He was a good citizen, and ever ready to work for the common weal. His earliest public services in the City were in connection with the Cheap Ward Benevolent Fund, of which he was for many years the Treasurer; and upon his recent retirement from that office the members accorded to him an emblazoned vote of thanks, as their testimony to the value of his labours. In 1865 he was elected to represent the Ward of Cheap in the Corporation of the City of London, and soon found a department in which his special qualifications met with congenial employment; he was at once appointed to the "Library Committee," and in 1868 was chosen its Chairman. A valued member of our Society, a colleague in the City Council, thus speaks of him:—"As Chairman of the Library Committee, he was over-zealous and over-anxious, and went to the work as if that alone were the labour of his days, instead of giving only that part which a man of business can afford to take from the steady routine of active and thoughtful life." He was greatly interested in the history of City life under the Tudors and Stuarts, and whilst he held office as Chairman of this Committee, he ascertained that, hidden amongst the old papers of the Town Clerk's Office in Guildhall, was a large collection of copies on parchment of letters from Queen Elizabeth, James the First, Charles the First, and their Ministers, to the Lord Mayor of London, between the years 1577 and 1640. He prepared an abstract of some of these relating to plays and players, and matters of religion, which was printed in the *Athenæum* last autumn; and in the spring of the present year he moved for and obtained an instruction to the Library Committee to examine and report upon the discovery referred to, and generally upon the condition of the Corporation Archives.

His literary labours were chiefly directed to archæological subjects. In 1868, he published a work entitled 'The Citizens of London and their Rulers,' the historical portion being reprinted from Norton's 'Commentaries of London;' and in the following year was a contributor to the 'Proceedings of the London and Middlesex Archæological Society.' At the time of his death he had a volume in the press on 'The City Friends of Shakespere,' which we understand is likely to appear almost immediately. Had his life been spared, these might have been but the beginning of a series of such works, for which he always maintained that material enough existed in neglected and forgotten corners of the City.

Need we say more? His monument is with us in the Benevolent Fund; may the loss it has suffered in his removal be more than compensated by the increased activity of those younger members of our body whose welfare was ever an object of his solicitude.

H. B. Brady.

Poisoning by Carbolic Acid.—An inquest has been held at Ulverston, upon a man named Lace, whose death had resulted from the drinking of some carbolic acid. It appears that it is the custom to use carbolic acid as a disinfectant at the sewage tanks, by pouring it in as often as a bad smell arises. On the day in question two gallons had been obtained for this purpose, and when the men went away to get something to eat, the bottle was left standing by the side of the tank. The deceased who had formerly been employed on the premises, seems to have mistaken the contents for raw spirit, which was sometimes served out to the men who worked at the tank, and, although it was labelled "Poison," drank about a gill of it. He was immediately seized with symptoms of poisoning, and died about twelve hours afterwards.

The following journals have been received:—The 'British Medical Journal,' Sept. 10; the 'Medical Times and Gazette,' Sept. 10; the 'Lancet,' Sept. 10; the 'Medical Press,' Sept. 14; 'Nature,' Sept. 8; the 'Chemical News,' Sept. 9; 'Journal oft he Society of Arts,' Sept. 9; 'Gardeners' Chronicle,' Sept. 10; the 'Grocer,' Sept. 10; the 'English Mechanic,' Sept. 9; the 'Pharmacist' for September.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

THE KEEPING OF POISONS.

Though there has been much discussion upon the keeping of poisons since the passing of the Pharmacy Act, there do not appear to have been any regulations suggested which have met with general approval. Throughout the discussion my impression has been that legitimately the subject *might be*, and perhaps *should be*, allowed to subside without any immediate steps being taken beyond those which are already prescribed by the Pharmacy Act.

Clause 1 provides that we shall conform to such regulations as to the keeping, dispensing, and selling of such poisons as *may from time to time* be prescribed by the Pharmaceutical Society, with the consent of the Privy Council.

And clause 2 provides for a schedule of poisons, and "the Council of the Pharmaceutical Society *may from time to time* by resolution" add to the schedule list.

We are thus enabled—maybe I should say required—to add in two ways to the provisions of the Pharmacy Act *from time to time*. Under all ordinary circumstances I should have understood that to mean whenever the Society considered that additions were required.

Keeping in view the Society's long struggle to make educational qualifications the only legal restriction upon the dealing with poisons, and their repeated protests against angular bottle contrivances and other proposed substitutes for the responsibility of reading the label in every instance, I think the Society might reasonably be allowed to give a fair trial to regulations at present required by the Act before it commenced to make additions to them. But if it is required of us to do something more without delay, as appears to be the case, I would not by any means have us neglect that duty, though we may undertake it with some reluctance and hesitation. It would not do for us to prescribe any ill-considered or unsatisfactory regulations, by way of showing our willingness to do our best, and as yet I have not seen any which I would willingly see enforced.

In offering another plan for discussion, I do so upon the ground of its being useful as far as it goes, and its not attempting too much. In the keeping of poisons, each poison shall be kept in a box, bottle, vessel, or package distinctly labelled with the name of the article.

All poisons not intended for medicinal use shall also be distinctly labelled "poison" immediately under the name of the article.

All poisons to be used externally as medicines, but not intended for internal use, shall be labelled either with the word "poison," or "for external use," immediately below the name of the article.

All poisons intended for internal use as medicines, the usual adult dose of which is less than one dram, shall bear a label immediately under the name of the article, stating the usual adult dose; and upon such articles the usual adult dose of which is less than (say 5) grains there shall be added the label "poison" immediately below the label indicating the dose.

The code of regulations submitted to the last Annual Meeting proposed that all poisons should have the poison label attached, but considering that the number of poisons by Act of Parliament is very considerable, and liable to grow by additions from time to time,—two evils attached to it which are obviated in the proposition which I have just made, namely, that the word poison would, in the former case, become so common as to lose its value as a caution to the dealer, while it would add to the uneasiness of the patient to find how numerous were the poisons and how freely many of them were dispensed. The only articles in the present amended list of poisons not used in medicine are oxalic acid, essential oil of almonds and vermin killers; they, of course, would bear the poison label.

Red and white precipitate, liniments, ointments and plasters containing aconite, belladonna, opium, etc., would naturally be labelled "for external use."

The mild preparations of opium and poppies would require no addition to their names; the more potent tinctures of opium, aconite, belladonna, etc., would have the dose attached, as indicated in the pharmacopœia, or such dose as might be fixed by some competent authority (say the Pharmacopœia Committee), and the most potent poisons only would have the poison label attached.

I have suggested 5 grains as the dose which should mark the boundary between the more and the less dangerous drugs, but this is matter for discussion, the object being to include all that are specially hazardous, and at the same time not to include *too many*. Arsenic should have the poison label, though its solutions would probably be sufficiently protected by having the dose indicated. So of the alkaloids, morphia and strychnia would have the poison label, while their liquors would be labelled respectively "Dose 10 to 60 minims" and "Dose 5 to 10 minims."

If it be considered necessary to adopt poison cupboards, angular bottles or sand-paper, I think they should only be applied to those articles the dose of which is 5 grains and under, or some other limitation which shall not involve the absurdity of using the same precautions to all the articles in so crude a list as the official schedule of poisons. It is no protection to use an angular bottle if angular bottles become too common, as they would do if used for all poisons, from syrup of poppies to strychnine. It may be said that a label stating the dose would also become too common, but it would always give useful information, and would, when read, indicate the degree of danger, and the degree might be in some measure indicated pictorially. Thus, the most virulent might have red angular labels for the dose [$\frac{1}{30}$ gr. Dose to 1 gr.] [1 to 5 gr. Dose.] the next less dangerous having angular white labels [Dose 5 to 10 gr.] [Dose 10 to 30 gr.] and the least dangerous of the articles requiring to have the dose affixed should have it upon a circular green label, thus— [Dose ʒss to ʒi]

This arrangement would have the advantage of leaving any one to carry out such additional precautions as best suited his premises and his requirements. Many of us would probably put the articles with the red angular labels into a poison cupboard; some would also keep a separate part of the shop for those bearing the white angular labels; while those with the green circular label would come under the ordinary classification of alphabetical order in the wet and dry departments.

BARNARD S. PROCTOR.

Grey Street, Newcastle, September 6th, 1870.

Sir,—You have invited the members of the Society to express their opinions as to the advisability or otherwise of adopting certain regulations with regard to the storing of poisons.

I shall be glad if you will allow me space for a few remarks on the matter.

The discussion of the subject has given rise to much excited feeling, and perhaps for this reason it has obtained an importance it does not really deserve.

To consider it carefully and impartially now will probably do much to bring about a satisfactory solution next July.

Whatever importance the subject may have possessed before the passing of the Act of 1867, it must, in my opinion, be much diminished now that the Legislature requires a certificate of competency from all who would enter the profession of pharmacy. For may it not be reasonably inferred that a man who is considered fit to undertake the greater responsibility of dispensing may be entrusted with the lesser office of distinguishing between one drug and another, or of storing them safely?

But here, as experience everywhere else abundantly shows, our action must be guided, not by the standard of a logical theory only, but also by the necessities of the case.

The public, through the Legislature, has given us a corporate existence, and has endowed us with a monopoly not for our own aggrandizement, nor that we may hold a semiprofessional status; these may be results, but the public safety was the reason, and the Legislature will jealously watch that we use our best efforts to attain that end.

Now the public safety is as much a matter of solicitude to us as to the Legislature, but there exists a difference of opinion as to whether that is best assured by the imposition of minute regulations added to proved competency, or whether after having provided competent men, all details are not better left to their individual discretion. The public generally believes in poison bills and regulations, pharmacists, as a rule, do not; they think that a qualified man is not only worthy of, and entitled to confidence, but that his competence is the best safeguard for the public against the risk of accidental poisoning. Unfortunately, even the highest ability united to long experience is not an absolute guarantee against accident or mistake, and instances have occurred within the recollection of us all where, through some unaccountable mischance, caution and ability, successfully applied for many years, have suddenly failed, and fatal accidents have happened, which some simple mechanical contrivance or local arrangement might probably have rendered almost impossible.

It is this fatal liability that forms the real argument in favour of a code of compulsory regulations, and the argument receives additional weight when it is remembered that there are few pharmacists who are not assisted by young men whose education is incomplete and in various stages of progress.

In reply it may be said, if in the case of a medical man who is not better acquainted with drugs and their preparations than a pharmacist, and is assisted in the same way by younger men and students, no interference is considered necessary, why should it be required from him? But it must be borne in mind that medicine is an old profession, and has long held the confidence of the public, while pharmacy, as a recognized profession, dates from yesterday. Moreover, we are in a transition state, and cannot use the educational argument so forcibly as we shall be able to do in a few years' time, when the standard of qualification will be more equal.

For these reasons, among others, I may perhaps be allowed to say that it is desirable that for our own and for the public safety, some means should be devised to prevent, if possible, these accidents which happen in our unguarded moments, rare in their occurrence, but which without some physical bar *will* happen in spite of the extremest caution, and which are so lamentable in their character and effects that they warrant us in adopting every means in our power to prevent them.

The area of the proposed regulations then is limited to accidents of this kind, and it is further limited by the fact that the guarantee required is already given by a large proportion of chemists.

Were poison regulations adopted, they would do no more than make universal a practice which is now general. Would this be worth doing? I am inclined to think it would be. Would it be worth doing by compulsory legislation? Certainly not. The best men in the Society, the men who are most competent and most careful, the men who do most to ensure the public safety and preserve their own reputation, would deprecate anything like police interference as being personally offensive and destructive of anything approaching to a high-toned feeling of responsibility.

In lieu of anything like compulsory regulations, I would suggest, and commend the idea to the consideration of my fellow-pharmacists, that a code of reasonable rules should be drawn up after ample consideration and issued by the Council, with the sanction of a general meeting, with an *urgent recommendation for their adoption.* Few in number, simple and inexpensive in character, and interfering as little as possible with generally existing arrangements, they might be made thoroughly efficacious, and be a real safeguard. Issued by the present Council, they would be free from the objection raised last July, that they could be framed in the interests of the London members only; and the London members could not refuse to adopt regulations not different from or more stringent than those recommended by the last Council, in which they were represented by a majority, while country members would stultify themselves by objecting to rules framed by a Council pre-eminently provincial.

Since the somewhat stormy discussion in July, the subject has been in abeyance, and it was a question with me before writing this letter whether it were judicious to reopen it, but as indications are not wanting that the Legislature still looks to us for a solution of the difficulty, I have ventured, I trust without unreasonable bias, to suggest a course which, if pursued, would, I think, meet the views of all parties and lead to a satisfactory result. By its adoption the public would obtain the additional guarantee against pure accidents for which it asks, and the pharmacist would not be subjected to intrusive interference from without.

United action alone can procure its success, or that of any course which shall be alike satisfactory to the Legislature and honourable to ourselves.

"VIA MEDIA SALUS."

PHARMACEUTICAL TITLES.

Sir,—In glancing over the correspondence inserted in the Journal these last few weeks, I am rather struck with the desire of one or two parties to parade their intellectual status before the eyes of their *confrères.* It is a remarkable fact that the more sound doctrine a man has instilled into his mind, the more he is persuaded by that knowledge to humiliate himself before men. A great man has said, "Wisdom is the standard of the soul, therefore get wisdom;" but our friends the "Aspirant to the Major" and "T. C." seem to think that the only reward for their great attainments is to be realized in the appendage of F.R.C.P.G.B. to their names. I, for one, would grant them what they ask without a moment's reflection; else (as with some people) they may be unable to bear the slight, and consequently withdraw their energies from the field of "Major operations," leaving us to exclaim, "They have fallen, and great has been the fall thereof." Before closing my letter I would ask our friends to show a little brotherly love towards the persons of retiring demeanour who "go in" for the *very modified* curriculum, and who do not wish to place themselves side by side with "Major fellows," except as gentlemen; also, I would just note the great justice in granting a "grand flaming diploma" of M.P.S. to persons solely on the ground of their having been in business prior to the late Pharmacy Act, whereas all those who have been at some expense (though not to be compared to the Major) to pass the *Modified* have not even a decent scrap of paper to show, but only the threadbare consolation of a yearly subscription. My advice to all whom it may concern is the motto of "Aspirant,"—*agitate* until the rights of every one connected with the business are fully acknowledged by the Council, whether Major, Minor, Modified, or non-modified men.

I remain,

Barnsley, August 30th, 1870. OMEGA.

Liebig's Malted Extract Biscuits.—We have received from Messrs. Millard and Sons specimens of two varieties of these biscuits.

R. Thomas (Merthyr).—The price of the French Codex is 9 fr. 50 c., and the London agent is Mr. Baillière, Regent Street.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to ELIAS BREMRIDGE, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. CHURCHILL, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

The General Index to the first Fifteen volumes of this Journal may be obtained of the Secretary, 17, Bloomsbury Square, price 2*s.* 8*d.*, post free; bound in cloth, lettered, 3*s.* 8*d.*, post free.

THE ADULTERATION OF SAFFRON.

BY DANIEL HANBURY.

Saffron is, at the present time, the subject of a serious adulteration, to which I think it important to call attention, the more so as I find that its nature and extent are not fully known even to experienced druggists. Saffron adulterated in the manner I am about to describe, is for the most part, *undistinguishable to the eye* from the drug in a state of purity, yet the means of discriminating between the genuine and the fraudulent are of the most simple character.

Let me remark at the outset that there is, in my opinion, no method of testing saffron more effectual than that of scattering a very small pinch on the surface of a glass of warm water. The stigma of the saffron-crocus immediately expands, and exhibits a form so characteristic, that it cannot be confounded with the florets of safflower, marigold or arnica, or with the stamens of crocus itself.

It was in performing this simple operation that I detected that some saffron which I had just purchased had been treated with a heavy earthy powder, which speedily separated from the lighter stigmata, and fell to the bottom of the glass. Upon collecting and examining this powder I found it to be *carbonate of lime*, which, by some ingenious process of which I am ignorant, had been made to adhere to the thread-like saffron without in the least altering its general appearance.

To ascertain the amount of earthy matter thus fraudulently added, I subjected several specimens of saffron to incineration, each having in the first instance been dried in warm air until it ceased to lose weight. The results obtained in the examination of eight samples are indicated in the following table:—

Examination of Saffron.

Sample.	Description.	Percentage of Ash.
No. 1	Origin unknown, . *pure*	5·90
„ 2	„ „ „	4·48
„ 3	Valencia, ... „	4·41
„ 4	„ . . . . „	5·20
„ 5	Alicante, . . *adulterated*	21·22
„ 6	„ . . „	12·72
„ 7	„ . . „	28·01
„ 8	„ . . „	15·36

Sample No. 2 the quality remarkably fine. Sample No. 3, so-called *Valencia*, pure, but not of finest quality. Sample No. 7 adulteration perceptible to the eye, many of the stamens being crusted with an orange-coloured earthy powder.

The method of testing a sample of saffron for earthy adulteration which I recommend is this:—Place in a watch-glass a very small quantity (say, 1 grain) of the saffron, and drop upon it 8 or 10 drops of water; lightly touch the saffron with the tip of the finger, so as to cause the water to wet it. If the drug is free from earthy matter, a *clear*, bright-yellow solution will be immediately obtained; if adulterated, a white powder will *instantly separate*, causing the water to appear *turbid*; and if a drop of hydrochloric acid be now added, a *brisk effervescence* will take place.

Saffron almost always contains a few of the pale yellow stamens accidentally gathered; but the pollen from them which is detached when the drug is wetted, but which is minute in quantity, is easily distinguished from carbonate of lime by not dissolving when hydrochloric acid is added. Moreover, the form of pollen-grains may be easily recognized under the microscope.

*** Since the foregoing paper has been in type, I have received the *American Journal of Pharmacy* for September, in which I find a note by Professor Maisch calling attention to the adulteration which I have here described.—D. H.

THE WATERS OF THE BRITISH PHARMACOPŒIA.

BY GEORGE BROWNEN.

Distilled waters constitute an important class of preparations in the B. P. and have often attracted the attention of pharmacists. Haselden, Proctor and others have examined them, and thrown some light on their manufacture and preservation; but our knowledge of them is still incomplete. Much that is mysterious goes on in them; they alter in taste and appearance. Opaque waters become nearly clear, and their harshness gradually tones down to mellowness.

All the B. P. waters but one are distillates, and that one—aq. camphoræ—is made with distilled water. The apparatus for distillation is familiar to us all. By its use volatile oils, though possessing higher boiling-points than water, are diffused in steam, carried over and condensed, free from inert matter, which is left behind in the still. Forms are given in the British Pharmacopœia for preparing twelve of the thirteen official waters; the other one, aq. flor. aurant., is an imported article. For making some waters the directions are exceedingly minute, for others quite the contrary. In aq. camphoræ, for instance, the old stopper is no longer used; a glass rod must sink the camphor in the water. This may suit some, but not those who have to make this water in large quantities, as it is found that long glass rods are easily broken, and the advantages of long pieces of glass over short ones are not equivalent to the increased cost. On the other hand, the camphor is only ordered to be "in pieces," but whether large or small the B. P. does not say. Yet this vagueness greatly affects the time necessary for saturation. Again, in the case of aq. anethi, bruising dill fruit is not an easy task, but, having accomplished it, we distil the authorized quantity. Now, if we leave the residue in the still to macerate till the next day, and then distil again another and an equal quantity, it would puzzle most people to know the right from the wrong article. Yet none of the waters of the British Pharmacopœia, except aqua lauro-cerasi, are supposed to want maceration. This curious mixture of carefulness and uncertainty strikes us, if we look on these waters as a class or section of the B. P.

Upon examining each separately, aqua and aqua destillata first attract notice. A hard taste must be no taste at all, pharmacopœially speaking, or we should have to reject the waters of some of the London water companies. In distilling water, the first $\frac{1}{20}$th is rejected, the next $\frac{16}{20}$ths saved. The tests given in the B. P. refer only to mineral matters, which, of course, are separated; but many volatile bodies, and the results of organic decomposition, still remain in the water, as well as substances having a high volatilizing-point, but which come over with water in distillation. When a recently-distilled water, giving no precipitate with liq. calcis, has been mixed with a little peroxide of hydrogen and re-tested with liq. calcis, I have sometimes found a precipitate of calcic carbonate. I have attributed this to the oxidation of a carbon compound into carbonic acid. Another effect of this process of oxidation has been the destruction of that musty odour so common to recently distilled water. I have theorized on these facts in this way: these odours may be partly the result of electric action in the still, and partly the result of algæic or infusorial decomposition; slowly these forms of matter pass into more highly oxidized, stable and odourless states, and we say the water has improved by keeping. Well, for medical purposes so it has; and perhaps this may throw a ray of light on an after subject. Of substances volatilizing in connection with boiling water, ammonia nitrate may be taken as a type. If a solution of brucine be added to recently-distilled water, and sulphuric hydrate be allowed to trickle down the side of the test-tube, a rose-coloured zone, changing to yellow, may be seen at the line of union in the two fluids, indicating nitrates, and ammonia may be readily found by Nessler's test. I have obtained the same results in distilled water when more than double the Pharmacopœia quantity has been rejected.

Gases, as nitrogen, etc., distil over with water. According to the experiments of Douny and Grove pure boiling water has not been obtained; their experiments tend to show that nitrogen expanding by heat into a gaseous bubble carried away an atmosphere of aqueous vapour; that in the process of boiling, nitrogen was absorbed as well as evolved; that in sealed tubes boiled by electricity it was still eliminated; and these and other experiments go a great way to prove that the action of heat on pure water would cause decomposition. But such refinement is not required for the pharmacopœial article. I have referred to it as confirmative of a theory I shall shortly state.

In aqua destillata we possess the most powerful solvent known, and as such it is one of the most delicate articles to keep. It absorbs gases as rapidly as it is distilled; some, as oxygen and nitrogen, with remarkable avidity and force; and others, as the common laboratory gases, carbonic acid and ammonia, also with great rapidity, and then minute important and puzzling changes are the result. Not only salts and minutely-divided substances, but metals also, are attacked by water. Iron is dissolved as ferrous and ferric oxides, and lead, zinc, and its compound pewter, with their well-known injurious results. Copper is as easily dissolved as either of the others. Cupreous water gives the blue coloration with ammonia. Manganese, mercury, silver, gold and platinum are also attacked. Tin is dissolved from the worm, tinned vessels, etc., and after a little time thrown down as stannic oxide; to this action Parrish attributed the unpleasant odour of distilled water. Cadmium, bismuth, silica and glass may be added to the list, and it is probable, if I could have experimented with the whole list of elements, nothing would have completely resisted aqueous action, or the almost, if not entirely, nascent condition of its gases. What, then, should we use as vessels for aq. destillata? I think this shows that glass, or metallic cisterns coated with their most insoluble compound, would be the safest and best. And yet we need not wish the absorptive and changeful properties of water less, or nature's great sanitary operations might be interfered with. Sewage and decaying matter soon find their way into water, and if water could not quickly change them into innoxious compounds there would be death in the pot of teetotallers and non-abstainers alike. Especially should Londoners be thankful,—with chimneys overhead, dustbins and other surface pollutions, and sewage underfoot, evolving putrid gases, etc.,—that water is so industriously and incessantly turning the noxious into less hurtful compounds.

I have dwelt thus long on distilled water as all the substances found in that water, including the rejected distillate, are also found in the medicated waters of the Pharmacopœia. To these waters I now briefly call attention.

Aqua Anethi.—1 lb. of the fruit yields from 3 to 7 drachms of oil, sp. g. ·90. In a note to his translation of the P. L., Phillips says that this oil is soluble in 1500 parts of water; if so, it is evident the proportion of fruit or oil is excessive in the B. P. form. This is a fact, and, if maceration had been ordered, the quantity might have been halved and a superstratum of oil still obtained.

Aq. Flor. Aurant.—The foreign preparation, with which a syrup is made, often substituted for syr. capillaire. The tests given for this water should have Gobley's test. Ph. J. Ap. 66, added to them; this test detects orange leaf and oil of neroli water. 1 lb. of orange flowers yields about ʒss of oil, sp. g. ·88.

Aq. Camphoræ I have already referred to. If the camphor is beaten in a mortar without spirit, I find it can be reduced to a coarse powder, incapable of sifting through the muslin, but sufficiently fine to make the water quickly.

Aq. Carui is very similar to aq. anethi; both preparations are reduced in quantity from the P.L., and by the adoption of maceration previous to distillation, might still further be reduced. 1 lb. of carraway fruit yields ʒiij to ʒx of oil of sp. g. ·94.

Aq. Cinnamomi is slightly altered in proportions from the B. P. Using the bark we are not so likely to use cassia. Pareira says these barks may be known apart by the iodine reaction, but the oils are not so easily distinguished. 1 lb. of cinnamon yields ʒi to ʒiij of oil, sp. gr. 1·006.

Aq. Fœniculi comes from Scotland; possibly Englishmen are not yet alive to its value, as it is not much in request amongst us. 1 lb. of fennel yields ʒij to ʒvj of oil, sp. gr. ·94.

Aq. Laurocerasi has been investigated by Draper, Pooley and others, it is one of the most uncertain articles in the Pharmacopœia. Draper advised standardizing its hydrocyanic acid; a weak solution of hydrocyanic and sulphuric acids has been praised by others; some say make a stronger water and dilute when wanted, others omit the maceration process; so altogether it is a dangerous and uncertain article. The oil varies from ·06 to ·6 per cent. (Umney).

Aq. Menth. Pip. and Aq. Menth. Vir. represent the Labiates; they are the only waters made from oils, as recommended by Haselden, and are improvements on the herb-distilled waters of the P. L. The oil should be divided by trituration with some solid before it is put in the still.

Aq. Pimentæ has been reduced $\frac{1}{8}$th, that is, 2 oz. less pimento to the gallon. A thin layer of oil lies at the bottom of the water; this opaque water becomes clearer by age and deposits crystals, to be afterwards noticed. 1 lb. of the berries yields ʒij to ʒv of oil, sp. gr. 1·02.

Aq. Rosæ, ordered to be made from rose petals, is often made with otto or rose geranium oil. Real otto is a scarce article, 100 lb. of petals yielding less than ʒiij of solid otto fusing at 86°. To the salt process I shall refer presently.

The last water of the Pharmacopœia is Aq. Flor. Sambuci; this, as well as aq. rosæ, the B. P. allows to be made from the salted flowers. I have found the use of salt unsatisfactory and injurious. Often after salting and keeping in a cool dry place, I have found that before the next flower-season came round an odour of chlorine and sawdust was developed by distillation. The metal still was corroded; the water smelt like a dilute solution of chlorine and precipitated argentic nitrate; I therefore discontinued the salting process, and distilled a stronger water and diluted it when wanted. This water I have found to keep; I have some two years old. Elder flowers yield scarcely ·32 per cent. of a volatile oil slightly lighter than water, yellow, solid, and with a powerful smell of elder-flowers even when largely diluted.

These are the waters of the Pharmacopœia,—lime water is among the liquors,—the B.P. definition of waters evidently being solutions of essential oils in water. Why is aq. pulegii omitted? It is wanted as much as some that are official. Standard forms are also wanted for aq. anisi and caryophylli.

When first made, many of these waters are harsh and musty, but by keeping they mellow down. What is the cause of this? Returning to what I noticed in aq. destillata, has there been any of that slow but surely oxidizing force of water at work on these aqueous solutions of oils? Alcohol has been shown by Warington to change in distilled water to acetic acid. And these essential oils, composed of alcohols and camphors, probably succumb to the same influences. At the bottom of such waters as aq. pimentæ and aq. cinnamomi resinous matter has often been noticed. But what is resin? The term is as correct chemically as copperas for ferri sulph.; it is only a generic name for a series of acids probably oxidized from oils. This goes a long way to show that essential oils are changed as well as alcohol. By which of the compounds in the oils is the resin yielded—the alcohol, the camphor, or both? But resinification or change commencing, what is to hinder the new product modifying or etherifying the remainder? Such action would, in the case of a water, be slow and small in quantity, but such a rearrangement of matter would remarkably alter some of the characteristics of the oil and water. In the laboratory it may be difficult to acidify some of these oils, but to acidify quickly and completely is one thing, to acidify or modify small quantities in the presence and by the aid of powerful agents constantly at work is another; some action, we know, takes place which mellows the waters as they are kept after distillation. So much for what is in solution. These waters should always have a superstratum of oil (except, of course, pimento and cinnamon) floating on them, as Haselden suggested; adding also that such oil is as good as the original oil. So it is, but I have sometimes noticed an oleographic difference. After long contact with water the oil drop does not give so good a "roll," and the figure is slightly altered and slower in its formation. Between the oil and the water there is always a muddy layer. A great deal of this is *débris*, or matter floated over by the steam, as well as the results of changes in the water. On examining these formations microscopically, I have sometimes noticed small crystalline forms, which, when carefully separated, easily melt, and give an odour resembling the essential oil used. These crystals, as in cinnamon, pimento, caryoph., and menth. pip., have been nearly colourless, few in number, only seen with high powers and possessed of polarizing properties. Are these the hydrates of a portion of oil similar to turpine hydrate? and if so, may not a hydration of the oil, especially of that dissolved, materially assist in maturing these waters? These are subjects opening a wide field of research from what appears a very simple subject.

Lastly, the modes of preparing medicinal waters require attention; the only authorized plan in B. P. is distillation (except in the instance of camphor). The first conclusion one draws from these notes is, that spirituous essences are objectionable; they make clear waters, but the result of oxidizing alcohol is acetic acid. This was found to be the fact by Warington in 1845, and every observer since has confirmed the fact. In rejecting the Dublin form for waters, the compilers of the Pharmacopœia were wise and justified by these facts. Oils have been rubbed down with magnesia and chalk; these, too, are objectionable, as soaps are formed as pointed out by Brady and Attfield; the water also acquires an unpleasant odour. Silex, according to the old London Pharmacopœia, and kaolin, or fine clay, as suggested by others, have been used for dividing the oil with variable results.

I find that if a small tube, containing an essential oil, is placed in water in a position opposite to the specific gravity of the oil, and the ends of the tube are closed with membrane, vegetable parchment, etc., exosmosis of the oil commences, and in twenty-four or forty-eight hours the water is saturated, and may be drawn off and replaced by a fresh portion. I do not propose this as a plan in opposition to distillation, it is too long in operation perhaps, but as a convenient way of making those waters only wanted occasionally, and which are frequently made by rubbing down the oil with some other substance.

RESEARCHES ON THE ELECTROLYSIS OF CERTAIN ORGANIC ALKALIES.*

BY M. EDME BURGOIN,

Pharmacien en Chef de l'Hôpital des Enfants-Malades.

Up to the present time but few experiments have been made to determine the action of the electric current upon the alkaloids, and such as have been undertaken have had in view, mainly, the demonstration that these bodies do not owe their birth to the influence of the mineral alkalies employed in their preparation, but pre-exist in the vegetable sources. From the facts observed by Lassaigne and Feneuille in their experiments with delphinine, and the researches of Pelletier and Couerbe upon picrotoxine, the following conclusion has been drawn, namely, that when a salt of an organic alkali is subjected to the influence of the electric current, the acid appears at the positive and the base at the negative pole.

Having continued these imperfect studies, I have recognized that, in addition to the facts noted, there

* This is the article by M. Bourgoin, referred to by the President of the Pharmaceutical Conference in his Introductory Address at Liverpool. The translation is taken from the Chicago *Pharmacist*, and is by the editor of that journal.

always occur secondary reactions, which have heretofore escaped the notice of experimenters.

Note first the action of the current upon the neutral sulphate of ammonia, thus:—

$$SO_3NH_4O = \underbrace{(SO_3 + O)}_{\text{Positive Pole.}} + \underbrace{(NH_4)}_{\text{Negative Pole.}}$$

Then at the positive pole, $(SO_3 + O) + 3HO = SO_3 3HO + O$,* at the negative, $NH_4 = NH_3 + H$.

Bearing this in mind, observe the results of my experiments upon the organic alkalies.

I.—ELECTROLYSIS OF ATROPINE.

Neutral sulphate of atropine. The reaction is very rapid at first, but gradually abates. The negative electrode recovers the pure atropine in very fine crystals,—in fact, the crystals when washed, and dissolved in boiling water, yield a solution which will not give a trace of precipitate when treated with chloride of barium.

At first pure oxygen only is disengaged at the positive pole, but carbonic acid and carbonic oxide soon appear, and at the same time the fluid in the corresponding compartment acquires a distinct yellow colour.

An analysis of the gas after twelve hours gave these results:—

Volume of gas	257	$C_2O_4 = 11$
After the action of KHO_2	246	
„ „ „ the pyrogallate..	14	$O_2 = 232$
„ „ „ „ acid chloride..	1·8	$C_2O_2 = 12·2$

Which gives the composition of the gas:—

Carbonic acid	4·28
Carbonic oxide	4·75
Oxygen	90·66
Nitrogen	0·31†

Secondly.—Acid sulphate of atropine. The decomposition is effected with great energy, and the positive solution acquires at once a fine yellow colour. From the start a mixture of oxygen, carbonic acid, and carbonic oxide is evolved. The experiment being arrested when the crystals of atropine commenced forming upon the negative electrode, the composition of the gas from the positive pole was found to be as follows:—

	After 24 hours.	After 48 hours.
C_2O_4	8·3	7·9
O_2	87·9	88·6
C_2O_2	3·8	8·9
N	——	0·4

At the close of the electrolysis, the positive solution had acquired a magnificent yellow colour, whilst the negative compartment was still colourless. But observe another result, still more remarkable and well worth attention. The positive compartment during the entire series of experiments had the characteristic odour of the essential oil of almonds; on the other hand, the negative liquid, after treatment with caustic potassa, gave abundant white fumes upon the approach of a stick impregnated with hydrochloric acid, showing the presence of ammoniacal compounds, the nature of which remain to be determined by thorough study.

These results are not without interest. They determine, substantially, what I have already announced in another paper, that the secondary phenomena at the positive pole arise from a combustion provoked by the oxygen; and, further, that at the other extremity the current has a single fundamental action—it decomposes a salt, an acid, into two parts, one basic, hydrogen or metal, which goes to the negative pole, while the remaining elements are set at liberty at the positive pole. All the other phenomena are but accessories, and can only be regarded as resulting from the oxidation of organic substances.

But to return to atropine. It is known from the studies of Pfeiffer, Kraut and Ludwig, that atropine, when treated with sulphuric acid and bichromate of potassa, yields benzoic acid. It may be anticipated that this acid, or possibly the essential oil of almonds, may eventually become a source for the derivation of atropine.

II.—ELECTROLYSIS OF BRUCINE.

Neutral sulphate of brucine. The electrolysis of this salt is easily accomplished; after a few moments a beautiful red halo appears around the inferior extremity of the positive electrode. This halo increases little by little until it pervades the compartment, the contents of which eventually become blood-red. It will be observed that this coloration is precisely the same as results from the application of nitric acid to the alkaloid.

There is no gaseous disengagement at the positive pole; it follows that all of the oxygen which is liberated is absorbed, serving to oxidize the brucine, and this is a demonstration that the red coloration is not due to the formation of any nitrogenous compound, but results from direct oxidation.

Secondly.—Acid sulphate of brucine. As soon as the current is established the positive solution acquires a fine red colour; this effect is instantaneous, and this experiment may be useful as a beautiful lecture illustration.

The oxidation is very energetic, and the gas from the first contains carbonic acid.

	First gas.	After 4 hours.	After 24 hrs.
Carbonic acid	4·9	10·6	4·4
Carbonic oxide	6·6	10·9	5·8
Oxygen	87·7	77·9	89·1
Nitrogen	0·8	0·6	0·7

Within twenty-four hours the red coloration gives place to a fine yellow colour, and small crystals commence to appear in the still acid negative compartment. By the fourth day the solution is about exhausted, and the yield of carbonic acid and carbonic oxide is very small. The crystals deposited are hard and granular; after being washed and dissolved in boiling water, their solution is acid to test paper, and gives a precipitate with chloride of barium, showing that acid sulphate of brucine contaminates the crystals. When treated with nitric acid the blood-red colour appears.

III.—ELECTROLYSIS OF STRYCHNINE.

First.—Acid sulphate of strychnine. The saline solution is a poor conductor of the current, so that the decomposition is but slowly effected. Oxygen is disengaged on one side, and hydrogen on the other, and the negative electrode recovers the strychnine in confused crystalline masses.

The positive solution assumes towards the close of the experiments a light yellow colour, indicating oxidation, an oxidation, however, which occurs within circumscribed limits, and does not seem able to take

* See the compilation, 'New Electrolytic Researches,' 1868.

† The nitrogen contained in the gas, and which appears in all of the succeeding analyses, is due to the presence of a small quantity of air which it is almost impossible to guard against.

place until the solution has become acid at the positive pole.

Second.—Neutral sulphate of strychnine. The solution of the sulphate, slightly acidulated, is soon filled with a magnificent needle-form crystallization. From the commencement the gas disengaged at the positive electrode contains carbonic acid and carbonic oxide.

	First Gas.	After 36 hours.
C_2O_4	1·3	1·4
C_2O_2	3·5	2·7
O_2	94·3	95·2
N	0·9	0·7

Upon continuing the experiment a fine yellow coloration manifests itself in the positive compartment, and, what is remarkable, the crystals disappear in the negative solution, the liquid becoming limpid, and remaining so during the continuance of the electrolysis.

When a very acid solution of the sulphate of strychnine is operated upon, the positive solution acquires immediately a yellow colour. The oxidation is very energetic, as may be seen by the following analysis:—

C_2O_4	6·4
C_2O_2	6·4
O_2	87·2

IV.—ELECTROLYSIS OF CODEINE.

First.—Neutral sulphate of codeine. While the escape of gas at the negative pole is quite rapid, it is almost nothing in the other compartment; the contents of the latter acquire a yellow coloration, passing afterwards to an orange-yellow. At the same time crystals of codeine are deposited upon the negative electrode.

Second.—Acid sulphate of codeine. The action is very energetic, the positive solution assuming a magnificent yellow colour, which changes rapidly to an orange-yellow, these phenomena being precisely those observed when the alkaloid is touched with nitric acid. The first bubbles of gas contain carbonic acid and carbonic oxide.

Analysis of Gas after 24 hours.

Volume of the gas	241	$C_2O_4 = 14·5$
After the action of potassa	226·5	
„ „ the pyrogallate	18	$O_2 = 208·5$
„ „ acid chloride	1·5	$C_2O_2 = 16·5$.

From which is deduced:—

C_2O_4	6·0
C_2O_2	6·7
O_2	86·5
N	0·8

V.—ELECTROLYSIS OF QUININE.

The electrolytic experiments which I have made upon the sulphate of quinine, furnished results analogous to the foregoing. It is notable, however, that a neutral solution of the sulphate of quinine is such a poor conductor of the current that decomposition takes place only with the greatest difficulty. From this observation I was led to believe, in the commencement of these researches, that the neutral salts of the alkaloids were not susceptible of electrolytic decomposition. On the contrary, the electrolysis of the acid sulphate is easily accomplished, the positive solution acquires a red tint, which subsequently becomes a deep red, and the gas evolved contains carbonic acid and carbonic oxide.

CONCLUSIONS.

The conclusions drawn from the foregoing experiments may be briefly stated as follows:—

First.—The electric current decomposes the salts of the alkaloids in the same manner that it does the neutral sulphate of ammonia; that is to say, the basic element goes to reconstitute the alkali at the negative pole, whilst the remaining elements are liberated at the positive pole.

Second.—In an acid solution, and in a neutral one with more difficulty, the positive liquid takes a coloration which is identical with that obtained by the direct application of nitric acid to the alkaloid, and this is independent of the formation of nitrogenous compounds.

Third.—The gas disengaged at the positive pole contains not only oxygen, but also carbonic acid and carbonic oxide, sometimes in equal volumes.

Fourth.—Besides these gases, there are formed various other products, principally ammoniacal compounds, resulting from the breaking up of the alkaloids under the influence of the oxygen, which produces the effects of a gradual combustion, and this is more energetic in proportion to the increased acidity of the solution.

The last fact is significant of the possibility of deriving the alkaloids from other than the natural sources, as remarked in connection with the electrolysis of atropine.

These experiments assume, therefore, considerable importance, since they may lead to the discovery of facts which some day may result in the synthetical production of the natural organic alkaloids.

Sulphate of Iron has been very successfully employed as a disinfectant of all discharges from the patients of the hospital, and it has been regularly put into the latrines, etc. This salt has the advantage of cheapness as well as most undoubted efficiency. It is extensively made in some parts of China by mixing together small coal and iron pyrites, covering over the mass very securely, and allowing decomposition to take place. After the violent chemical action has ceased the mass is broken up, dissolved in boiling water, and crystallized out in shallow vessels. It is used in various chemical processes, such as the making of the beautifully crystallized K'ing Fen, or calomel, produced by chemical manufacturers in Hankow, but ingeniously adulterated with selenite. Diluted iodine tincture and the ethereal preparation of iodidine have been found the best disinfectants and stimulants for unhealthy surfaces.—*Annual Report of the Hankow Medical Mission, by F. Porter Smith, M.B.*

Liquid Cement.—For cementing glass, crockery, wood, etc., the following compound is recommended:—Six parts of glue, in small pieces, are macerated for several hours in sixteen parts of water; one part of hydrochloric acid and one part and a half of sulphate of zinc are then added, and the mixture is exposed, for ten or twelve hours, to a temperature of 68° or 70° C.—*Pharm. Cent. Halle.*

Cure for Warts.—The best cautery for warts is said to be dichloracetic acid. It must be applied on the sharp point of a stopper made for the purpose, and great caution ought to be observed not to use too much of it, as it will eat a deep hole into the flesh. One application is frequently sufficient to drive away a wart.—*Scientific American.*

Condy's Patent Fluid.—In quoting the article under this title in last week's issue, the source from whence it was taken was omitted. It appeared first in the *Practitioner* for August.

THE BRITISH PHARMACEUTICAL CONFERENCE.

THE DINNER.

On Tuesday evening, after the first meeting of the Conference, the President and officers were entertained by the Local Committee at dinner, at the 'Adelphi Hotel.' The Executive Officers entertained were:—Mr. W. W. Stoddart, F.C.S., F.G.S., Bristol, the President. Mr. H. C. Baildon, Edinburgh; Mr. H. S. Evans, F.C.S., London; Mr. J. Ince, F.L.S., F.C.S., London, Vice-Presidents. Mr. H. B. Brady, F.L.S., F.C.S., Newcastle-on-Tyne, Treasurer. Professor Attfield, Ph.D., F.C.S., London; and Mr. R. Reynolds, F.C.S., Leeds, General Secretaries. Mr. E. Davies, F.C.S., Secretary for Liverpool. Mr. T. Dutton, Secretary for Birkenhead. Committee: Messrs. F. B. Benger, Manchester; S. C. Betty, London; M. Carteighe, F.C.S., London; T. B. Groves, F.C.S., Weymouth; W. Martindale, F.C.S., London; J. F. Robinson, Liverpool; and F. Sutton, F.C.S., Norwich. The Local Committee for Liverpool consists of Mr. J. Abraham, Chairman; Mr. R. Sumner, Vice-Chairman; Mr. J. Shaw, Treasurer; Messrs. H. S. Alpass; G. Barber; T. Britten, J. M. Buck; H. Coupland; F. D. Delf; T. Dod; E. Evans, sen.; W. J. Foulkes; A. T. Horton; W. Jarvis; S. Johnson; C. Jones; A. H. Mason; T. Martin; M. Murphy; J. Pendlebury; A. Redford; C. Sharp; J. Thompson; and J. Woodcock. Mr. J. Abraham occupied the chair, Mr. R. Sumner the vice-chair, and the party numbered upwards of one hundred.

The CHAIRMAN, after the loyal toasts had been honoured, referred to the American Pharmaceutical Association, now holding its nineteenth sitting in the city of Baltimore. It had been suggested to him that they should send a message of friendly greeting to their friends in the West, as under:—"From the President of the British Pharmaceutical Conference, at Liverpool, to the President of the American Pharmaceutical Association, at Baltimore. The most successful meeting ever held, sends hearty fraternal greeting." He then proposed the toast of the evening. That meeting was, he said, the seventh of the British Pharmaceutical Conference. It was an infant which had already, in seven years, grown up to be a giant; and it was so ably represented here that it needed no commendation from him. The very able address delivered that evening by the President, Mr. Stoddart, he was sure well deserved the warmest encomiums he could bestow upon it, and he only wished that any praise of his was better worth receiving. He was sure they would drink with the heartiest goodwill, "The success of the British Pharmaceutical Conference, and the health of Mr. Stoddart, its President."

Mr. STODDART, who was much cheered, said he returned his sincere thanks for the honour just done him in connecting his name with that of the Pharmaceutical Conference of Great Britain, and, as its President, an honour to which he had never thought to aspire. It was with the greatest affection and love that he had seen the Society grow as it had. What he had done for its progress had sprung from a liking for it. It was one of the most useful institutions; and it had done more good, both directly and indirectly, than any ever established for the furtherance of their interest for many a long year. He did not expect to see, in his time, the total benefit capable of being derived from the institution; but he looked forward with much pleasure, prophetically speaking, to the incalculable benefits which the younger members of the Society would derive. The advice given by the older members was given with hearty good will, and for the welfare of the younger members. The time would come when they would be thankful for the days when the British Pharmaceutical Conference had sprung from the ideas of a few at Newcastle-upon-Tyne, followed as it had been by the meeting at Bath, and those which had annually succeeded it down to the Conference at Liverpool.

Mr. R. SUMNER proposed "Prosperity to the Pharmaceutical Society," and associated with the toast the name of Mr. Sandford, the President of the Society. This toast was very warmly received, and

Mr. SANDFORD, in response, said the business of the Conference should be pharmacy, pure and proper. The Society had other business in which that Conference could help it. It had the duty of advancing pharmaceutical education, and he hoped it had not neglected that duty, and that the time might come when it might do it more extensively than it had done hitherto—when it might support pharmaceutical schools, not only in London but in the country. It would be the endeavour of the Society to carry out faithfully the duties put upon it by the Government. The members had the matter in their own hands, and so long as they used their powers properly they would have the support of the Government. The Conference had it in its power to promote that very much. To the Conference a great deal might be due for the passing of the Pharmacy Act. It was, therefore, with great pleasure that he had heard the chairman speak so highly of the Pharmaceutical Society. As for himself, he returned thanks for personal kindness to him, and he hoped the Conference would long continue to be the prosperous body it now seemed to be.

Professor ATTFIELD proposed "Success to the Liverpool Chemists' Association," the most important Association of the kind throughout the country. In 1849 Jacob Bell came to Liverpool to urge the claims of the Pharmaceutical Society, and one of the results of his visit was the formation of the Liverpool Chemists' Association. Jacob Bell characterized Liverpool as "a collection of men than whom there is not a man in the country having a greater amount of public spirit and energy." The same public spirit had characterized the chemists and druggists of Liverpool from that time to the present. In the index to the 'PHARMACEUTICAL JOURNAL' would be seen a very large number of titles of lectures and papers contributed from Liverpool, and the character of the papers was unequalled by any given to the parent society in London. The present Conference exhibited the same characteristic spirit and energy.

Mr. J. F. ROBINSON and Mr. J. SHAW responded.

Mr. A. REDFORD proposed "The Officers of the Conference," coupled with the names of Mr. Brady, Mr. Reynolds, and Professor Attfield.

Mr. BRADY expressed his regret that after seven years' duty he felt compelled to resign the office of treasurer, but he hoped that the Conference would not suffer, and that there would be no difficulty in finding a successor.

Mr. REYNOLDS and Professor ATTFIELD also replied.

Mr. STODDART acknowledged "the glorious reception" which the Conference had met with at the hands of the people of Liverpool, and proposed "The Local Committee," coupled with the names of Mr. E. Davies and Mr. Mason.

Mr. E. DAVIES and Mr. A. H. MASON responded, and expressed their gratification that their efforts in connection with the exhibition had met with such approval.

The CHAIRMAN announced that, although he was surrounded by the most brilliant array of pharmaceutical talent ever assembled in the provinces, he had received letters of apology from Mr. Henry Deane, Mr. Daniel Hanbury, Professor Bentley, Mr. Hill, Mr. Schacht, Mr. Cooper (of Exeter), and other prominent members of the Conference. He proposed "The Visitors."

Mr. GROVES, of Weymouth, and Mr. MACKAY, of Edinburgh, responded.

Mr. R. SUMNER proposed "Professor Archer, of Edinburgh," whose health was received with much applause.

The toast of "The Pharmaceutical Press," coupled with the names of Mr. Paul, editor of the *Pharmaceutical Journal*, Mr. Brough, editor of the *Pharmaceutical Year-Book*, and Mr. Wootton, editor of the *Chemist and Druggist*, together with other toasts, followed before the party separated.

The Pharmaceutical Journal.

SATURDAY, SEPTEMBER 24, 1870.

THE BRITISH ASSOCIATION.

The Parliament of Science that has been holding its annual session at Liverpool during the last week will by this time have been prorogued, and the opportunity it affords for communicating an impulse to scientific research, or for giving a scientific direction to various practical affairs, will have passed by for the present. There has been no lack of interesting topics for discussion in the several sections, while the addresses have been perhaps more than usually attractive, both as regards their subject-matter, and by reason of their authorship. Professor Huxley's historical review of the ideas connected with the doctrines of spontaneous generation could scarcely have been so successful in other hands than his; and the task of treating upon the imagination as an instrument of scientific research, could scarcely have been entrusted to any one more fitted to do justice to this theme than Professor Tyndall. The elucidation of scientific principles connected with ship-building, and the discussion of savage conditions of our ancestry, could not have been dealt with more appropriately than at the hands of Rankine and Lubbock.

The proximity of Liverpool to the smoky districts of St. Helen's and Widnes, the chief seats of the Lancashire chemical trade, was a sufficient reason for the presence of a large number of chemists at this meeting, and for the preponderance of papers relating to chemical manufactures. These papers have in several instances given rise to valuable discussions, besides being in themselves of great interest.

But that feature of the Association meeting which is probably at once the most beneficial and pleasant, viz. the excursions, has this year been especially developed in the chemical section of the Association and the Conference meeting. Last week the members of the Pharmaceutical Conference paid a visit to the Chemical Works at Widnes and Runcorn, where they inspected several new methods, and were afterwards very hospitably entertained by the Liverpool Chemists at Halton Castle. Two days after, the chemical section of the British Association made an excursion to St. Helen's, and, on Thursday, there was another excursion to Widnes. There were, on these occasions, so many interesting operations to be seen, that we are compelled to defer attempting any description of them for the present. But at the same time we cannot omit calling attention to the advantages resulting from these excursions. Apart from the mere instruction they afford, there is no phase of the proceedings of the Association or the Conference which is more calculated to promote good feeling amongst pharmaceutists throughout the country, by rubbing down individual asperities that have often no other ground for existence than what Professor Tyndall would call an unscientific use of the imagination. They also afford a stimulus to thought and an incentive to exertion, which probably could not be obtained in any other way so effectually or so agreeably. We have here spoken of the Conference together with the British Association, for the two are intimately related; and the founders as well as the supporters of the Association, should regard with pride and satisfaction such a realization of their objects as is presented by the British Pharmaceutical Conference.

THE SCHOOL OF PHARMACY.

Now that the scientific meetings in the provinces are nearly over, attention will naturally be directed to the addresses to students at the opening of the various schools in London. To pharmacists the most interesting of these will doubtless be that to be delivered at the commencement of the session in Bloomsbury Square. Mr. Schacht has been chosen by the Council this year to deliver the inaugural address on the occasion of the opening of the session, when the prizes and certificates awarded to the successful students of the past session will be distributed. He is well known for his efforts in favour of improved pharmaceutical education, and as one of those who were first to avail themselves of the educational advantages provided by the Society some twenty-five years ago, his words of advice will have great weight. The Council, in inviting the attendance of gentlemen connected with the Society, has been pleased to extend the invitation to ladies. We hope that a hearty response will be made, and that a very successful meeting will be the result.

A letter was read before the Chemical section of the British Association, which had been addressed to it on behalf of the Council of the German Chemical Society of Berlin by Professors C. A. Martius and A. W. Hofmann. The letter pointed out the great urgency for promptly doing something to counteract the effects of the overcrowding of the sick and wounded in the hospitals, and asked the co-operation of the section in obtaining from chemical manufacturers donations of the following disinfectants:—liquid residues of the manufacture of chlorine, chloride of lime, green vitriol, permanganate of potash, and carbolic acid (crude and purified).

Communications on the subject are to be addressed to Professor Hofmann, care of Dr. Wichelhaus, 33, Georgens Strasse, Berlin.

We think it right, in connection with this subject, to refer to the paper we extracted last week from our contemporary the *Practitioner*, showing the relative chemical value of the various materials which owe their disinfecting qualities to permanganic acid. From the results there stated, it will be evident that for transport great advantages are offered by the solid permanganates over solutions, containing in some instances only very small amounts of the active disinfecting material. To chemists this fact would of course be obvious, but we think it worth while to mention the matter here for general information, more especially since permanganates are now manufactured in quantity and at prices which would have been regarded as fabulously low some few years ago.

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

1 oz. quinine.
4 ,, Calvert's best carbolic acid.

George Baxter, Chester.
2 gross 1 gr. opium pills.
2 ,, ¼ gr. morphia pills.
2 ,, 2 gr. quinine pills.
2 oz. hydrate of chloral.
4 ,, chloroform.
8 ,, sal volatile.
½ doz. Condy's fluid.
½ ,, 2 oz. bottles laudanum.

William Lewin, Plymouth.
1 lb. pure chloroform.
1 ,, methylated chloroform.
1 lb. liq. ammon. in 8 bottles.
8 oz. chlorodyne.
1 gross 2 gr. quinine pills.
1 ,, ¼ gr. muriate of morphia pills.
1 ,, 1 gr. opium pills.
6 lbs. lint.

Septimus Roe, Salisbury.
1 doz. ½ pint bottles Condy's Fluid (Crimson).
1 pint bottle ,, ,, ,,
5 pint bottles ,, ,, (Green).
7 bandages, 2 yards in each.
Surgeons' tow.

The following have been received by the Edinburgh Auxiliary to the National Society from Messrs. Duncan, Flockhart and Co., Robertson and Co., Mr. R. S. Brown, Mr. W. R. Niven, of Edinburgh:—

Valuable donations of chloroform, laudanum, opium, quinine and morphia pills, sal volatile, citrate of magnesia, lint, adhesive plaster, oil-silk, prepared cotton, bandages, etc.

Extract of Calabar Bean.—J. B. Enz recommends the following process for preparing this extract: reduce the bean to a moderately fine powder, and macerate in alcohol, sp. gr. ·830, for ten days; then transfer the powder to a percolator and pass through alcohol until the percolate becomes colourless. Mix the tincture obtained by maceration with the percolate, distil off the alcohol, and evaporate the residue, over a water bath, to the proper consistence. The yield of extract is about 2 per cent.—*Pharm. Cent. Halle.*

Proceedings of Scientific Societies.

BRITISH PHARMACEUTICAL CONFERENCE.

Tuesday, September 13th.

Examined and found correct,
JOHN SHAW.
JOSEPH F. ROBINSON.

Liverpool, September 5th, 1870.

The TREASURER explained that he was reluctantly compelled to look to the resignation of his office, especially since the large accession to the numbers of the Conference would add very materially to the duties which he felt he had not the time to perform. He would be glad to retire to the ranks of the Conference, and continue in that position to do his best to serve its interests.

Mr. EKIN (Bath) much regretted to hear this announcement from their friend Mr. Brady, and thought that it suggested they ought to elect a paid officer to assist both the Treasurer and the General Secretary.

The PRESIDENT said that Mr. Ekin's suggestion should be considered at a later stage of the proceedings.

Mr. DYMOND moved that the following members form a committee to report on the exhibition of objects relating to pharmacy:—Messrs. Carteighe, Davies, Ekin, Ince, Paul, Sutton.

This resolution was seconded by Mr. GREENISH, and carried unanimously.

The following papers were then read:—

THE PURITY OF THE YELLOW BEESWAX OF PHARMACY.

BY EDWARD DAVIES, F.C.S.

In this paper I am only able to give the result of the examination of some samples of wax purchased in Liverpool, five samples of crude wax obtained from a wholesale house, and four samples sent to me for analysis from a Liverpool firm, of the history of which I am ignorant.

I shall first give the methods employed, then a table of the results and conclude with a few remarks. The melting-point presents a little difficulty, and, after trying various methods, it was found better to take the solidifying-point. A test-tube containing about 100 grains of wax was immersed in hot water in a beaker until perfectly melted. A thermometer was inserted in the tube and the water allowed to cool gradually, the wax being constantly stirred until the bulb of the thermometer could not be seen when in the middle of the wax. The temperature then remains steady during the solidification for about two minutes, and there is no difficulty in getting the same result any number of times within half a degree.

The presence of paraffin is shown by the low melting-point, but no idea of its amount can be obtained from the degree shown, owing to the varying melting-points of different samples of paraffin. The only method of determining the amount of paraffin found at all practical, consists in destroying the wax with fuming sulphuric acid. 50 grains of the wax, with $1\frac{1}{2}$ oz. by measure of fuming sulphuric acid, are put into a small beaker holding about 5 oz., and gradually heated in a water-bath. Great care must be taken to stir it very slightly at first, especially if only a small quantity of paraffin is present, as the action is apt to become unmanageable. When the violence of the action is over, the heat is raised to 100° C. for about an hour and a half and the mixture occasionally stirred. It is then left to cool very slowly in the water-bath, and, when quite cold, the paraffin will be found forming a layer on the black semi-liquid mass. It is carefully removed, washed with water to remove as much of the adhering acid as possible, dried, and again heated for an hour in a smaller beaker with $\frac{1}{2}$ oz. of the acid. This gives the paraffin perfectly white, and it is then washed, dried, and weighed. There can be no doubt that there is some loss, as the common paraffin employed contains colouring matters destroyed by the acid; but I know of no other method at all useful, though I have carefully tried some which have been proposed.

For the estimation of rosin, the action of cold alcohol seems sufficient. To 90 grains of pure wax, 10 grains of rosin were added, by melting them together and thoroughly incorporating. On exhausting with cold alcohol, by rubbing the wax in a mortar with successive small portions of alcohol, filtering, and evaporating on a water-bath, a residue was obtained weighing 10·54 grains. It was brittle and, when heated, gave an unmistakable smell of rosin. Pure wax yields 2·4 per cent. to cold alcohol, and rosin is not entirely soluble, but one of these about balances the other.

No starch was found in any of the samples, and they were all perfectly soluble in turpentine.

Specimens.	Solidifying Point.	Soluble in Alcohol.	Paraffin.
Pure Scotch wax..........	151·5	2·4 p.c.	none
Crude wax, Gambia	152·5	3·10	not tested
" " No. 1....	154·0	2·40	"
" " No. 2....	153·0	3·60	"
" " No. 3....	147·5	......	"
" " No. 4....	147·0	......	"
" " No. 5....	146·0	......	none
Purchased samples, No. 1 ..	153·5	1·8 p.c.	not tested
" " No. 2 ..	153·0	2·28	"
" " No. 3 ..	152·0	3·18	"
" " No. 4 ..	152·0	2·34	"
" " No. 5 ..	150·5	5·20	"
" " No. 6 ..	147·0	......	"
" " No. 7 ..	145·0	......	none
" " No. 8 ..	139·0	......	13·30
" " No. 9 ..	137·5	......	36·60
Samples sent for analysis, No. 1	142·0	......	42·60
" " No. 2..	140·0	......	43·36
" " No. 3..	135·0	......	56·50
" " No. 4..	134·0	......	56·00

These results show that the degree given in the P. B. of 140° F. is too low; pure yellow wax melts at 151·5° F., and no sample, not containing paraffin, has a melting-point below 145°. I think that 150° should be the standard, for samples containing more than 40 per cent. of paraffine may be made to agree with the Pharmacopœia standard, if a paraffin with a sufficiently high fusing-point be selected. The question may seem an unimportant one, but a difference of 16° in the fusing-point of two samples of wax must considerably affect the quality of ointment made from them, especially in hot weather.

The effect of the application of paraffin to the skin, though probably not injurious, is not sufficiently known to render its presence a matter of indifference. Most of the samples were bought in the lower parts of the town, and the results show that in Liverpool there is not much cause to complain. I have to thank Mr. Thomas Williams for valuable assistance in working out the above results.

The Chairman said that the fatty material referred to by Mr. Davies might probably be stearin, which was used in the neighbourhood of Bristol for adulterating wax sometimes to the extent of fifteen or twenty per cent. He had found as the result of experience that if there was a crack about an inch from the upper edge of the cake, together with a greasy appearance, these characters indicated the presence of stearine.

Professor Attfield remarked that this was an interesting practical paper, and that the results were in favour of his suggestion that the melting-point assigned to beeswax in the Pharmacopœia should be raised ten degrees above the number now given. Some discussion took place as to the mode of determining the melting- or rather solidifying-point of wax and similar materials.

Mr. Groves (Weymouth) pointed out that a difference of ten degrees in the result of experiment might be due to the method adopted. He recommended dipping a thermometer bulb in the melted wax, and after the film of wax had solidified upon the bulb, suspending the thermometer in water, which was gradually heated until the film of wax became transparent and liquid; then reading off the temperature at which this took place as the melting-point.

It was also mentioned that the presence of Japan wax would render the melting-point of beeswax low, but no known means seemed to be available for detecting th's admixture, except the occurrence of that kind of bloom on the surface of the wax so adulterated, which is characteristic of Japan wax itself, as stated by Mr. Parkinson, Ph.D., Bradford.

Mr. Davies said that he had found that pure wax, when melting, passes suddenly from the opaque to the transparent condition, but that when paraffin was present the transition was gradual.

Mr. Brady (Newcastle) recommended that as this was a subject of much pharmaceutical interest, well-authenticated samples of wax should be sent to Mr. Davies for examination, and that he should be requested to continue his inquiries so as to report on the subject at a future meeting of the Conference.

Saccharo-Chirettine, a New Preparation of Chiretta.

BY MR. D. S. KEMP, BOMBAY.

The two official preparations of Chiretta, the *tincture* and the *infusion*, although efficient as containing the active matter of the drug, present inconveniences for habitual administration. The *tincture* becomes impaired in strength by keeping, and is partially incompatible with salts of iron and of the alkaloids; and the infusion, besides having the same incompatibilities, will not keep longer than a few hours.

The *Extract*, prepared in the usual way, is a still more unsatisfactory preparation, containing, as it does, a mere fractional part of the bitter originally in the dried plant. I have not seen an extract of chiretta prepared entirely *in vacuo;* probably such would be a valuable product, although still liable to deterioration. No preparation can, in my opinion, be good which undergoes evaporation by heat or exposure to the air, as I have always found that the bitter principle in such a process disappears, and is replaced by a tasteless brown resinous matter, separating from the aqueous solution. The following is the process by which I have succeeded in obtaining a trustworthy preparation of chiretta:—

An infusion of chiretta was made at 120°, and the colouring matter precipitated by an excess of solution of subacetate of lead; the product, after filtration, was a nearly colourless but very bitter liquid. The addition of a sufficiency of ammonio-acetate of lead (mixture of ammonia and solution of acetate of lead) then produced a white precipitate, consisting of the whole of the chirettine in combination with lead. The precipitate being well washed, first with ammoniacal water, then with alcohol, was treated with a mixture of sulphuric acid and alcohol and filtered. The filtrate containing the chirettine was further treated with carbonate of lime to remove the excess of acid. The filtered liquid, which was of indescribable bitterness, I had no means of subjecting to more appropriate evaporation than spreading out on a clean glass plate; the result being a transparent extract, pale yellow in colour, dry at first, but in time becoming moist. This product I consider to be impure chirettine; and the same has always resulted when modifications of the above process were tried.

It is a neutral substance, quite soluble in water and alcohol. Its aqueous solution, when evaporated in the air, deposits a tasteless brown resin, into which the chirettine becomes entirely converted if the evaporation is continued to dryness. It is very difficult to preserve the pure solution at all from this change; if aqueous, it deposits the resin; if alcoholic, it darkens in colour. But the addition of glycerine will preserve either solutions apparently unchanged for many months. Dilute acids do not affect chirettine; but liquor potassæ hastens its conversion into resin.

I now prepare two pharmaceutical forms of chiretta founded on this process, one, saccharo-chirettine, a dry product; the other, liquor chirettine, a liquid.

Saccharo-chirettine.—To prepare this, I follow the process above described with an economical modification, namely, instead of drying the chirettine, I add to its pure solution a proportion of sugar (20 lb. for each 60 lb. of chiretta used), dry the whole by gentle evaporation, and powder it. The quantity of bitter principle present causes quite a minute increase in the weight of the product, which is, notwithstanding, so bitter that 1 grain is perceptible in a gallon of water.

When well prepared, in a dry atmosphere, saccharo-chirettine is nearly white. It forms a clean solution with water, and in portability and handiness for administration I submit that it is a most convenient pharmaceutic form of the drug it represents. The strength of saccharo-chirettine is as one to three of the herb; 10 grains being equal to 30 grains of chiretta, or about 2½ fluid ounces of infusion. It is given as an antiperiodic in doses of 10 to 15 grains, three times daily, and here, in Bombay, considered equal to 3 to 5 grains of quinine.

A decided advantage that can be given it over chiretta is that some uniformity of strength can be guaranteed by regulating the quantity of sugar used according to the proportion of ammonio-acetate of lead required to precipitate the chirettine.

That chiretta varies considerably in strength I have found by experience.

The Chairman stated that he had not found the tincture of chiretta give any deposit on keeping in this country. Probably the difference in this respect might be due to climate.

Professor Attfield remarked on the peculiarity of the active principle of chiretta in undergoing decomposition when its solution was evaporated, as being a character worth examination from a chemical point of view, as well as in its bearing on the making of pharmaceutical preparations of chiretta.

Mr. Groves approved highly of the principle on which the manufacture of saccharo-chirettine was based. He also thought that the satisfactory results obtained by the author in this instance seemed to show the wisdom of using sugar in certain pharmaceutical preparations as a preservative, and he referred to the old practice of preparing medicines in the form of troches, etc., as one probably useful on that account, which might with benefit be reverted to in our day, especially in the case of medicines destined for export to foreign countries.

The Strength of Twenty-four Specimens of Saccharated Carbonate of Iron.

BY J. J. NICHOLSON, SUNDERLAND.

I have recently had occasion to examine several samples of saccharated carbonate of iron, and have been struck with the great difference in their composition. It is surprising that so great a diversity should exist, for the process of manufacture is exceedingly simple, although a certain amount of care is necessary to secure a good and permanent preparation.

However, the result of my examination shows a discrepancy which, were the article of a more active nature, would be rather alarming; even as it is, we know what importance is attached to the action of this preparation in many serious cases, and to say the least, it would be well if we could have an article of more uniform strength.

Each of the twenty-four samples I have examined was obtained either by myself or friends from pharmacists of position in their several towns, and nothing can show more plainly how little reliance is to be placed on the saccharated carbonate of iron as a medicine than a glance at the following table, where its strength may be seen to range from No. 1, which contains 41·9 per cent. of carbonate, to No. 24, which only contains 22·6 per cent. The principal cause of this difference, I believe, is to be found in the preparation, which requires care, rapidity, and attention, as when finished and properly dried, the change from keeping is so slow and gradual as to be scarcely worth taking into consideration; and among the samples here shown the oldest have not, by any means, turned out the worst; as, for instance, No. 10, which has been kept in paper for seven years, and yet comes up to the ordinary commercial standard of strength, which Professor Attfield gives in his 'Manual of Chemistry' as 37 per cent.

Table showing amount of real Carbonate of Iron in twenty-four specimens of Saccharated Carbonate of Iron.

	Iron.	Iron in the ferrous state.	Carbonate Iron.	
Ferri Carb. Sacch. ought to contain.	22·0	22·0	45·50

In No. 13, which was sent to me as a very old sample, only 5·4 per cent. of carbonate has become useless through oxidation. This is not at all above the average quantity lost in the preparation.

No. 24 is known by my informant to have stood thirteen years in a wide-mouthed bottle without a cork, and how many before that, he is not able to say, which probation may certainly be considered a fair trial of its permanence.

The relative age of different samples may be pretty nearly determined by their degree of solubility in dilute hydrochloric acid; those I know to be old have always required a considerable amount of heat for their solution, while a recently prepared specimen will dissolve in acid of the same strength at ordinary temperatures. I think it is shown by these examples that the sugar is a very efficient preservative when the preparation is finished, but during the process there is scarcely a sample that escapes oxidation. Some makers appear to have tried to get over the difficulty by largely increasing the quantity of iron, so as to allow for the oxidation of a considerable portion, as instanced in Nos. 5, 8, 10, 17, where the iron is considerably in excess of the normal quantity, but in these cases the loss has been proportionately great, while in No. 21, where the proportion of iron is much smaller, it has been nearly all preserved in the active ferrous state, the quantity in the ferric form being much less than 1 per cent.

In No. 1 also, the whole, or nearly so, of the carbonate has been preserved, and I think this may be classed as a perfect specimen of *ferri carbonas saccharata*. In all these there are traces of the presence of sulphates, but in none have I found any appreciable quantity.

The PRESIDENT stated that according to his experience the crystallized sugar prepared by the centrifugal process by Messrs. Finzel of Bristol, yielded a better product than was the case when ordinary loaf sugar was used. He attributed this to this sugar retaining less atmospheric air.

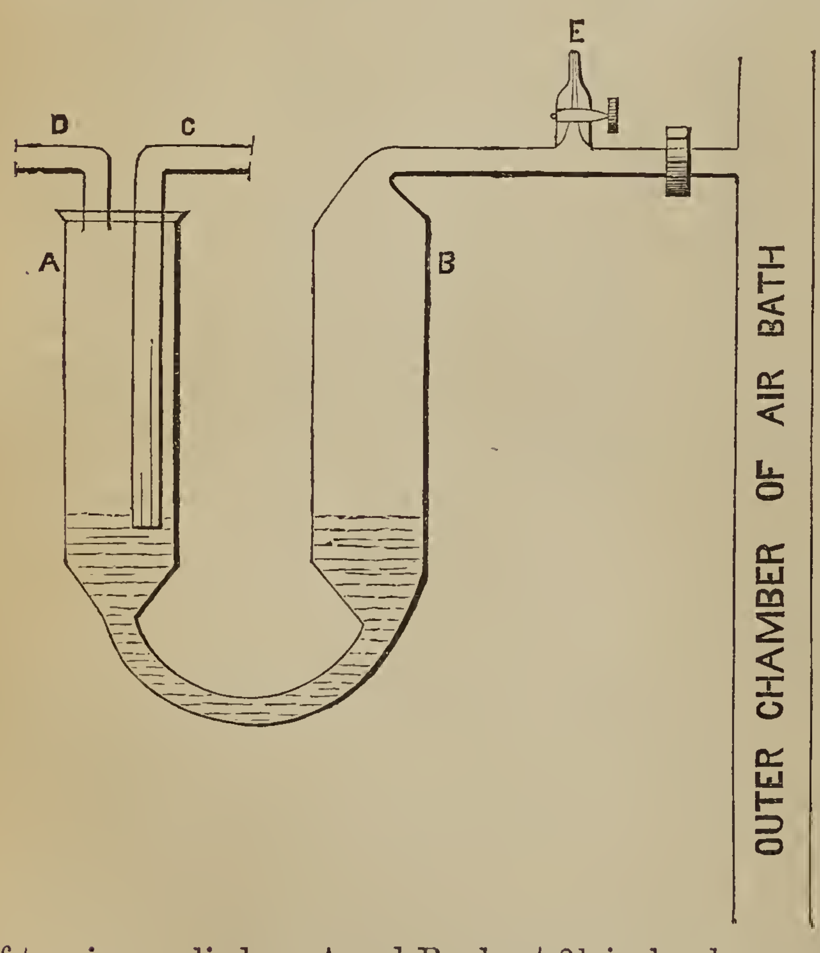
Mr. WILLIAMS said that in his experience he had found the oxidation of the iron-precipitate depended very much on its bulkiness and the amount of liquid mixed with it. He recommended that it should be made as dense and as free as possible from adherent moisture before mixing it with the sugar. For this purpose, the solutions used should be concentrated, the precipitation effected at the boiling-point, and, after washing the precipitated carbonate, it should be pressed to make it as dry as possible.

Dr. WATTS pointed out the method of the French Codex, in which all the operations involved in the preparation of the carbonate were performed in the presence of sugar, with the object of preventing oxidation.

AN AUTOMATIC REGULATOR FOR MAINTAINING CONSTANT TEMPERATURES IN SOME CHEMICAL AND PHARMACEUTICAL OPERATIONS.

BY F. BADEN BENGER.

The advantages claimed for this arrangement are extreme sensitiveness, certainty of action and simplicity of construction; it is applicable to any operation in which gas is used as a source of heat, whenever it is desirable to maintain a constant temperature without continual watching, as in the air-bath or drying closet, fractional distillations, evaporations, etc. The regulator consists



of two iron cylinders, A and B, about 2½ inches long and ¾ inch diameter, communicating with each other at the bottom. Through the movable top of A is passed an iron pipe, C, reaching almost to the bottom, and another, D, going only just through the corner, B is connected by a union-joint with the outer chamber of the air-bath; sufficient mercury is placed in the cylinders to fill the tube connecting them, and to stand about ¼ of an inch above the bottom in each, the outer end of the tube D is now connected with the gas, and that of C with a Bunsen's or other burner placed beneath the air-bath; the air in the outer chamber becoming heated, expands, and pressing on the mercury in B, forces it towards A, where, by rising, it gradually closes the slits in the tube C, and diminishes the supply of gas at the burner; by opening the small tap E, the pressure is immediately removed and the gas again passes freely. When the desired temperature is attained in the drying-chamber, the tap E must be closed, after which the apparatus acts automatically, any slightly higher temperature produced by increased pressure of gas from the "main" or other cause instantly rectifying itself by diminishing the supply at C, whilst cooling by draughts, etc., is at once balanced by a greater flow.

Upon the table are specimens of a drying closet and an evaporating dish, constructed on this principle.*

THE APPRENTICESHIP AND EARLY TRAINING OF PHARMACISTS.

BY F. BADEN BENGER.

The education question being one of the foremost and most important of the day, I trust that a few observations on the early training of those connected with our own vocation may not prove uninteresting to the members of this Conference. It must be evident to all those who have thought seriously on the subject that our present system of apprenticeship is inadequate to the higher standard of scientific education required in our calling. It has answered its purpose in the past, but requires modification to adapt it to the new pharmaceutical era.

Apprenticeships are, for the most part, served in small businesses, where pharmacy proper is subservient, and necessarily so, to less dignified but more remunerative employments. The proprietors are but too glad to add to their scanty incomes the premium received with a pupil, and they maintain the advantage by getting as much as possible out of him in the way of useful service. The leisure of some and the ability of others is too limited to afford much personal instruction or direction in scientific matters to those they have undertaken to instruct in the art and mystery of pharmacy; at the end of his term the youth has, we will assume, gained much useful information connected with his business; has taught his fingers to fold a parcel neatly, and his eye to guess a pennyworth of hair-oil in a Worcester sauce bottle, but in how few cases has he any accurate systematic knowledge of even the elements of chemistry, botany, or materia medica! He then proceeds, at a very small salary, to one of those superior establishments where "neither apprentices nor arsenic are kept on the premises." At length it becomes necessary for him to pass an examination; his knowledge has increased, but it is a disorderly knowledge. If he has worked, he probably feels how much of his precious time he has wasted in working in wrong directions; he finds that, instead of getting, as he expected, more leisure for study as he grows older he gets less, and he sees no other course open to him but to cram under the direction of a professional crammer. A friend who has been prepared by Mr. So-and-so recommends that gentleman's services, and night after night he crams his memory with formulæ, decompositions, diagrams, antidotes, natural orders, and very unnatural methods of keeping certain names and facts within reach for, say, ten days. With these, if he can keep calm, and does not lose his presence of mind at critical moments, he probably gets through. But this large meal of many courses disagrees with a mind not accustomed to generous diet; assimilation does not follow; a reaction takes place, accompanied by a lasting distaste for similar mental food, and by the time the holiday which usually follows a pass is over he has become confused as to his facts, and foggy as to his formulæ, but he thanks his stars that the ordeal is over.

The outline I have given of the studies and opportu-

---

* The author claims originality only in what appears to him the main feature of the apparatus, viz. the regulator,—the air in the outer chamber of the bath acting by its expansion and contraction on an india-rubber diaphragm having been suggested as a means of regulating the gas by Mr. W. Dancer, of Cornbrook Chemical Works, and others; but the substitution of the mercurial regulator for the india-rubber valve removes all the difficulties met with in the practical application of the principle.

nities of the apprentices of the period, though happily contradicted by many bright examples, is, I believe, broadly true. Now this system, whilst it swells the ranks of pharmaceutical chemists, and adds to the funds of the Pharmaceutical Society, is not conducive to our real progress. We must remember that the knowledge which will be useful to a man is not that which he possesses on an examination day, but that which he retains afterwards. I think we may take it as a proven fact that very few apprentices do, or even can, qualify themselves during their term. The range of studies has become so wide that very much must be done either before or after, and the advantages of doing it first appear to me many and great. A boy who had received sound elementary instruction in chemistry, botany and materia medica before entering upon his apprenticeship would be to a great extent self-dependent; it would then be entirely his own fault if he did not find daily opportunities of applying and increasing his knowledge; work which would have been mere irksome drudgery to him would be interesting and instructive, because he would find in it the application of principles and laws with which he had previously become familiar.

The next question is, how is this knowledge to be given? I think by the establishment of special technical schools for boys intending to become pharmacists. Mr. Schacht has estimated the number of young men entering the business annually as 1693. Is it too much to expect that a sufficiently large proportion of these to support the experiment would be able and willing to do so? The laboratories at Bloomsbury Square are overflowing; there is no lack of students now ready to spend money for knowledge which they would have found doubly useful if obtained earlier. There is reason to believe that our body will be recruited from a wealthier class than hitherto. A considerable sum will, in most cases, have to be expended one way or another, earlier or later, on the scientific education of the chemist if he is to attain, or, at any rate, to maintain a position, and I think the earlier in his career some of it is invested the better. Moreover, I am disposed to believe that some such plan as I propose would be in the end cheaper as well as better. A pupil having spent twelve months in this technical school would be a much more useful, or at least less troublesome, appendage to most businesses than the apprentice of to-day. Possibly some of the leading firms might be willing to take him at a more moderate premium. At the end of a three years' indenture he should pass the Minor with honours, and would then be certainly able to command higher remuneration than most men who have been four years in the business can now do.

I do not propose any detailed scheme, but make this suggestion in the hope that some of you may be able and willing to help its elaboration. The course of instruction should be elementary, but *thoroughly sound*, the main object being to set up signposts, warranted, as Mr. Ince says, to point in the right direction. When the apprentice sets up his own, they too commonly direct him by supposed short cuts, which lead him into all sorts of tangled difficulties. The teachers in the various departments should be men of real ability and experience. I have not much faith in the educating power of the "certificated science teacher," who is now ubiquitous. Much as we may respect a young man who, in addition to the practice of some honest handicraft, such as shoemaking, lectures on chemistry, botany, and one or two other branches of natural science, to the mechanics and artisans of his neighbourhood, we may doubt if he is the most suitable person to influence boys better educated in ordinary subjects than himself. It is generally admitted that a thorough master of a science is required to impart quickly and accurately the rudiments of his subject, and these are what we want.

The establishment should possess a good museum of drugs and a garden of medicinal plants, and should be under the direction of a thoroughly practical pharmacist. How much might be learned by a boy in such a school in, say, twelve months! It should give him such an impetus as would last whilst he lived. How interesting to him would be the occasional half-hour's stroll in the country, for he should know much of physiological and something of systematic botany by that time! He would pursue his studies with the signposts full in view; and would he make a less successful business man for the scientific bias he had received? I think not. The acquirement of business tact would be just as necessary, but none the more difficult. Amongst the minor advantages to be derived from this proposed year's training may be mentioned the bond of fellowship which would be formed between kindred spirits, and which, thus early established, would greatly tend to the diffusion of pharmaceutical knowledge and the furtherance of the objects aimed at by our own Conference.

If the introduction of this subject brings about a discussion from which any more practical conclusions shall be derived, I have not wasted your time this morning.

The discussion on this paper was postponed until the next day, when the subject of Pharmaceutical Education in the Provinces was to be brought before the Conference at the suggestion of the Council of the Pharmaceutical Society.

The meeting then adjourned at 12.30.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Meeting at Liverpool.

Professor Huxley's inauguration of this scientific parliament has gone off with considerable *éclat* and with general satisfaction. Abstaining from that general retrospective representation of achieved scientific progress, which is so attractive to a man of comprehensive attainments and acute perception, the President has this year confined his address to one special subject. In doing so he has probably been influenced by the fact that the subject chosen is one possessing such stupendous interest as to command attention in any case, while it was certain to do so when treated of by Professor Huxley. The scientific problem of the origin of life has always attracted the consideration of a certain class of philosophic inquirers, and at intervals it has given rise to the enunciation of doctrines that excited violent controversy.

Quite recently, experiments conducted by Dr. Bastian have again brought this subject to the front, and those who are familiar with Professor Huxley's general views or scientific labours will not wonder that he should have selected the germ theory and the correlative question of spontaneous generation as the theme for his inaugural address. Starting with the statement that as a matter of every-day experience it is difficult to prevent articles of food and similar materials from becoming mouldy; that fruit, apparently sound, often contains grubs at the core; that meat, left to itself, is apt to putrefy and swarm with maggots,—Professor Huxley reminded his audience that from the ancients down to the seventeenth century, there was a belief in the proposition that life may and does originate in that which has no life.

But this was merely a belief; it did not rest on any scientific foundation, and Francesco Redi was the first to subject the observations of ordinary experience to scientific criticism. He pointed out that though maggots make their appearance in flesh and similar materials exposed to the air, that was not the case if the flesh was put into a jar covered over with fine gauze, while putrefaction took place just the same. He inferred hence that maggots were not generated by the act of putrefaction, and that the cause of their formation was something which was kept away by the gauze. He showed, moreover, that something to be the eggs deposited by blow-flies. Redi's experiments were extended to many other things besides flesh, always with similar results, and generalizing on them he arrived at the presumption that in all cases of the appearance of life in previously dead material the real explanation of the fact was the introduction of living germs or eggs from without into that dead material. Hence originated the hypothesis of Biogenesis, or what is now termed the germ theory, which may be stated in the aphorism "omne vivum ex vivo." But even in Redi's time there were difficulties in the way of reconciling known facts with that hypothesis, and he candidly admitted them. However, the subsequent progress of microscopic research revealed such a prodigality of provision for multiplication in the lowest and minutest forms of life by germs of some kind that the old belief in spontaneous generation began to appear not only untrue but absurd, and at the middle of last century it was almost universally discredited.

But the aid afforded by the microscope soon reached a limit, and, in some cases where development of life took place, the existence of extremely minute germs had to be assumed in order to make observation accord with the hypothesis of biogenesis. Thus, for instance, an infusion of hay, left for some days, will swarm with living things, among which any one reaching the diameter of $\frac{1}{3200}$th of an inch is a giant. In such cases the microscope was no longer competent to reveal the existence of germs. At that stage Buffon and Needham took up the question whether the development of infusorial animalcules was due to germs or not, and they endeavoured to submit this to a crucial test. Assuming that the vitality of all germs is destroyed by heat, Needham boiled the infusion of hay, corked it up and excluded air; but nevertheless animalcules were developed. Hence he inferred that living germs were not essential for the development of infusoria; still he did not altogether adopt the alternative hypothesis of spontaneous generation, but took refuge in a kind of compromise. Spallanzani followed, by showing that if air was absolutely excluded in Needham's experiment no infusoria were developed. Schulze and Schwann's experiments with air that had been heated to redness gave the same results, but all they proved was that this treatment of air destroyed something essential for the development of life. That something might be gaseous, liquid or solid; but it still remained only an hypothesis that it consisted of germs.

Pasteur was the first to show that by straining air through cotton-wool clearly recognizable germs were retained, that these germs were competent to give rise to living forms in a solution fit for their development, and that the incapacity of air strained through cotton-wool to give rise to life was not due to any occult influence on the constituents of the air. The evidence he obtained as to the existence of myriads of living particles in the air was both directly and indirectly of great weight in favour of Biogenesis. On the other hand, the fact that hermetically-sealed liquids, after being exposed to heat for a long time, have sometimes exhibited slow forms of life, are the only evidence in favour of spontaneous generation. In regard to these instances, they are not invariable in their results, nor do they indicate with certainty spontaneous generation, inasmuch as the resistance of living material to heat varies within considerable limits.

This slender statement of the history of this question given by Professor Huxley in his address, will serve to show that his review was comprehensive and impartial; and the opinions he offered himself are no less so. In the present state of science, the alternative is offered to us of adopting the opinion that germs can stand a greater heat than has been supposed, or of assuming the molecules of dead material to be capable of arranging themselves into living bodies exactly such as can be shown to originate in another way; and it is a strong argument against the doctrine of spontaneous generation to find Professor Huxley declaring that under these circumstances he does not think the choice can be doubtful for a moment. But at the same time he adds, that though he cannot too strongly express that conviction, he guards himself against the supposition of suggesting the impossibility of spontaneous generation. That he considers would be presumption. How far it may be possible to bring together the conditions under which matter assumes the properties we call vital, is a question we cannot yet decide on scientific grounds. Looking back through the prodigious vista of the past, we find no record of the commencement of life that would indicate the conditions of its origin. To say, in the absence of evidence, that we have any belief as to the mode in which existing forms of life originated would be, from a scientific point of view, to use words in a wrong sense. But, in such a case, expectation is permissible where belief is not, and if it were possible to look back beyond the abyss of geologically recorded time to that remote period when the material of the present earth was passing through physical and chemical conditions which it can no more see again than a man can recall his infancy, the man of science might expect to see the solution of living protoplasm from material not living. That is the expectation to which Professor Huxley is led by analogical reasoning, though he begged his audience to recollect that he had no right to call his opinion anything but an act of philosophical faith.

It would be impossible here to follow the President further in his address, than by stating that he dealt with the subject in its relation to epidemic disease, and, in a manner that was deeply interesting, reminded his audience that in regard to this point, the study of a problem, curious to investigators but apparently of no conceivable utility to mankind, had led to the discovery of fields laden with a harvest of golden grain immediately convertible into those things which even the most sordidly practical men admit to be of value,—namely, money and life. The cases he referred to as illustrating this truth, were the silkworm disease, known in France as 'Pébrine,' and the mortality from scarlet fever. He urged these instances as an admonition that "the people perish for lack of knowledge," and that the alleviation of misery as well as the promotion of man's welfare, must be sought in that diligent, patient, loving study of Nature in all its multitudinous aspects, from the results of which we arrive at exact knowledge or science.

On Thursday, the 15th inst., the sections commenced their meetings. In section B, which is devoted to Chemical Science, the President, Professor H. E. Roscoe, delivered the following address:—

Gentlemen,—In the midst of the excitement of the horrible war in which the two most scientific nations of the Continent are now plunged, let us endeavour to turn our thoughts into channels more congenial to the scientific inquirer; and allow me to recount to you, as far as I am able, the peaceful victories which, since our last meeting in Exeter, have been achieved in our special department of chemistry. But first may I be permitted to draw your attention to the fact that whilst, on the one hand, we hear of professors of chemistry and their students volunteering in the humane offices of field-apothecaries or hospital attendants, we learn, on the other hand, that a distinguished chemist has accepted the chairmanship of a scientific committee called together for the express purpose of employing all the resources of modern chemistry in the horrible destruction of their fellow-creatures; for to what do such resources in the last instance amount, but to sudden explosion, fire, or poison? The application of such means in such an age as this cannot surely be justified in any sense either by patriotism or public duty. And yet, in spite of all this, it is, in my mind, mainly to the brotherly intercourse of those interested in science and in its applications to the arts and manufactures in different countries that we must look as the small but living fire, which, in the end, will surely serve to melt down national animosities, and to render impossible the breaking out of disasters so fatal to the progress of science and to the welfare of humanity as that of which we are now, unfortunately, the spectators.

With regard to the position of chemical science at the present moment, it will not take a careful observer long to see that, in spite of the numerous important and brilliant discoveries of which every year has to boast, we are really but very imperfectly acquainted with the fundamental laws which regulate chemical actions, and that our knowledge of the ultimate constitution of matter upon which those laws are based is but of the most elementary nature. In proof of this I need only refer to the different opinions expressed by our leading chemists, in a discussion which lately took place at the Chemical Society on the subject of the atomic theory. The President (Dr. Williamson) delivered a very interesting lecture, in which the existence of atoms was treated as "the very life of chemistry." Dr. Frankland, on the other hand, states that he cannot understand action at a distance between matter separated by a vacuous space; and although generally granting that the atomic theory explains chemical facts, yet he is not to be considered as a blind believer in the theory, or as unwilling to renounce it if anything better presented itself. Sir B. C. Brodie and Dr. Odling both agree that the science of chemistry neither requires nor proves the atomic theory; whilst the former points out that the true basis of this science is to be sought in the investigation of the laws of gaseous combination or the study of the capacity of bodies for heat, rather than in committing ourselves to assertions incapable of proof by chemical means. Agreeing in the main myself with the opinions of the last chemists, and believing that we must well distinguish between fact and theory, I would remind you that Dalton's discovery of the laws of multiple and reciprocal proportions—I use Dr. Odling's word—as well as the differences in the power of hydrogen replacement in hydrochloric acid, water, ammonia, and marsh gas, are facts, whilst the explanation upon the assumption of atoms is, as far as chemistry is as yet advanced, a theory. If, however, the existence of atoms cannot be proved by chemical phenomena, we must remember that the assumption of the atomic theory explains chemical facts as the undulatory theory gives a clear view of the phenomena of light. Thus, for instance, one of the most important facts and relations of modern chemistry which it appears difficult, if not impossible, to explain without the assumption of atoms, is that of isomerism. How, otherwise than by a different arrangement of the single constituent particles, are we to account for several distinct substances in which the proportions of carbon, hydrogen and oxygen are the same? Why, for instance, should forty-eight parts by weight of carbon, ten of hydrogen and sixteen of oxygen united together, be capable of existing as three different chemical substances unless we presuppose a different statical arrangement of the parts by which these differences in the deportment of the whole are rendered possible? If, then, it be true that chemistry cannot give us positive information as to whether matter is infinitely divisible and therefore continuous, or consists of atoms and is discontinuous, we are in some degree assisted in this inquiry by deductions from physical phenomena which have been recently pointed out by the genius of Sir William Thomson. He argues from four different classes of physical phenomena, and comes to the conclusion, not only that matter is discontinuous, and, therefore, that atoms and molecules do exist, but he even attempts to form an idea of the size of these molecules, and he states that in any ordinary liquid, transparent or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than the hundred millionth, and greater than the two-thousand millionth of a centimetre. Or, to form a conception of this coarse-grainedness, imagine a rain-drop or globe of glass as large as a pea, to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion; the magnified structure would be coarser-grained than a heap of small shot, but probably less coarse-grained than a heap of cricket balls.

There is, however, another class of physical considerations which render the resistance of indivisible particles more than likely. I refer to the mechanical theory of gases by means of which, thanks to the labours of eminent English and German philosophers, all the physical properties of gases, their equal expansion by heat, the laws of diffusion, the laws of alteration of volume under pressure, can be shown to follow from the simple laws of mechanical motion. This theory, however, presupposes the existence of molecules, and in this direction again we find confirmation of the real existence of Dalton's atoms. Indeed, it has been proved that the average velocity with which the particles of oxygen, nitrogen, or common air are continually projected forward, amounts, at the ordinary atmospheric pressure, to 50,000 centimetres per second, whilst the average number of impacts of each of these molecules is 5000 millions per second. The mention of the molecular motions of gases will recall to the minds of all present the great loss which English science has this year sustained in the death of the discoverer of the laws of gaseous diffusion. Throughout his life Graham's aim was the advancement of our knowledge in the special subject of the molecular properties of gases. With this intent he unceasingly laboured up to the moment of his death, in spite of failing health and pressure of official business, unfolding for posterity some of the most difficult as well as the most interesting secrets of nature in this branch of our science. "What do you think," he writes to Hofmann, "of metallic hydrogen, a white magnetic metal?" And yet now, through his labours, the fact of the condensation of hydrogen in the solid state by metallic palladium, and to a less extent by other metals, has become familiar to all of us. Then, again, I would remind you of Graham's recent discovery of the occlusion of hydrogen gas in certain specimens of meteoric iron, whilst earth-manufactured iron contains not hydrogen but absorbed carbonic oxide gas, proving that the meteorite had probably been thrown out from an atmosphere of incandescent hydrogen existing under very considerable pressure, and therefore confirming in a remarkable degree the conclusions to which spectrum analysis had previously led us. The position in the ranks of British science left by Graham's death will not be easily filled up; he accomplished to a certain extent for dynamical chemistry what Dalton did for statical chemistry, and it is upon his experimental researches in molecular chemistry that Graham's permanent fame as one of England's greatest chemists will rest.

As closely connected with the above subjects, I have next to mention a most important research by Dr. Andrews, of Belfast, which, marking an era in the history of gases, shows us how our oldest and most cherished notions must give way before the touchstone of experiment. No opinion would appear to have been more firmly established than that of the existence of three separate states or conditions of matter, viz. the solid, the liquid and the gaseous. A body capable of existing in two or more of these states was thought to pass suddenly from one to the other by absorption or emission of heat, or by alterations of the superincumbent pressure. Dr. Andrews has shown us how false are our views on this fundamental property of matter, for he has proved that a large number of, and probably all, easily condensable gases or vapours possess a critical point of temperature at and above which no increase of pressure can be made to effect a change into what we call the liquid state, the body remaining as a homogeneous fluid; whilst below this critical temperature certain increase of pressure always effects a separation into two layers of liquid and gaseous matter. Thus, with carbonic acid, the point of critical temperature is 30·92° C., and with each given substance this point is a specific one, each vapour exhibiting rapid changes of volume and flickering movements when the temperature or pressure was changed, but showing no separation into two layers. Under these circumstances, it is impossible to say that the body exists either in the state of a gas or of a liquid; it appears to be in a condition intermediate between the two. Thus, carbonic acid, under the pressure of 108 atmospheres, and at 35·5° C., is reduced to the 1-430th of the volume which it occupies at one atmosphere, it has undergone a regular and unbroken contraction, and it is a uniform fluid: if we now reduce the temperature below 31° C. the liquid condition is assumed without any sudden change of volume or any abrupt evolution of heat. We can scarcely too highly estimate the value of the researches of Andrews.

As examples of the power which modern methods of research give of grappling with questions which only a few years ago were thought to be insoluble, I may quote the beautiful observations, now well known, by which Lockyer determined the rate of motion on the sun's surface, together with those of Frankland and Lockyer respecting the probable pressure acting in the different layers of the solar atmosphere; and lastly, the results obtained by Zöllner, respecting solar physics, and especially the probable absolute temperature of the sun's atmosphere, as well as that of the internal molten mass. These last results are so interesting and remarkable as being arrived at by the combination of recent spectroscopic observation with high mathematical analysis, that I may perhaps be permitted shortly to state them. Starting from the fact of the eruptive nature of a certain class of solar protuberances, Zöllner thinks that the extraordinary rapidity with which these red flames shoot forth proves that the hydrogen of which they are mainly composed must have burst out from under great pressure: and if so, the hydrogen must have been confined by a zone or layer of liquid from which it breaks loose. Assuming the existence of such a layer of incandescent liquid, then applying to the problem the principles and methods of the mechanical theory of gases, and placing in his formulæ the data of pressure and rate of motion as observed by Lockyer on the sun's surface, Zöllner arrives at the conclusion that the difference of pressure needed to produce an explosion capable of projecting a prominence to the height of 3·0 minutes above the sun's surface, a height not unfrequently noticed, is 4,070,000 atmospheres. This enormous pressure is attained at a depth of 139 geographical miles under the sun's surface, or at that of 1-658th part of the sun's semi-diameter. In order to produce this gigantic pressure, the difference in temperature between the enclosed hydrogen and that existing in the solar atmosphere amounts to 74,910° C. In a similar way Zöllner calculates the approximate absolute temperature of the sun's atmosphere, which he finds to be 27,700° C., a temperature about eight times as high as that given by Bunsen for the oxyhydrogen flame, and one at which iron must exist in a permanently gaseous form.

Passing on to more purely chemical subjects, we find this year signalized by the redetermination of a most important series of chemical constants, viz. that of the heat of chemical combination, by Julius Thomsen, of Copenhagen. This conscientious experimentalist asserts that the measurements of the heat evolved by neutralizing acids and bases hitherto considered most correct, viz. those made with a mercury calorimeter by Favre and Silbermann, differ from the truth by 12 per cent., whilst the determination by these experimenters of the heat of solution of salts is frequently 50 per cent. wrong. As the result of his numerous experiments, Thomsen concludes that when a molecule of acid is neutralized by caustic alkali the heat evolved increases nearly proportionally to the quantity of alkali added until this reaches 1, $\frac{1}{2}$, $\frac{1}{3}$, or $\frac{1}{4}$ of a molecule of alkali, according as the acid is mono-, di-, tri-, or tetra- basic. Exceptions to the law are exhibited by silicic, and also partly by boracic, orthophosphoric and arsenic acids. In the two latter the heat of combination is proportional for the two first atoms of replaceable hydrogen, but much less for the third atom. A second unexpected conclusion which Thomsen draws from his calorific determinations is that sulphuretted hydrogen is a monobasic acid, and that its rational formula is therefore HSH.

Another important addition made to chemistry since our last meeting is a new, very powerful and very simple form of galvanic battery, discovered, though not yet described, by Bunsen. In this second Bunsen's battery only one liquid, a mixture of sulphuric and chromic acids, and, therefore, no porous cells, are employed. The plates of zinc and carbon can all be lowered at once into the liquid, and raised again at will. The electromotive force of this battery is to that of Grove—the most powerful of known forms—as 25 to 18; it evolves no fumes in working, and can be used for a very considerable length of time without serious diminution of the strength of the current, so that Bunsen writes me that no one who has once used the new battery will ever think of again employing the old forms. I had hoped to be able to exhibit to the section this important improvement in our means of producing a strong current, but war has demanded the use of other batteries, and Bunsen has been unable to send me a set of his new cells.

Amongst the marked points of interest and progress in inorganic chemistry during the past year, we have to notice the preparation of a missing link amongst the oxysulphur acids by Schützenberger. It is the lowest known, and may be called hydrosulphurous acid, H_2SO_2. The sodium salt, $NaHSO_2$, is obtained by the action of zinc on the bisulphite; as might be expected, it possesses very powerful reducing properties, and bleaches indigo rapidly. The metallic vanadates have also been carefully examined, and the existence of three distinct series of salts proved, corresponding to the phosphates, viz., the ortho- or tribasic vanadates, the pyro- or tetrabasic vanadates, and the meta- or monobasic vanadates. Of these the ortho-salts are most stable at a high temperature, whilst, at the ordinary atmospheric temperature, the meta-salts are most stable. In the phosphorus series, as is well known, the order of stability is the reverse; and thus the points of analogy and of difference between phosphorus and vanadium become gradually apparent.

As an illustration of the results of modern organic research—for in viewing the year's progress in this ever-widening branch of chemistry it is impossible to do more than give a few illustrations—I may quote Baeyer's remarkable investigations on mellitic acid. Originally discovered by Klaproth in honeystone or mellite (a substance which yet remains the only source of the acid), mellitic was supposed to be a four-carbon acid. Baeyer has quite recently shown that the acid contains twelve atoms of carbon, or has a molecular weight three times as great as was originally supposed. He has shown that mellitic acid is benzolhexacarbonic acid, $C_{12}H_6O_{12}$, or benzol in which the six atoms of hydrogen are replaced by the monad radical, carboxyl (COOH); as benzoic is benzol-mono-carbonic acid, or benzol in which one of hydrogen is replaced by carboxyl. The most interesting portion of Baeyer's research, however, lies in the intermediate acids, partly new and partly acids already prepared, which he has shown lie between mellitic and benzoic acid, and in which from one to six atoms of hydrogen in benzol are respectively replaced by carboxyl. Nor is this all, for he has proved that, with two exceptions, each of these six acids is capable of existing in three isomeric modifications, thus giving us an insight into the arrangement of the molecule of these aromatic compounds. For the simplest mode of explaining these numerous isomers is that given by Baeyer in the different order in which the several atoms of hydrogen in the benzol molecule are replaced. Thus, in the first, or ortho series, the hydrogen atoms in benzol, being numbered in regular succession, are replaced in the same regular succession; in the second, or meta series, the order is 1, 2, 3, 5, etc.; whilst the third, or para series, take open order, as 1, 2, 4, 5, etc. Thus we have—

	Ortho series.	Para series.	Meta series.
$C_{12}H_6O_{12}$ Hexa-basic	Mellitic or Benzolhexacarbonic.		
$C_{11}H_6O_{10}$ Penta	Unknown.		
$C_{10}H_6O_8$ Tetra.	Pyromellitic or Benzoltetracarbonic.	Isopyromellitic.	Unknown.
$C_9H_6O_6$ Tri . . .	Trimesinic or Benzoltricarbonic.	Hemimellitic.	Trimellitic.
$C_8H_6O_4$ Di . . .	Phthalic or Benzoldicarbonic.	Isophthalic.	Tetraphthalic.
$C_7H_6O_2$ Mono .	Benzoic or Benzolmonocarbonic.		

Amongst the most interesting series of new organic bodies are those in which tetrad silicon partly replaces carbon. Our knowledge of these substances is gradually becoming more complete; the last new member prepared by Friedel and Ladenburg is silico-propionic acid—

$$\begin{matrix} C_2H_5 \\ SiO_2H \end{matrix}$$

the first of a series of carbo-silicic acids containing the radical SiO_2H. The interesting researches of Matthiessen and Wright on morphine and codeine have thrown a new light on the constitution of these opium alkaloids. Treated with hydrochloric acid morphine loses one molecule of water, and gives rise to a new base called apomorphine, thus:—

$$\underbrace{C_{17}H_{19}NO_3}_{\text{Morphine.}} = H_2O + \underbrace{C_{17}H_{17}NO_2}_{\text{Apomorphine.}},$$

which differs in a remarkable manner from morphine, both in its chemical and physiological actions, being soluble in alcohol, ether and chloroform, whereas morphine is nearly insoluble, and acting as the most powerful emetic known, one-tenth of a grain producing vomiting in less than ten minutes. Codeine, which only differs from morphine by CH_2, also yields apomorphine on treatment, at a high temperature with hydrochloric acid, methyl chloride being at the same time eliminated.

An important application of the dehydrating and carbon-condensing power of zinc chloride, long known in its action on alcohol to produce ether, has been made by Kekulé in the reduplication of aldehyde to form croton aldehyde with loss of water: $2(C_2H_4O)-H_2O=C_4H_6O$. This croton aldehyde is also probably formed as an intermediate product in the manufacture of chloral from aldehyde, and gives rise to the formation of croton chloral, $C_4H_3Cl_3O$.

The discovery of the sedative properties of chloral hydrate by Liebreich marks an era in medical chemistry second only to the discovery of the anæsthetic properties of chloroform. Chloral not only combines with water to form a solid hydrate but also forms solid alcoholates; but these bodies appear to possess quite different medicinal properties from the hydrate, and it is important that no alcoholate should be present in the official preparation.

The chemistry of colouring matters has lately received an enormous impetus in the practical working of the brilliant discovery of the production of artificial alizarine, the colouring matter of madder, by Messrs. Graebe and Liebermann. This discovery, announced at our last meeting, is of the highest importance—whether we regard its scientific interest or its practical and commercial value—and it differs from all the former results which have been brought about by the application of science to the production of colouring matter, inasmuch as this has reference to the artificial production of a natural vegetable colouring substance, which has been used as a dye from time immemorial, and which is still employed in enormous quantities for the production of the pink, purple and black colours which are seen everywhere on printed calicoes. During the past year much progress has been made in the practical working of the processes by which this colouring matter is obtained from the hydrocarbon anthracene contained in coal tar, and new and more economical plans for effecting the transformation have been independently proposed by Perkin and Caro, and Schorlemmer and Dale. The theoretical investigation of the reaction—and especially of the nature of some other peculiar products formed in addition to alizarine, which render the artificial colouring matter different from natural alizarine—has been carried out by Mr. Perkin, and especially by Dr. Schunck. As we are promised papers on this subject from both these gentlemen, I need not at present enter further into these interesting questions.

The surest proof of perfection in a manufacture is the degree in which the waste products are utilized, and in which the processes are made continuous. One by one the imperfections of the original discovery are made to disappear, and the products which were wasted become sources of profit, while in many cases their utilization alone renders possible the continuance of the manufacture in the midst of a rapidly-increasing district. The section will have the opportunity of inspecting the practical working of at least two of the most valuable of these new processes which have lately been introduced into our most important chemical manufacture—that of alkali. The first of these has been at work for some time, it is that of the recovery of sulphur from the vat waste, that *bête noire* of the alkali makers and of their neighbours. Dr. Mond has now, I believe, satisfactorily solved the difficult problem of economically regaining the sulphur by oxidizing the insoluble monosulphide of calcium in the lixiviating vat itself to the soluble hyposulphite, and decomposing this by hydrochloric acid when all the sulphur is deposited as a white powder. The second of these discoveries relates to the recovery or regeneration of the black oxide of manganese used for the evolution of chlorine in the manufacture of bleaching powder. This subject has long attracted the attention of chemists, and a feasible, though somewhat costly, process, that of Dunlop, has been at work for some time at Messrs. Tennant's works at St. Rollox. During the last year a very beautifully simple and economical process proposed by Mr. Weldon, and first successfully carried out on a practical scale at Messrs. Gamble's works at St. Helen's, has quickly obtained recognition, and is now worked by more than thirty-seven firms throughout the kingdom. The principle upon which this process depends was explained by Mr. Weldon at the Exeter meeting. It depends on the fact that although when alone the lower oxides of manganese cannot be oxidized by air and steam under the ordinary pressure to the state of dioxide, yet that this is possible when one molecule of lime is present to each molecule of oxide of manganese. The manganous oxide is precipitated from the still liquors with the above excess of lime, and by the action of steam and air on this, a black powder, consisting of a compound of manganese dioxide and lime, MnO_2CaO, or calcium manganite, is formed. This, of course, is capable of again generating chlorine on addition of hydrochloric acid, and thus the chlorine process is made continuous with a working loss of only $2\frac{3}{4}$ per cent. of manganese. The section will have the advantage of seeing Mond's process at work at Messrs. Hutchinson's, and Weldon's process at Messrs. Gaskell, Deacon and Co.'s, at Widnes. A third process, which may possibly still further revolutionize the manufacture of bleaching powder, is the direct production of chlorine from hydrochloric acid without the use of manganese at all. In presence of oxygen and of certain metallic oxides, such as oxide of copper, hydrochloric acid gas parts at a red heat with all its hydrogen, water and chlorine being formed. This interesting reaction is employed by its discoverer, Mr.

Deacon, for the direct manufacture of bleaching powder from the gases issuing directly from the salt-cake furnace. Air is admitted together with hydrochloric acid gas, and the mixture is passed over red-hot bricks, impregnated with copper salt. The oxide of copper acts as by contact and remains unaltered, whilst the chlorine, watery vapour and excess of air pass at once into the lime chamber. There are many practical difficulties in working this process, some of which have still to be overcome, but I believe we shall hear from Mr. Deacon that, notwithstanding this drawback, he has accomplished his end of making good bleaching-powder by this process.

On the motion of Professor Williamson a vote of thanks was tendered to the President for his address.

Mr. D. Forbes read the Report of the Committee appointed to inquire into the chemical nature of cast iron.

The reading of papers upon the following subjects was then proceeded with:—

A New Chlorine Process without Manganese. By Mr. Henry Deacon.

The Weldon Process for the Manufacture of Chlorine. By Walter Weldon, F.C.S.

Air Pollution from Chemical Works. By Alfred Fletcher, C.E.

Phenomena of the Crystallization of a Double Salt. By J. Berger Spencer, F.C.S.

In the Anatomy and Physiology Department of Section D (Biology) Dr. Richardson read an important report on methyl compounds. With some small aid from the funds of the Association, he has for some years carried on a series of investigations into the uses of various ethers and alcohols in medicine and surgery; and he was this year able to point out new remedies, the fruit of his labours, that have won, and promise to hold, a high place among the agents employed for the relief of pain and the cure of disease. He finds that it is becoming possible to predict the action of new compounds with great exactness from their chemical composition, and also by modifying composition to remove sources of inconvenience or of danger. By this line of work he hopes to arrive ultimately at an agent that will supersede chloroform and its analogues, and that will suspend sensation without danger to life. As a step in this direction, he announced the discovery of "tri-ethylic ether," a new substance, which had already been used as an anæsthetic, and from which excellent results might be expected. Dr. Richardson's report was very well received by a large audience, and called forth expressions of warm commendation of his labours from several speakers.

On Friday, in Section B, the following papers were read:—

Artificial Alizarine. By W. H. Perkin, F.R.S.

The Lancashire Alkali Trade. By W. Gossage, F.C.S.

The Hydrogenation and Hydriodate of Cyanogen. By Mr. T. Fairley.

The Distillation of Sulphuric Acid. By Mr. T. Fairley.

The Time needed for the Completion of Chemical Change. By Dr. Hurter.

Reciprocal Decomposition, viewed with reference to Time. By J. H. Gladstone, F.R.S.

A Method for the Determination of Sulphur in Coal Gas. By A. Vernon Harcourt, F.R.S.

The Estimation of Sulphur in Coal Gas. By W. Marriott, F.R.S.

Note on Thermal Equivalents. By J. Dewar, F.R.S.E.

In the evening Professor Tyndall delivered his lecture on the Scientific Uses of the Imagination to a crowded audience at the Philharmonic Hall. Professor Huxley, the President of the Association, occupied the chair.

On Monday, the Report of the Committee on the Treatment and Utilization of Sewage was read by Mr. Grantham, C.E.

A Supplementary Report on the Analysis of Sewer Gases, by Professor Caulfield.

The Phosphate Process applied to the treatment of Sewage. By Professor Forbes.

At the meeting of the General Committee, after the various invitations had been read, Professor Balfour moved, and Sir Walter Elliott seconded, that Edinburgh should be visited in 1871. The proposal was supported by Sir Roderick Murchison and Mr. Cowan, late M.P. for Edinburgh, and carried unanimously. Lord Houghton then moved, and Mr. Gassiott seconded, that the meeting should be held at Brighton in 1872; this also was carried. Upon the proposition of Professor Stokes, seconded by Mr. Spottiswoode, Sir William Thomson was chosen to succeed Professor Huxley in the office of President.

ANDERSON'S UNIVERSITY.

ELECTION OF PROFESSOR OF CHEMISTRY.

A *pro re natâ* meeting of the members of Anderson's University was held on 23rd ultimo, for the purpose of electing a professor to the chair of Scientific Chemistry, vacant by the death of Dr. Frederick Penny; Mr. Young, the President, in the chair.

The Secretary stated that applications for the vacant office had been received from the following gentlemen:—Dr. J. E. Thorpe, Owens College, Manchester; J. C. Brown, B.Sc. Lond., F.C.S., School of Medicine, Royal Infirmary, Liverpool; Thomas Ward, Ph.D., F.C.S., London; R. C. Moffat, Ph.D., Glasgow; Robert R. Tattock, F.R.S.C., F.C.S., Glasgow; and Dr. John Clark, F.C.S., Glasgow.

The Rev. Dr. Forbes said he was fully persuaded that the trustees were deeply sensible of the important bearing which this election of a successor to Dr. Penny must exercise upon the Andersonian University, and that they were conscientiously desirous that their choice might be such that the gentleman elected should not only sustain, but, if possible, advance the celebrity of the chemical chair, extend the knowledge of chemistry in this great commercial city, and enlarge the ever-increasing domain of discovery by important contributions, which might redound not only to his own celebrity, but to the honour of the institution. He then concluded by proposing that Dr. John Clark be appointed to the vacant chair. Dr. Ritchie seconded the nomination.

Mr. A. Harvie, after a few remarks in favour of Dr. Thorpe, read a note to the trustees from W. H. Perkin, of London, on the qualifications of Dr. Thorpe, and concluded by proposing his election. Mr. James Napier seconded the nomination.

Mr. J. H. M'Clure proposed Mr. Tattock.

The meeting proceeded to vote by ballot, Mr. G. Anderson, M.P., and Mr. W. Kedder being appointed scrutineers. The voting papers having been carefully gone over by the scrutineers, Mr. Anderson intimated as follows:—Dr. Thorpe, 28; Dr. Clark, 23; Dr. Brown, 4; Mr. Tattock, 2. Dr. Thorpe was declared duly elected.

Obituary.

At Hull, on the 16th inst., aged 33, Mr. Thomas Toogood, jun.,—of the firm of Messrs. T. Toogood and Sons, Chemists, and son of Alderman Toogood,—much respected.

The following journals have been received:—The 'British Medical Journal,' Sept. 17; the 'Medical Times and Gazette,' Sept. 17; the 'Lancet,' Sept. 17; the 'Medical Press,' Sept. 21; 'Nature,' Sept. 15; the 'Chemical News,' Sept. 16; 'Journal of the Society of Arts,' Sept. 16; 'Gardeners' Chronicle,' Sept. 17; the 'Grocer,' Sept. 17; the 'English Mechanic,' Sept. 16; 'American Journal of Pharmacy' for September; 'Chemist and Druggist,' Sept. 15; 'Chemists and Druggists' Advocate,' Sept. 20; 'Produce Markets Review,' Sept. 17; 'Philadelphia Medical and Surgical Reporter,' Nos. 691 to 702.

Correspondence.

Communications for this Journal, and books for review, should be addressed to the EDITOR, 17, *Bloomsbury Square.*

*** *No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.*

PHARMACEUTICAL TITLES.

Sir,—I had hoped that the opinions expressed by your correspondent on the 20th ult. on the subject of pharmaceutical titles would have been supported by an abler pen than mine; but, rather than the matter should be allowed to drop, I would fain ask for a small space in your Journal to say how fully I endorse his sentiments.

It seems to me, Sir, that this distinction of titles is the one great desideratum to the younger members of our profession. While all right-minded men would be disposed to grant a certain licence to the older members of the Society, those who have borne the burden and heat of the day, and have laboured hard to bring the Pharmaceutical Society to the prominent place it now holds among the scientific bodies of the country, I think they would also be equally disposed to insist upon the younger ones standing on their own merits. No wonder the public is bewildered by the multiplicity of titles now adopted to impose upon their credulity,—titles, we must admit, perfectly just in themselves, but which fail to distinguish the mere chemist and druggist from the man who has qualified himself by passing an examination of so high a standard as that of the "Major" of our Society.

Nor can we wonder at men stopping short at the "Minor," when the only recompense in the way of title they get for their time and toil devoted in qualifying themselves for the Major is the vague and now almost meaningless name of "Pharmaceutical Chemist."

This subject cannot be too strongly urged upon our Executive Council, and I hope they will not be slow to appreciate its importance, and act upon it accordingly; and I would suggest that other members who feel interested in the matter should ventilate it in these columns.

I am, Sir, your obedient servant,
ANOTHER ASPIRANT TO THE MAJOR.

"FREE TRADE IN SURGICAL INSTRUMENTS."

Dear Sir,—Seeing a letter from Messrs. Maw, Son and Thompson in your Journal of 10th inst. defending their policy, and explaining their reasons for sending their catalogues to surgeons, I shall feel obliged if you will give these observations of mine a place in your columns in reference thereto. A year or two ago Messrs. Maw asked us to forward to each of our surgeon-customers one of their catalogues, and, at the same time, to inform them that we could supply Messrs. Maw's goods at catalogue prices (off which they allowed us 25 per cent.). Some months after this they issued a fresh catalogue (net at six months or 5 per cent. cash), but, strange to say, many of the articles at net prices were the same as those formerly subject to 25 per cent. The effect of this was to compel us to break faith with our customers, or else to sell Messrs. Maw's goods at no profit; the latter course I preferred to adopt. Messrs. Maw explained this in saying that by taking 25 per cent. off they were selling at a loss; and yet these were their own terms, and should have been discovered before the first catalogue was issued. I think we are fully justified in condemning Messrs. Maw's conduct towards us. They made use of us to distribute their catalogues, and they now supply surgeons (who keep no stock, only buy an article just as they want it, and who make extraordinary prices of the same) upon precisely the same terms as ourselves.

There is one other feature in Messrs. Maw's conduct towards us which presses still more heavily upon retail chemists. Upon this Messrs. Maw do not touch.

I should very much like their explanation and defence upon what appears to me a most extraordinary and unparalleled course of conduct for a wholesale house to adopt towards its customers. I refer to their sending their catalogue to the chairman or clerks of the various Poor Law Boards throughout the kingdom.

Is it common justice to the trade that every Poor Law Guardian throughout the kingdom (and, of course, their friends) should be made acquainted with the cost price of druggists' sundries,—elastic stockings, bandages, waterproof sheeting, trusses, air- and hotwater-cushions, ladies' belts, enemas, breast-bottles, conversation tubes, electro-magnetic machines, inhalers, spray producers, suspenders, riding-belts, bottles of all kinds, lint, sponges, piline, medicine chests, elastic syringes, spread-plasters, etc.?

I have heard of Messrs. Maw's catalogue being used in some instances by the union clerks as a drawing-room book. The policy Messrs. Maw are adopting towards the trade is to me even a greater evil than the co-operative store system, of which doubtless, whether in London or in country, we all feel more or less.

I asked Messrs. Maw's representative when he called on me last if he had waited upon the chairman of the Yeovil Board of Guardians for an order, for I scarcely thought it consistent for him to call upon me after having sought to do business directly with my customers. T. C. MAGGS.

BRIGHTON CHEMISTS' ASSOCIATION.

Sir,—In the list of delegates from the various provincial societies to the Pharmaceutical Conference I see the name of Mr. Savage mentioned as representing the Chemists' Association of Brighton. May I be allowed, through the medium of your columns, to inquire in what part of Brighton the Association is located, and who are its officers? I have been a resident in the town for a period of two years, and during that time have made several inquiries respecting the said Association, but have never received any definite reply that it at present exists. That such an Association did exist at some remote period there is not a doubt, and a recent correspondent in the Journal has informed us that there is still a nucleus for the reconstructing of one; if such be the case, why do not the pharmacists of so large and popular a place as Brighton awake out of their present dormant state, and, by incorporating the whole body of principals and assistants located here, establish an Association worthy the reputation of the town, so that at future Conferences the veteran worker in the cause of pharmacy—Mr. Savage—may be the representative of a reality, and not of a Society that has ceased to exist? VERITAS.

Brighton.

HOSPITAL DISPENSING.

Dear Sir,—I who have been for sixteen years a hospital dispenser, see nothing extraordinary in a hospital physician or surgeon writing (scrawling, if that term better suits Mr. Fitch) as well as he can upon a patient's *greasy* card or paper, ℥j mist. cinch. rosæ c. acid. I used to consider it very thoughtful on the part of the doctors when they did "write it short." The prescriber knows very well that it is only intended for their own dispenser, and that he will understand it. Most hospitals have private formulæ, and for very good reasons. Mr. Fitch is evidently not well up in hospital work. As a rule, hospital prescriptions are dispensed as well and with as good articles as those used in private establishments.

To try to "run down" the medical profession, is not the way to elevate ourselves.

Let us not copy the *Lancet.*

EDWARD BARBER, *Another M.P.S.G.B.*

P.S. "Mist. D.D.D. t.d." and "Mist. M.A.C. t.d." would puzzle Mr. Fitch, but hospital dispensers here understand it.

Sir,—If Mr. Simon reflects and looks a little farther, he will find larger dispensing establishments requiring his nursing other than the pharmacists. Early this month a respectable married woman obtained advice at Bartholomew's Hospital; a prescription was handed her for the dispensary; there the first words were, "Your bottles!" The woman answered, "I have none." "Then go and buy some." This she did (two wine bottles); the one was filled with a "gargle," the other a "mixture," both being handed to her, together with *two* corks and two labels, with the sweet sound from some one within, "Take them away." This, I fear, is an average type of hospital dispensing,—in other words, a waste of public money. If the corks fitted, why not have kept them there? if not, it was an insult to have given them; and, again, was this poor woman to be made the judge as to which was to be taken, and which was "*not*"? To discern between them was accomplished by some difficulty by

London, 13th September, 1870. A PHARMACIST.

The Pharmacy Act in its Relation to the Sale of Poisons by Grocers, etc.

Sir,—The Members of the Pharmaceutical Society, and all connected with pharmacy, will be grieved to hear what I have to relate respecting a sight which I saw in a large town in the north of Scotland about a fortnight since. On sauntering along its principal street I happened to look into a grocer's window, and, to my astonishment, I saw a bottle (about 2 lbs.) more than three-fourths full of a bluish powder, and distinctly labelled arsenicum alb. The bottle was in the midst of three or four dozen of apples, the other part of the window being filled with packets of Brown and Polson's Corn Flour. On making inquiries as to the use to which it was put, I was told it was good for killing rats, and very much used for that purpose. There were no precautions taken; the cork was not even tied over with leather, and there it was lying on its side in the most careless manner possible. Surely such a piece of right-down carelessness and ignorance should not be allowed to pass unnoticed. Where are the limits of the Pharmacy Act? I know nothing about the qualifications of the man selling such a poisonous substance as arsenic any further than that he pretends to be neither more nor less than a grocer and meal dealer. I hope that such a case will not pass without some notice being taken of it by the Pharmaceutical Society, and if you think of making any inquiry I shall gladly provide you with particulars. Apologizing for trespassing so largely, and hoping that this may not be considered an unwarrantable encroachment upon your valuable space,

I remain, dear Sir,

Prevention better than Cure.

State Aid for Pharmaceutical Education.

Sir,—Your remarks on this subject seem to imply that we are indebted to Mr. G. F. Schacht for procuring us the privileges of the Science and Art Department Examinations. I beg to say that those privileges have always been accessible to us, and that teachers have always received payment on the result of our passing. As a proof of this, I may mention that nine chemists' assistants passed at the last May Examinations at Birmingham in inorganic chemistry and botany, four of whom obtained Queen's prizes.

I am, Sir, yours, etc.,

An Assistant.

Concentrated Medicine.

Sir,—While reading the correspondence part of your Journal of the 10th instant, my attention was drawn to a copy of a prescription, headed, "Concentrated Medicine," the correspondent of which wishes to know the proper mode of dispensing it. Although these few lines are from one of less experience than others, still I give my opinion as to the manner of dispensing it. No doubt that the dispenser at first sight is puzzled, knowing that a mistake has been made by the prescriber, on account of the strength and proportions of the ingredients in the mixture being in so concentrated a form, and the absence of directions for administration. The following is a copy of the same as I should have dispensed it, with the addition of the aqua, which when mixed with the inf. calumbæ conc. forms the ordinary strength of the same in the Pharmacopœia, viz.:—

℞. Ferri Pot. Tart. ʒiij
Ammon. Carb. ʒiss
Tinct. Aurantii,
Inf. Calumbæ Conc., aa ℥iss
Aquæ Destillat., ad ℥xij.

Misce et signa, Sumenda Coch. Med. bis aut ter in die.

The above dose is one which I deem perfectly safe for the patient, who appears, according to the ingredients of the prescription, to have been an adult.

I am, Sir, yours obediently,

Atherstone, September 12th, 1870. George Sant.

Sir,—Having had considerable experience in dispensing, I tender my method of dispensing the prescription ("Concentrated Medicine") in the Journal of the 11th instant.

Well rub down the iron and ammonia in a mortar, add the infusion by degrees, lastly the tincture.

Respecting Mr. Coles's prescription in the Journal of the 3rd, in the absence of any information from the patient, I should put up the mixture as prescription, and the pills divided into 24; ij p. r. n.

Perhaps some of your correspondents would inform me what they would have done in a case of this sort:—

A gentleman presented a prescription a few days since, handing over with it a 16-ounce bottle, saying he wanted half the quantity made up, which just filled the bottle.

℞. Sulph. Sublimat. purif. ʒiv
Potass. Bitart. ʒiss
Magnes. Sulph. ʒij
Ac. Nit. Mur. dil. ʒiss
Inf. Quassiæ ℥xxiiiss

M. A wineglass or less or more on rising, "shaking the bottle well."

According to the label on the bottle it had been dispensed at one of the first firms in town, but no sign of a shake-the-bottle label thereon. Is it possible that a London firm would have sent out medicine in that style? If nothing more, it gives the public an idea that a country chemist who dispenses it accurately is not up to his business.

Eastern Medical Hall, Yours, etc.,
Brighton, September 15th, 1870. W. C. Hales.

Improvement in Stoppered Bottles.

Sir,—Allow me to suggest to bottle manufacturers the utility of making a little groove for string at the tops of stoppers. Capping with paper is wholly insecure, and with leather not much less so. For some time past I have in dispensing tied stoppered-bottles with string, I need scarcely say with what inconvenience, for want of a little groove in the stoppers. I am, Sir, your obedient servant,

Glastonbury, September 12th, 1870. T. Mayhew.

Extra Charges after Business Hours.

Sir,—Through the medium of your next issue, I should much like to ask the question of "extra charge for medicines after or before business hours."

Many people are in the habit of calling up the chemist at all unreasonable times, knowing that "medicines can be had at any hour by ringing the bell," for things which I am sure could, in many cases, be left until a more suitable time, and, if we were to charge some 25 per cent. extra, would be.

The opinion of yourself or subscribers will oblige.

Yours obediently,

J. H. Jessop.

15, *Princes Street, Hanover Square, Sept. 7th,* 1870.

Material for Stanching Blood from Wounds.

Sir,—In the American civil war equal parts of flour and salt, thoroughly mixed, were found very efficacious in stanching the blood from wounds. Would it not be as well at this juncture to revive the fact, and give it as much publicity as possible?

I had an opportunity of testing its efficacy in two instances, one in a cut artery, and the other where a man's posteriors were frightfully eaten away by disease. He found he could sit with less pain by using the powder.

I am, Sir, your obedient servant,

September 12th, 1870. Pax.

A. P. S. desires to be informed, through the medium of the Journal, as to the best mode of dispensing the enclosed prescription, and whether it is intended to give sulphate of soda or lime in the mixture.

℞. Conf. Aromat. ʒij
Sodæ Bicarb. ʒj
Acid. Sulph. dil. ʒss
Aq. Menth. ad ℥viij

Capt. ℥j ter in die. J. G. D.

W. R. L. (Islington).—Ammoniated mercury (white precipitate) is included in the second part of the schedule of poisons.

J. E. George (Aberdare) wishes for a recipe for administering Santonin in a liquid form.

W. B. P. asks what are the best means "for preserving animal substances for some length of time in a pure condition, without poison, fit for culinary purposes."

Instructions from Members and Associates respecting the transmission of the Journal should be sent to Elias Bremridge, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements to Messrs. Churchill, *New Burlington Street, London, W. Envelopes to be endorsed for "Pharm. Journ."*

THE PROCESS OF NUTRITION.

BY BARON LIEBIG.

The achievements of that art which relates to the preparation of food are really surprising in regard to the economy of power and the increased efficacy of food materials within a given time. Under the influence of heat, as already mentioned, the digestibility of the chief constituents of food is rather augmented than diminished. The operations of roasting and boiling, the long-continued simmering practised in the preparation of various kinds of flesh, either of mammalia, fish, or birds, the selection of vegetables and sauces to accompany particular dishes, are all means calculated for effecting the disintegration of the food or complementing and increasing its action, as well as for shortening the time required for the work of digestion. With the child we find a difference even with sugar and milk-sugar, while both are preferable to starch.

Experienced cooks attach the greatest value to the soluble constituents of the muscles of mammalia as an adjunct to their viands. To obtain this working material of muscle, they prepare from the waste fragments of the kitchen an extract, the importance of which is characterized by its name, "stock," which is understood to denote its applicability as a basis or for enriching other preparations of food.

It is wholly unintelligible that the dietetic value of the extractive material of flesh should not have been recognized long ago and regarded as perfectly well established; it is equally unintelligible that doubts should still exist in regard to it even among physicians, while the efficacy of this material in the form of broth for promoting the strength of convalescents has been well known, not only for years, but since the time of Hippocrates.

It is clear that this material, taken in the form of soup or sauces, or as an adjunct to vegetable food, must have the same effects on the animal body as when it is taken as a part of meat.

In regard to the selection of food corresponding to the wants of man, instinct is an infallible guide, when aided by that watchman of health, the sense of taste; it may be misled for a time, but not permanently. At the entrances of the Munich beer-cellars we find a law of nature expressed by the proximity of the never-failing cheese-booth. The beer-drinker consumes his respiratory material in the form of beer, while in the form of cheese he obtains the material indispensable for production of blood and for generating force. Since beer serves as respiratory material more readily than fat would do, he dislikes fat and declares it to be unwholesome. With the beer he eats his cheese without butter.

The extractive substances of flesh when added to food do duty as true nutritive materials in the place of those substances which are otherwise produced from albumen. The most simple observation will suffice to dispel any doubt of this.

The experiments of Bischoff and Voit have established the fact that gelatin has a considerable nutritive value when combined with meat—about one-fourth that of albumen,—so that while a dog weighing 36 kilograms lost in about four days one pound in body-weight when fed with 500 grams of meat alone, he gained in three days about 134 grams when the same quantity of meat was given together with 200 grams of gelatin.

According to our knowledge of the nature of gelatin and its composition, this power of nutrition cannot be accounted for on the assumption that the gelatin, or any part of it, is converted into albumen, so as in this way to add to the quantity of albumen consumed; but we must infer that it has this power, because it replaces certain substances necessary for the animal organism, which are produced more readily from gelatin than from albumen; so that, in consequence of this, the animal is relieved from work, to some extent, while a certain quantity of albumen remains available for other purposes.

A dog may be fed with boiled porridge made of the entire grain when bone-meal is added to it, and the animal will thrive almost as well as if fed upon meat.

I believe that the imperfect appreciation of laws of nutrition and dietetics is to be ascribed to two erroneous ideas; one is that, in experiments on nutrition, *a particular* animal has been regarded as the representative of all animals, and it has been deemed proper to draw general conclusions as to the process of nutrition from experiments made with that particular animal alone. From observations on carnivorous animals inferences have been drawn as to the phenomena in herbivorous animals; and from the action of vegetable food in the body of a carnivorous animal attempts have been made to draw conclusions as to the nutritive value of meat.

The dissimilar expenditure of power in individuals of different classes of animals, or the generation of power for the performance of interior and exterior work, is but little regarded by some physiologists; with many, indeed, the animal body is nothing more than a machine that converts albumen into urea.

A second equally great error consists in ascribing to albumen, as some physiologists do, an action which it does not at all possess, according to its nature.

Albumen is, for the animal body, nothing more than what carbonic acid, water and ammonia are for plants; and in this its value is sufficiently high. Besides the importance that water has for the plant, inasmuch as it yields hydrogen to it, there is another chemical value it has for the plant, in being the means by which carbonic acid is taken up, and by which mineral food is supplied. In like manner, carbonic acid, which yields carbon, has the particular virtue of rendering soluble several substances which are insoluble in water. Albumen, also, possesses similar characters, but it does not exercise any special action; and it is a misconception of the nature of albumen to suppose that physiological phenomena are to be explained by means of the idea we have of albumen. It is only by means of the things produced from albumen that this substance acts, and therefore it is impossible for me to concur in the modern notions of organized albumen and circulating albumen, which are, nevertheless, one and the same thing. These notions introduce confusion to such a degree that one does not know how to distinguish left from right.

All combustible plastic constituents of the animal body are, in fact, altered atoms of albumen, just in the same way that the constituents of the plant are altered atoms of carbonic acid; and it is quite certain that most of the products originating from albumen in the animal organism are capable, when taken as food, of replacing albumen in the processes of nutrition and force production, as well as in special processes, as is the case with sugar and fat, or their derivatives, such as alcohol, etc., in the process of heat production. The limited conceptions of food materials, which rest upon observations of the processes taking place in the organisms of herbivorous and carnivorous animals, must be considerably extended in the case of man.

Since the term digestion cannot be understood in a chemical sense, otherwise than as the process by which the colloids of the food—comprising albumen, casein, gelatin, starch and gum, etc.—are transformed into a diffusible condition, it may be understood that the constituents of muscular juices, when taken in the food, require, for the most part, no digestion; and that they are, when taken in meat diet or alone, first of all brought into the circulation, exercising the action peculiar to them, long before the albumen has been rendered soluble in the stomach. They are among the normal constituents of flesh, and must be regarded as highly efficient nutritive material; not, however, in the sense in which albumen is nutritive, but in a much higher sense. It is impossible for these substances to replace albumen in its functions; but they have an activity independent of albumen, they are nutritive materials which economize work and augment power in certain directions.

In like manner, gelatin must be comprised among the nutritive substances that economize albumen.

Studied from this point of view we shall, it is to be hoped, have to anticipate an entirely different view of the action of various articles of diet, and even the action of some medicines may become explicable by such an expansion of the idea of nutrition.

I regard it as quite indubitable that vegetable diet may, by addition of the extractive substance of flesh, acquire an action upon the human body just the same as a meat diet exerts; of course, under the assumption that there is in the vegetable food a sufficient quantity of digestible albuminates. Certainly, the extract of meat is the only available means of making up for a dearth of animal food. In regard to matters of this kind controversy is inadmissible, and the dietetic value of the material must be tried upon men, and not upon dogs.*

It is right to investigate details in order to comprehend the whole in its origin and action, but in order to interpret details correctly, it is necessary to have a clear conception of the whole in its many-sided aspects and surroundings.

I know pretty well how to estimate the significance of experiments or facts, and how unlike they are in value for drawing conclusions. The simple observation of a natural phenomenon which takes place without our aid is very much more important, though frequently much more difficult, than the processes set going in experiments at our will. In the former, reality is always reflected, while experiments reflect only the imperfection of our ideas.

I remember years ago in walking along the road from Berchtesgaden, on the König lake, to have arrived at a conviction as to the source of carbon in plants by means of a very simple observation. At that time great uncertainty prevailed in regard to this matter, and it was difficult to get beyond the belief in humus being the source of the carbon in plants. But at the place I have mentioned there is evidence that the carbon of plants can only be derived from carbonic acid, and the proof of this is furnished by nature herself. There masses of rock which have fallen down from the surrounding mountains may be seen with trees thirty or forty feet high growing upon

* Experiments undertaken at my suggestion by Dr. E. Bischoff, in which extract of meat was added to bread in order to increase its nutritive power and facility of assimilation in the case of a dog, have not been successful, as might have been foreseen by a more judicious consideration of facts previously known. Their failure was due to the nature of the carnivorous animals. The animal could not eat a sufficient quantity of vegetable food to meet the requirements of maintaining the body-weight, neither could the starch consumed be digested completely.

In one experiment made by Bischoff and Voit, it appeared that a dog, weighing 34 kilograms, fed for forty days with as much bread as he could eat, did not consume more than 771 grams of bread daily, while he digested only seven-eighths of this quantity, the remainder passing away in the fæces, which contained a recognizable quantity of starch.

In the 676 grams of bread assimilated, there were contained:—

Bread albuminate,	Starch,
$55\frac{1}{3}$ grams.	299 grams.

Calculating the starch into its equivalent of fat (24 starch = 10 fat), and assuming the addition of meat-extract to have, as it were, converted the bread-albuminate into flesh, the dog would have consumed:—

In the form of flesh,	Of fat,
257 grams.	125 grams.

But this ration would be insufficient for a dog weighing 34 kilograms in order to maintain his body-weight. The dog remained in a state of hunger. The maintenance of his body-weight could have been expected only when the assimilated starch had been mixed with four times as much vegetable albumen, in the form for instance of gluten, or when it had been possible for the dog to digest twice as much starch in addition to the bread-albuminate consumed; but he could not fully digest even the quantity consumed.

Assuming that the dog fed with bread gives off as much nitrogen as intestinal secretion in the fæces as the dog fed with meat, and calculating from this quantity of nitrogen, it would appear that the dog digested the bread-albuminate to within $6\frac{1}{2}$ per cent.

Comparing the ration of pure vegetable diet, which wlll maintain a man in a state of perfect ability to work, with that which a dog can digest, the difference in their capacity of digestion at once becomes apparent. A wood-cutter receives from his employers when he goes after breakfast on a Monday into the forest, 3·4 pounds of dripping, 7·8 pounds of meal and 4·5 pounds of bread. He comes home on Saturday evening to supper. This quantity of food is, therefore, sufficient for five days, it represents—when the starch is calculated as fat and the bread as meat, 100 meal = 140 bread, in which there is 8 per cent. albuminate—a daily quantity of:—

Flesh,	Fat,
540 grams.	626 grams.

Taking the weight of the wood-cutter as double that of the dog or 68 kilograms, he would receive in his meal and fat diet nearly the same quantity of meat as the dog, but $2\frac{1}{4}$ times as much respiratory material. It is this that is deficient in the case of the dog, and this is what must be supplied from its body. The wood-cutter provides himself also with a portion of baked fruit, certainly not merely for the sake of his palate, for he thus increases the quantity of alkalies in his food. These wood-cutters work steadily, but not rapidly; they are powerful and have a good muscular development.

Experiments with dogs are evidently destitute of any practical value for judging as to the nutritive power of vegetable food, and it is in no degree more possible to test the value of meat-extract for improving vegetable diet by experiments on carnivorous animals, for in their case we have no measure of the capacity for work. The addition of meat-extract to the meal diet of the wood-cutter would have exercised an entirely different influence in regard to his power of working.

The statistics of consumption of food among the Bavarian wood-cutters, which I have received from trustworthy sources, disprove the very general opinion that these people are capable of hard work with a diet consisting chiefly of sugar and bacon. Opinions of this kind are, from a scientific point of view, not worth consideration.

them, with the roots extending into fine cracks in the rock, and covered only with moss and a thin layer of earth consisting of accumulated dust. In this case a supply of carbon by humus was quite out of the question.

There is no deficiency of similar facts which afford indications of the laws of nutrition, all that is required is the inclination to see them.

It appears to me almost inconceivable that the high value which a French family sets upon the *pot au feu* should be merely due to fancy or prejudice, nor can I believe that one of the most distinguished men in the medical department of the army should venture to say, "Soup makes the soldier,"* if he was not fully convinced as to the high efficacy of meat broth mixed with the necessary vegetables, while we know this is a form of food which the French soldier frequently prefers even to meat.

Is it possible to believe that the enthusiastic praise bestowed upon the extract of meat as a means of strengthening wounded soldiers by two of the most celebrated members of the French Academy, thirty-six years ago, before extract of meat was an article of commerce, could have rested only on imagination, or that the opinion expressed by these two men was not based upon extensive experience ?†

Daily experience teaches us that a decoction of peas, fat and salt is inferior in nutritive power to pea-soup made with strong meat broth. Their effects are also different in every way, and the difference is decidedly in favour of the soup prepared with meat. Nevertheless, it is only to the extractive constituents of the meat, and not the albuminous portion of it, that this difference is due.

Since my investigation of the chemistry of flesh in 1847, I have incessantly endeavoured to make the surplus meat-supplies of South America and the Colonies available in the form of extract for the population of Europe; and it is a most remarkable circumstance that now, when my endeavours are at length being realized, a question is raised by some medical men as to the efficacy of meat-broth, and, for the first time, this is being disputed, as if the idea were a novel one that had not previously been heard of. However, there are always individuals who cannot pardon the success of others, who consider it quite proper that those who benefit mankind with useful inventions should be persecuted, and that the fruits of their labour should be disparaged.

This is an old experience. "My case," says Göthe, "should verify the old proverb, that if one has rendered the world a service he will have learnt to take care he does not do so again."‡

Medical men have never troubled themselves about the meat-lozenges (tablettes de bouillon), which have been an article of commerce for half a century, and though represented to be extract of meat, are really nothing but gelatine.

It appears to me that progress in the doctrine of nutrition, in pathology and in therapeutics is, in the first place, dependent upon the application of the fundamental laws of mechanics, which obtain in the animal organism and throughout nature in reference to motion and work.

* Dr. Baudens, "Une Mission Médicale dans la Crimée," *Rev. des Deux Mondes*, vii. 1857.

† Parmentier was General Inspector of Health during the Revolutionary War; Proust was through the whole Spanish war.

‡ Eckermann, "Conversations with Göthe."

The greatest hindrance to the appreciation of, and insight into the actions of the animal machine, is the constant confusion of the physiological sense of power with actual power.

One of the most distinguished medical investigators considers "that the food consumed strengthens much sooner than the actual digestion takes place, and that by the absorption of a very small quantity of material into the blood a stimulus is produced sufficient to overcome or reduce the state of fatigue; in this way may be explained the fact that a drink of fresh water, a glass of wine, beer, or spirits, appears for a time as powerful a means of restoration, or even more so, than a beef steak."

It is true that even the smell of a roast joint makes one forget fatigue; but it seems going too far to make us believe that thirst and hunger are identical conditions. A draught of cold, fresh water is doubtless in the case of thirst a stronger restorative than roast beef, while in the case of hunger roast beef is a stronger restorative than a glass of water. Spirits or wine stimulate but do not strengthen; a whip would do the same. It may happen that a man has to work immediately after taking his meal, but he does not do so willingly; the rule is that a labourer should rest after his meal-time for an hour, and it is only after several hours that he becomes again capable of intense exertion.

(*To be continued.*)

NOTE ON THE CONSTITUTION OF ALBUMEN.

BY J. ALFRED WANKLYN.

M. Béchamp has recently repeated his statement that urea is obtainable from albumen by means of permanganate of potash, and has published details which seem to leave little doubt on the subject. The fact that urea is itself oxidizable by permanganate of potash will go a long way towards explaining the failures experienced by other chemists in their attempts to get it from albumen.

Some results obtained by Chapman, Smith and myself, in the course of investigations undertaken for the purpose of establishing the ammonia method of water-analysis, would seem to indicate that urea exists ready formed in albumen; or rather that albumen is, like creatine, a compound wherein urea and something else are joined together, with loss of the elements of water.

When albumen is mixed with aqueous solution of caustic potash and then dried-up in the oil bath, it yields one-third of its nitrogen in the form of ammonia, the remaining two-thirds being obtainable as ammonia on boiling the dried-up mass with a solution of permanganate of potash. But, if the preliminary evaporation to dryness with caustic potash be omitted, the action of strongly alkaline permanganate of potash converts only two-thirds of the total nitrogen of albumen into ammonia.

Now, a caustic alkali converts urea into carbonic acid and ammonia; but permanganate of potash oxidizes it, so as to yield no ammonia, the nitrogen in this case making its appearance either in the state of gas or as nitric acid.

So likewise in the case of creatine, one-third of its nitrogen is evolved as ammonia when permanganate of potash is employed, and in creatine one-third of the nitrogen is present in a form other than urea, while two-thirds of it exists as urea.

It would, therefore, appear that one-third of the nitrogen in albumen exists in the state of urea, while the remainder is in some other state of combination.

ON THE DISCRIMINATION OF FIBRES IN MIXED FABRICS.*

BY JOHN SPILLER, F.C.S.

In the course of an experimental inquiry undertaken for the purpose of identifying the fibres entering into the composition of mixed fabrics, the author was led to the discovery of the fact that silk alone, of all the materials ordinarily used in the production of textile fabrics, is soluble in concentrated hydrochloric acid. The chemical properties of the silk solution so prepared were described, and a photographic application pointed out by the author, who exhibited in this connection a matt paper print, which was stated to have been produced in a much shorter time than that commonly required for an ordinary print on a plain salted paper. A hydrochloric acid solution of silk was used, which, being made as concentrated as possible and neutralized by addition of ammonia, furnished a new organic chloride, particularly suitable for salting paper intended for solar camera enlargements. For the purpose of identifying wool in the presence of cotton, flax, jute, etc., it is recommended to immerse the fabric or loosened fibres in a warm aqueous solution of picric acid, which dyes the wool of a bright yellow without imparting any colour to cotton. Thus, by treating a mixed fabric successively with hydrochloric and picric acids, valuable indications are afforded regarding its constitution.

BEECH MORELS.

BY M. C. COOKE, M.A.

There are five or six species, forming a genus of fungi peculiar to the southern hemisphere, most, if not all, of which are available as food. These are the beech morels, or *Cyttaria*, first made known to science by the Rev. M. J. Berkeley.

All the species hitherto discovered have occurred on beech-trees, each one, with but a single exception, on a separate species of beech. Their geographical limit is confined within a narrow zone, enclosed between the parallels of lat. 30° and 60° S. Four of them are South American, two having been collected in Chili, one in Tierra del Fuego, and one at Cape Horn,—one species being indigenous to Tasmania.

DARWIN'S BEECH MOREL (*Cyttaria Darwinii*, B.) occurs on *Fagus betuloides*, in Tierra del Fuego. Small specimens, half an inch in diameter, are globose, but depressed above and below, so as to resemble a little button mushroom, strongly umbilicate below, with the edges of the umbilicus slightly puckered, and supported by a short brown stem, one and a half lines high and two lines thick, which proceeds from the umbilicus, and is granulated like shagreen, as if beset with a small black parasitic *Sphæria*. The epidermis is tough, very smooth, and shining. A vertical section presents a brown fibrous mass springing from the stem, which gives off on every side elongated radiating fibres, divided from each other by a dark line, but which do not easily separate from one another. The divisions of the internal mass towards the circumference are more minute, but well marked, and the epidermis quite distinct. In a more advanced stage of growth, when the balls are from one to two inches in diameter, the cups begin to appear, the interior presenting in other respects nearly the same appearance as before, except that the divisions are larger. They are formed beneath the cuticle, and are at first covered by a portion of the matrix. The cuticle becomes depressed, though still tough and thick. The hymenium is separable in a body from the surrounding substance, except at the top. The cells or cups themselves are ovate, lined almost to the top by the hymenium. The substance interposed between the top of the cells and the cuticle is gradually absorbed, and the cuticle itself becomes thinner and tightly stretched over the cavity, and at length bursts and forms a membranous border to the irregular orifice. The margin appears to be a little reflected. The hymenium consists of very slender paraphyses, and abundant large, slightly flexuous asci, which contain eight sporidia, mixed with a few globose granules. The asci at length become free, in which case they are generally slightly swollen at the base, and at last, in old specimens, there is scarcely any trace of them in the hymenium, which consists of paraphyses only. When the cups are quite formed, and perforated, the cellular arrangement of the contents of the balls has wholly vanished, and there are only a few faint radiating lines in place of the regular divisions. The whole substance is composed of branched, more or less flexuous threads. Occasionally the stem is not at all distinct, and the general form less globose, probably from the individuals having grown more deeply in the fissures of the bark. Mr. Darwin states further of them, "They are of the colour of the yolk of an egg, and vary in size from that of a bullet to that of a small apple; in shape they are globular, but a little produced towards the point of attachment. They grow both on the branches and stem, in groups; when young they contain much fluid, and are tasteless, but in their older and altered state they form a very essential article of food for the Fuegian. The boys collect them, and they are eaten uncooked with fish. Some of these balls remain on the trees nearly the whole year."

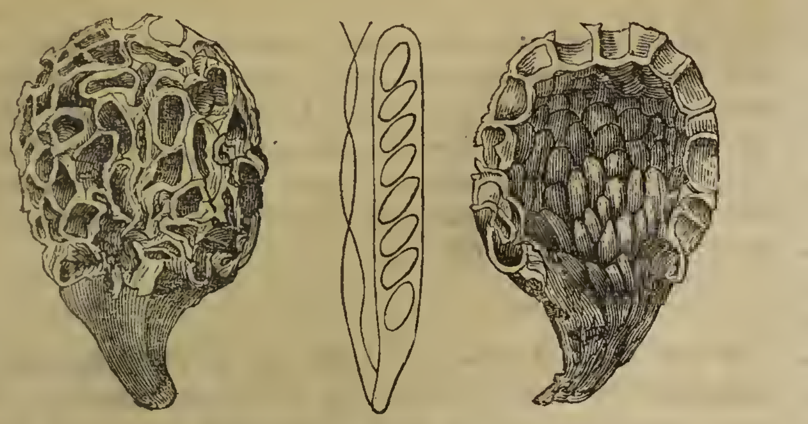
BERTERO'S BEECH MOREL, *Cyttaria Berteroi*, B.—Of a paler colour than the last, from an inch and a half to three inches in diameter, not regularly globose, but lengthened at the base. Cups large, three-tenths of an inch or more broad; aperture more or less decidedly pentagonal, bordered by the revolute margin, which is split into portions corresponding with the sides of the aperture. Asci more slender and longer than in Darwin's Beech Morel; sporidia elliptic, smaller, separated by a granular mass. The flesh in the full-grown plant is mottled, consisting of branched, flexuous filaments. There are a few black granules about the base. On *Fagus obliqua*, in Chili.

This species was first noticed by Bertero, and afterwards found by Mr. Charles Darwin, who says, "I found a yellow fungus very closely resembling the edible ones found on the beech at Tierra del Fuego. Speaking from memory, the difference consists in these being paler coloured, but the inside of the cups of a darker orange. The greatest difference is, however, in the more irregular shape; in place of being spherical, they are also much larger. Many are three times as large as the largest of my Fuegian specimens. The footstalk appears longer; this is necessary from the roughness of the bark of the tree on which they grow. They are occasionally eaten by the poor people."

TASMANIAN BEECH MOREL, *Cyttaria Gunnii*, B.—This is found on living branches of *Fagus Cunninghamii* and *Fagus Gunnii*, in Tasmania. It grows in tufts or clusters on swellings of the branches, at first pear-shaped, and without any distinct stem, becoming afterwards more decidedly globose and hollow. In size this species attains from one to two inches in diameter, closely studded with the cups, which are numerous, and have broad, irregular orifices. The asci are rather short and cylindrical, each containing eight broadly elliptical sporidia. The hymenium very speedily becomes obliterated.

* Read in Section B. of the British Association, on Friday September 16th.

This fungus abounds in the dense forests to the westward in Tasmania, and was freely eaten by the aborigines



Cyttaria Gunnii, Bert.

in their wild state. It has also a reputation amongst the settlers for its esculent qualities.

Hooker's Beech Morel, *Cyttaria Hookeri*, B.—Found on the living branches of *Fagus antarctica*, at Cape Horn. The common receptacle does not exceed an inch in height, with a diameter of from half to three-quarters of an inch, attenuated at the base, and obtusely papillæform at the apex, universally smooth. The cups are few in number, at first filled with a gummy matter, and at length empty. The asci are somewhat linear, intermixed with linear, sometimes forked, paraphyses. Whether this small and rather singular species is at all used as an article of food has not apparently been ascertained.

Chilian Beech Morel, *Cyttaria disciformis*, Lev.—The smallest species yet discovered, scarcely exceeding a quarter of an inch in diameter. It is flattened like a button, with a convex upper surface, on which are scattered a few point-like cells at some distance from each other. These cells have, at present, only been found to contain long filaments, with a layer of compressed cellules, terminating in globular swellings, each of which contains an opaque and irregular body. Of course this species, which is found in Chili, is too small to be of any value as an esculent.

Allusion having been made in a previous number of this Journal to esculent fungi, it has not been considered out of place to give a short account of these singular Beech Morels of the south. As food products, they do not seem to differ much from our own Morels, although botanically and generically distinct. Unfortunately, we have very little information regarding their edible qualities beyond the fact that they are employed as food. No medicinal virtues appear to have been assigned to them. It is a remarkable fact that the practice of eating some species of fungus seems to be almost universal in all countries where fleshy fungi are found, and in all to be confined to a very few species. Only very recently we have been enabled to identify the Morels which are eaten at Kashmir, and much still remains to be learnt of the esculent fungi of other parts of the world. Certainly some are esteemed in Persia and other parts of Asia, of which we know nothing. In the course of time we hope to record something of these; meanwhile, we wait and hope.

MUSTARD.

BY M. COMMAILLE.

White mustard possesses medicinal properties which are very difficult to be explained. Our knowledge of its chemical composition, like that of many other organic substances, leaves much to be desired. Let us glance first at the actual state of science concerning this substance.

White mustard, *Sinapis alba*, belongs to the important family of the *Cruciferæ*, which furnishes products for use in medicine, food and the arts. Like all its congeners, it contains sulphur among its constituent elements, which sulphur readily manifests its presence when putrefaction takes hold of a plant of this family.

It is admitted that one part at least of the sulphur present in the crucifers, and consequently in white mustard, is in a form which gives easily hydrosulphocyanic acid, represented by the chemical formula $HCyS_2$, or HC_2NS_2.

This acid is rich in sulphur, containing 54 per cent. of its weight, and is very poisonous in its free state. It was discovered by Kinck in 1804. The same acid is met with normally in human saliva.

In white mustard the hydrosulphocyanic acid is combined with a particular base, sinapine, which has not yet been obtained in the dry state. When attempts are made to do so, it splits up into an acid, sinapic acid, $C_{22}H_{12}O_{10}$, and a new base, sincaline, $C_{10}H_{14}NO_2$. But as the formula for sinapine is $C_{32}H_{24}NO_{10}$, it follows that in the separation it has taken up two equivalents of water. The sinapine, it will be observed, is not sulphurized, but is nitrogenized, as are nearly all the organic alkalies. It gives well-crystallized salts. The formula for sulphocyanate of sinapine is $HC_2NS_2 . C_{32}H_{24}NO_{10}$.

Black mustard, *Sinapis nigra*, is distinguished from white mustard by the absence of sinapine. The sulphocyanic acid is also found there united to another substance, allyle, which exists also in garlic. It is an alcoholic radical, of which a great number of combinations are known. The sulphocyanate of allyle is represented by $C_2NS_2 . \underbrace{C_6H_5}_{\text{allyle.}}$. It is much more rich in sulphur than the sulphocyanate of sinapine.

This difference explains how it is that white mustard in contact with water gives off, upon putrefaction, an odour, disagreeable no doubt, but very far from the horrible stench given off by black mustard under the same conditions.

But the sulphocyanate of sinapine does not pre-exist in the white mustard any more than the sulphocyanate of allyle in the black. They are both the result of a reaction between the natural principles of these seeds in contact with water by a fermentation that is developed very quickly. So likewise the odoriferous and sapid principle in black mustard, which is so well known, the volatile oil, is produced by the action of a certain substance named myrosine upon the myronic acid combined with the potash in the seed.

The myronate of potash ought, according to MM. Will and Kœrmer, to be considered as the essence of mustard, sugar and the acid sulphate of potash. Thus, we have—

$$\underbrace{NC_{20}H_{18}O_{20}S_4K}_{\text{Myronate of potash.}} = \underbrace{C_8H_5NS_2}_{\substack{\text{Essence of mus-}\\ \text{tard or sulpho-}\\ \text{cyanate of allyle}\\ =C_6H_5C_2NS_2.}} + \underbrace{C_{12}H_{12}O_{12}}_{\text{Sugar.}}$$

$$+ \underbrace{KO . SO_3HOSO_3}_{\substack{\text{Acid sulphate of}\\ \text{potash.}}}.$$

A fermentation, possible only in the presence of water, is absolutely necessary in order that black mustard may acquire its pungent properties.

Further research is necessary upon this subject, since, according to received opinions, fermentation is never produced except under the influence of organized living bodies. Now, myrosine, the presumed ferment of mustard, does not fulfil this condition. However that may be, myrosine is met with in white mustard, but myronic acid is not, hence the absolute impossibility of its furnishing essence of mustard. Myrosine in the presence of water and sinapisine gives a principle very different from the essence of black mustard. This principle is the sulphocyanate of sinapine before spoken of.

Sinapisine, discovered by MM. Henry and Garot, is sulphurized, crystallizable and soluble in alcohol. It is a crystalloid, like myronic acid; whilst myrosine, which does not crystallize, and is coagulated by alcohol, warmth or acids, like other substances that approximate to albumen, is a colloid.*

To finish this brief history of the chemistry of mustard it may be added that the white contains much mucilage, and that its ash contains 10 per cent. of sulphate of potash, arising from the destruction of the sinapisine.

If now we take advantage of the knowledge previously acquired, we shall be enabled perhaps to raise a corner of the veil which has hitherto hidden the mysterious therapeutic virtues of white mustard.

The purgative properties of this seed have been explained as a mechanical action of carrying through and expulsion,—a sweeping of the intestine. The purifying properties have been attributed to the presence of sulphur and to a specific action which, considering the integrity of the mustard in the fecal matter, is not very clear.

If we examine a mustard-seed by the eye or under a microscope, we see that it is nearly round, scarcely wrinkled at the surface, neither very large nor very small. Left in cold water, it soon becomes ropy and very mucilaginous, acquiring a perceptible, but not disagreeable, flavour. The action of warm water produces this result much more rapidly. The seeds then roll one upon another with the greatest facility.

It is to these peculiarities that it appears in part to owe its purgative property. Seeds of larger size, the surface of which could not be acted upon by the liquids of the stomach and intestines, might, without doubt, purge more or less, but would greatly fatigue the organs, which could not support a large quantity of them; besides, the total surface being much less, the mucilaginous principle would be dissolved in smaller quantity.

Very small seeds, like the poppy, for instance, would be often arrested in the long course that they have to run; soon the whole intestinal passage would be covered, and there would be no progression of the mass. Black mustard, independently of its very irritating properties, is too small.

The extreme readiness with which white mustard gives with water an abundant mucilage (for which reason that having a thin perisperm should be chosen) adds to the facility, already very great, of the movement of the seed due to its convenient size and round form. Until the contrary is proved, it would appear that it is to this union of properties that white mustard owes its value as a purgative.

The depurative properties of this seed do not appear so easy to explain, since it is rejected in the excreta apparently without having undergone any modification. But this appearance is deceptive. The penetration of a liquid into seeds which have not a thick perisperm is easy. By osmose a very rapid exchange takes place with uncontrollable force, between the liquid charged with the soluble substances of the seeds and the liquid that surrounds them. Moreover, we know by the law which governs dialysis, which has been so well explained by the late Mr. Graham, that membranes allow crystalloids to exude easily (sinapisine is a crystalloid) while they retain colloids (myrosine is a colloid). It is not impossible, then, that sinapisine should be rapidly carried off from the mustard-seeds, although they remain intact, to be absorbed by the liquids of the digestive canal, and transferred by assimilation into the entire organism. That the sinapisine should be carried off as such, or that it should be transformed beforehand into sulphocyanate of sinapine, would matter little, sulphur being found in both substances.

Sulphocyanate of sinapine is, without doubt, an energetic poisonous principle, but it is among such substances we find the most medicines. It is only necessary that the doses should be so suitably apportioned, that they may not accumulate in the stomach, and that the elimination or destruction should keep pace with the administration of a fresh quantity, without which there would soon be symptoms of poisoning.

The less energetic character of black mustard, and its apparent inertness when employed as a condiment, should not be quoted in opposition to these views; for there the sulphocyanic acid is not combined with a base but with an alcohol radical, forming the sulphocyanate of allyle, a very irritating substance; not a salt, but an ether,—that is to say, a substance absolutely different.—*Journal de Pharmacie et de Chimie.*

* See the researches of M. Bussy and MM. Boutron and Frémy upon myrosine, myronic acid and sinapisine.

Fire and Loss of Life at a Wholesale Chemist's.—A fire, involving a serious destruction of property and the loss of four lives took place on Tuesday afternoon last at No. 30, Liverpool Street, Bishopsgate Without. The premises in which the disaster took place were occupied by Mr. John Bush, wholesale chemist, and were of considerable extent, consisting of stores, packing-rooms and receiving offices. Whilst the hands were employed on the ground floor packing goods, some one in the warehouse gave the alarm that the place was on fire. At that time only a slight blue glimmering light could be seen at the end of the warehouse, and those present, instead of at once sending across the road to call the engines, tried with the aid of buckets of water to subdue the fire. The flames, however, soon reached the bottles of tinctures which were on the shelves, bursting and then seizing on the carboys of spirits. On the first floor two females and a lad were employed in cutting and preparing labels. These poor creatures were either blown into or took refuge in a cupboard, where they were found dead, shrivelled up and burned in a dreadful manner. Mr. James Woolley, the manager, was suffocated by the fumes of the ignited chemicals while making an effort to save the other people employed on the premises, as well as his wife, who was in the first floor. His wife, who was with difficulty rescued, was in such a state as to necessitate her immediate removal to the hospital. The fire was not extinguished until that part of the building where it had originated was considerably damaged.—*Times.*

Adulteration of Saffron with Chalk.—M. Constantin, of Brest, has pointed out this adulteration in the August number of *L'Union Pharmaceutique.* The sample he examined was obtained from a drug house of good repute, but it contained as much as 15 per cent. of chalk. The observations of Mr. Hanbury and Professor Maisch, to the same effect, would appear to indicate that this adulteration is extensively practised.

University of Edinburgh.—It is announced that Professor Allman is about to resign the chair of Natural History in the University of Edinburgh, which he has held since 1855, on account of ill-health. It is also said that Sir Roderick Murchison has resolved to give £6000 towards the endowment of a chair of Geology and Mineralogy in the University, if the Government show equal liberality in the matter.

Puff-Balls for the Wounded.—It has been suggested that dry puff-balls, which are frequently used in some country districts for stanching blood, might be employed with advantage in the place of lint for dressing the wounds of the sufferers in the war. They possess the property of adhering closely to the wound, which is rather a merit, perhaps, when it cannot be frequently dressed, and at present they might be obtained in great abundance.

Hydrochlorate of Quinine in Whooping Cough.—Dr. Breidenbach calls attention to the benefit that may be derived from this remedy when other means have failed. It requires to be administered in comparatively large doses. To a child of three weeks Dr. Breidenbach gave a grain and a half per diem; and to one of eight years as much as fifteen grains per diem.—*Lancet.*

The Pharmaceutical Journal.

SATURDAY, OCTOBER 1, 1870.

PHARMACY AND MEDICAL PRACTITIONERS.

Where could our good friend the Editor of the *Lancet* have been when the article on "Pharmacy and Medical Practitioners" found its way into his columns on the 17th ult.? Off to the wars or, it may be, to the British Association for the Advancement of Science. Clearly a spirit quite new to our contemporary guided the pen of the writer when, after descanting on the enormity of a chemist receiving as much as "2*s.* 6*d.* or 3*s.*" for dispensing a physician's prescription, he discovered that at such a rate the patient's "drug bill is equal to, or even exceeds, the doctor's bill."

On reading the first half of the article in question, we certainly felt its statements to be, in the main, correct, and that the duties of the dispenser should be separated from those of the prescriber. We do not, however, agree that the preparation of drugs is "a mechanical thing, to be done by a pupil in his second year," but believe rather in the other proposition, that it is "a matter of pharmaceutical chemistry," and for that very reason we are astonished at the complaint afterwards made against us.

Pharmaceutical chemistry is a science requiring brains as well as industry and application for its acquisition, and if we cannot say that a pharmacist should be paid for "opinion" as the doctor is, we do say unhesitatingly that he should be remunerated for skill in addition to the bare price of the drugs he is called on to compound. He does not expect the statutable 3*s.* 6*d.* for a six-ounce mixture, which an apothecary demands, but he surely cannot be accused of extortion in charging at most half as much, and very often as little as one-third. We know not what may be the nature of the writer's prescriptions; he begins by saying the drugs must be good and in sufficient quantity. Does he ever see a mixture ordered to contain ½ a drachm of quinine and 2 or 3 ounces of tincture, to be taken in teaspoonful doses; enough of it prescribed to last the patient ten or twelve days? Does he reflect that if the profit on drugs were calculated on the same scale as on the common necessaries of life, there is not a chemist in the whole kingdom who could keep his doors open? The butcher's bill of a week would in many families be equal to the chemist's of a year, and, without disparagement to the former, we may say that the latter must be a man of superior education; in attaining that education he must have expended a certain amount of hard cash, and worked for four or five years of his life without remuneration; that being an educated man, called into communication with his customer in a somewhat confidential manner, he must at least maintain a respectable position in society. As a rule chemists are "not paid at once over the counter," but have to wait at least as long as doctors for their money.

We will tell our friend what would be the effect of such a reduction of charges as he proposes. The chemist would be driven more and more, in self-defence and for mere maintenance, to "feel pulses over the counter, even the pulses of affluent ladies," and seeing so many more prescriptions (as of course, according to the new system he would do), would be still better qualified than he now is to play the part of the doctor, which we agree with the *Lancet* in thinking he should never undertake.

Perhaps, too, even the affluent ladies might, with their poorer neighbours, imbibe yet greater faith in his skill and experience, and be even more inclined to consult him by reason of his moderate charges.

SANDFORD TESTIMONIAL FUND.

At the request of the Honorary Secretaries we have great pleasure in announcing to the subscribers to the above Fund, that the portrait of Mr. Sandford, which forms part of the testimonial, will be handed over to the Pharmaceutical Society at their Evening Meeting on Wednesday next.

At the present time, when the subject of pharmaceutical education is attracting so much attention, we think the discussion on the general subject of education at the meeting of the National Association for the Promotion of Social Science worthy the notice of our readers, especially with reference to the preliminary education of apprentices, and have therefore given a brief report of the proceedings on a subsequent page.

We are given to understand that the subject of the Betts' suits was not brought before the Pharmaceutical Conference at their late meeting on account of its being considered by several members of the Conference Committee to be purely a trade matter, and one foreign to the scope and object of the Association.

The Thursday evening meetings of the London Chemists' Association will be recommenced on the 6th of October, when an address will be delivered by Mr. J. Sands, the President.

At King's College the Introductory Lecture of the medical session will be given by Professor Wood, F.R.C.S., on Monday, October 3rd, at 3 P.M.

M. E. Gonod, Secretary of the Executive Committee of the French Pharmaceutical Congress, has informed his colleagues that on account of grave events which occupy the minds of all, it has been judged impossible to hold the meeting at Clermont-Ferrand at present, and it is accordingly adjourned until further arrangements can be made.

A letter has been addressed to the Editor of the *Daily Telegraph*, signed by Mr. Berkeley Hill and Mr. Ernest Hart, disputing the truthfulness of the statement made by a special correspondent of that journal concerning the medical officers in connection with the International Society, "that in no single military ambulance have any of these amateur medical assistants taken off their coats, so to speak, and gone to work like men at what they are engaged to do." Messrs. Hill and Hart give it as their opinion, founded upon personal observation, that, although there is a great want of organization, consequent upon the sudden and marvellous development of the Society's resources, and the entire absence of any previous machinery for the purpose, the conduct of the medical officers in the service of the British Society has been beyond praise, and characterized by the purest motives, as well as the most devoted zeal. A large number of Fellows and Members of the College of Surgeons, and Doctors of Medicine, sinking all distinctions, have willingly devoted themselves to dressers' work. There is a crowd of loafers wearing the red cross, but it is not believed that if their badges were examined any one of them would be found to bear the stamp of the International Society, or to be directly attached to the foreign ambulances.

The publishers of the American reprint of the *Chemical News* have decided to discontinue that publication, and in its place to offer to all interested in the progress of chemistry a new journal, entitled *The American Chemist*, to be devoted to theoretical, analytical, and technical chemistry.

The *Lancet* announces the failure of an experiment made to test the method proposed by Professor Gamgee for the preservation of meat. Two cases, a cask and an iron cylinder, to all appearance securely packed and thoroughly air-proof, were opened at the Melbourne Custom House in the presence of members of the Intercolonial Conference and others interested in meat-preservation. On the iron cylinder being opened, gas burst out with a hiss and immediately affected the organ of smell most powerfully. The meat in the cases also was in a putrid state. The whole consignment, weighing 527 lbs., was disposed of to the tallow-melters at 1*d.* per lb.

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

The following contributions have been received since last week:—

	£.	s.	d.
Wm. Bray, Buntingford	0	5	0
J. D. Fisher, Halifax	0	5	0
J. S. Robinson, St. Leonards-on-Sea	0	5	0
R. Rowe, 40, Alfred Pl. West, S. Kensington	0	10	6
Septimus Piesse, New Bond Street, for purchase of medicines for the sick and wounded French only	50	0	0
W. H. Stickland, ,, ,, ,,	2	2	0

Collections per Mr. I. H. Evans, Lymm:—

	£.	s.	d.
Edwin Brown	0	5	0
R. Dutton	0	2	6
J. Edwards	0	1	6
I. H. Evans	0	4	1
Thomas Hind	0	1	0
Charles Leech	0	2	6
Peter Mairs	0	2	0
Thomas Pearson	0	2	6
William Pearson	0	2	6
Miss Sharp	0	2	6
James Warburton	0	2	6
P. Warburton	0	1	0
George Watson	0	5	0
			£1 14 7

The above £1. 14*s.* 7*d.* was spent in the purchase of calico, etc., which was made into the following by Mr. and Mrs. Evans:—

28 cholera belts, stout flannel.
14 bandages, cotton, 10 yds. × 4 in.
41 ,, ,, 8 ,, × 3 ,,
20 ,, ,, 6 ,, × 3 ,,
24 ,, ,, 4 ,, × 3 ,,
19 ,, ,, 4 ,, × 2 ,,

I. H. Evans, Lymm:—
6 2 oz. bot. tinct. opii.
6 2 oz. ,, spt. ammon. co.
2 8 oz. ,, liq. ammon. fort.
1 8 oz. ,, chloroform.
6 gross pil. opii gr. i in bots. 4 doz. each.
3 ,, ,, quiniæ gr. ij ,,
3 ,, ,, morphiæ gr. ¼ in bots. 6 doz. each.
2 tins extract of meat biscuits.

J. Middleton, Middleborongh-on-Tees:—
20 lb. of lint.

The Food of the Armies.—The Germans appear to be a more hardy race than their opponents. They can eat black bread, the issue of which had to be prohibited among the French prisoners on account of their inability to digest it. *En passant*, we may state that the Germans have practically managed to solve for themselves the difficult problem of an economical and compressed ration for field purposes. Their soldiers, we read, on several occasions during forced marches consumed a diet composed of mixed peas and meat—a highly nitrogenous but not very digestible compound. The Rhine wines were always consumed where they could be procured, and we do not hear of a rum or spirit ration being issued, as in our army. The craving for tobacco exhibited by the troops, and their almost universal use of it, corroborate the opinion entertained by practical men that the consumption of tobacco is of real value to men undergoing the hardships of physical exertion incidental to a campaign.—*Lancet.*

Provincial Transactions.

CHEMISTS' DINNER, CARDIFF.

On Thursday, September 22nd, for the first time in the history of Glamorganshire, the chemists and druggists of the county sat down to dine together and inaugurate a personal intimacy and trade association amongst themselves. It was felt that the Exhibition of Fine Arts and Manufactures now being held in Cardiff, to which thousands are drawn daily from all the surrounding neighbourhood, was an opportunity not to be lost. Invitations were accordingly issued to about one hundred chemists throughout the county. The call, however, was not so liberally responded to as might fairly have been expected. To the honour of Pontypridd be it told that that town unanimously accepted the invitation, and subsequently furnished the chairman. All the chemists of the Rhonda Valley and Taff's Valley were also present, and Aberdare found a representative in Mr. Abel James. The majority of the trade in the town of Cardiff availed themselves of the opportunity of meeting their friends from the country. But it is to be regretted that such important towns as Merthyr, Swansea, and some others allowed the gathering to pass off without taking any part in it. The dinner was excellently served by Messrs. Cousins and Son at the 'Angel' Hotel, Cardiff.

The usual toasts, loyal, patriotic and clerical, having been duly acknowledged, the Chairman, Mr. CHARLES BASSETT, then gave "The Town and Trade of Cardiff," which was responded to by Mr. KERNICK, who from his long acquaintance with the town was well able to speak of its great and still rapidly-extending increase since the time when he came a stripling to assist the late Mr. Charles Vachell.

"The Outlying Districts" quickly brought Mr. JOHN JAMES, of Pontypridd, to his feet, who spoke well of the common interest each ought to feel in the welfare of the other, for whereas Cardiff would be nothing without the rich minerals of our hills and valleys, so those same districts would have ever remained unproductive but for the great outlet of our ports.

The CHAIRMAN then gave what may be called the toast of the evening, "The Pharmaceutical Society," and in speaking of the great opportunities held out by the Society, he gave some amusing anecdotes illustrative of the laborious trials and troubles of the apprentice in days gone by, and of the local peculiarities and nomenclature of the hill districts, which would completely baffle the scientific and successful student from Bloomsbury Square.

Mr. F. W. JOY, Hon. Local Secretary, responded, shadowing forth the great advantages offered to the rising generation of chemists, through the means of the Society, its well-appointed laboratory, courses of lectures and extensive library; he also enlarged upon the subject of the Benevolent Fund, which is open to any deserving distressed member of the trade, and strongly urged that each one should forthwith add his own name to the annual subscription list. Mr. Joy next spoke of the objects of the meeting, which he described as threefold, viz. the promotion of more personal and friendly intercourse among the members of the trade; the development and protection of trade interests, and though last, not least, the formation of some plan for the systematic education of the apprentices and younger assistants, which, since the passing of the Pharmacy Act, had become quite a necessity. He concluded by giving the health of the Chairman, the oldest member of the Pharmaceutical Society in the district, who had so ably presided at this their first meeting.

The CHAIRMAN thanked his friends for the honour they had done him. He had looked forward, he said, to the present meeting with some anxiety, for he considered in a town like Cardiff there were greater advantages for scientific pursuits than he could obtain in the country, and he felt considerable diffidence in occupying so prominent a position, but the kindly support he had received had so lightened his labours that he had never occupied the presidential chair with greater pleasure, and expressed his willingness to render the trade of the district all the assistance in his power on any future occasions.

The health of the "Vice-Chairman" (Mr. Joy), "Our Visitors" and "The Host," terminated a very pleasant and successful meeting.

NORWICH CHEMISTS' ASSISTANTS' ASSOCIATION.

A well-attended Meeting of the assistants and apprentices of the chemists in this city was held at the St. John's Rooms, on September 22nd.

Mr. HILL, having been unanimously voted to the chair, stated that the circular convening the meeting was issued by Messrs. Nuthall and Perkins. He therefore called upon those gentlemen to lay the first resolution before the meeting.

It was moved by Mr. E. NUTHALL, seconded by Mr. T. J. PERKINS, "That, in the opinion of this meeting, it is desirable to form an Association of Chemists' Assistants and Apprentices in Norwich, for the purposes of educational improvement and social intercourse; and that the said association be called 'The Norwich Chemists' Assistants' Association.'"

Moved by Mr. W. BUTLER, seconded by Mr. T. W. RICHARDSON, "That the affairs of the society be conducted by a President, Vice-President, Treasurer, Secretary, and a Committee of five, the President, Vice-President, Treasurer, and Secretary, to be *ex officio* members of the Committee."

Moved by Mr. E. MARTIN, seconded by Mr. P. H. MASON, "That Mr. Hill be elected President."

Moved by Mr. BUTLER, seconded by Mr. EKIN, "That Mr. Nuthall be elected Vice-President."

Moved by Mr. MASON, seconded by Mr. N. LINCOLN, "That Mr. W. Butler be elected Treasurer."

Moved by Mr. J. GOODENOUGH, seconded by Mr. R. BATEMAN, "That Mr. T. J. Perkins be elected Honorary Secretary."

Moved by Mr. NUTHALL, seconded by Mr. BUTLER, "That the following gentlemen form the Committee:—Mr. Canham, Mr. Ekins, Mr. J. Goodenough, Mr. N. Lincoln, and Mr. P. H. Mason."

Moved by Mr. BUTLER, seconded by Mr. T. J. PERKINS, "That the Committee frame a code of rules, to be submitted for approval to a general meeting of members, to be held within ten days."

After cordial votes of thanks to Messrs. Nuthall and Perkins for the active steps taken by them in promoting the formation of the society, and to Mr. Hill for his able conduct and courtesy in the chair, the meeting dissolved.

The greatest unanimity of feeling prevailed throughout, and at the close of the meeting the Secretary enrolled thirty-six members out of forty-two present.

The Wine Supply of Paris.—The *Pall Mall Gazette* says that if all the fermented liquors that pay the octroi duty are consumed in Paris, the inhabitants manage to dispose in the course of the year of no less than 365,000 tuns of wine—equal to forty-four gallons per head of the population, or almost a pint a day for every man, woman and child in the French capital; and this, too, in addition to 225,000 barrels of beer, nearly a couple of million gallons of cider, and more than that quantity of spirit. The authorities in Paris state that the water-supply of the city cannot be stopped by the Prussians; and the two immense depots which furnish France with wine are both within the line of the fortifications, and quite full. There appears, therefore, to be little fear of suffering from thirst, whatever prospect there may be of misery from starvation

Proceedings of Scientific Societies.

NATIONAL ASSOCIATION FOR THE PROMOTION OF SOCIAL SCIENCE.

Meeting at Newcastle-on-Tyne.

The Fourteenth Annual Meeting of the Social Science Congress was commenced at Newcastle-on-Tyne on Wednesday, Sept. 21, by a special service, at St. Nicholas Church, when a sermon was preached by the Rev. Canon Norris.

In the evening the Inaugural Address of the President, his Grace the Duke of Northumberland, was delivered in the New Town Hall to a very large assembly.

On Thursday the business of the Congress was commenced with an address by Mr. G. W. Hastings, the Chairman of Council, who said that in reviewing, according to annual custom, the work of the Association, the first place must be given to education, in respect of which the last session of Parliament had done so much to realize the hopes expressed at previous congresses. During the session the Education Committee had framed a report, many suggestions in which had been adopted by Government; and others which had been set aside would ultimately be demanded by public opinion. It recommended that public instruction should be placed under a minister of education responsible to Parliament, and until this was done the work of the department will never be carried on in the most efficient manner. Dr. Lankester and others have repeatedly urged the necessity for instruction in elementary physiology and the laws of health. Canon Kingsley had pleaded that physical science, and the use of the senses on objects immediately surrounding us, ought to form part of ordinary instruction. These suggestions are good, but practically of little avail unless we can improve the character of the teaching. Then we shall be prepared to take the serious step of deciding what was to be taught. At the bottom of the whole matter of improved school teaching there lies the question of the amalgamation of schools. At present the inspectors' return show a higher average of efficiency in large schools than small. It is better to have one school of 300 children than six of 50 each. The number of classes in the larger need scarcely be greater than in the smaller; but while the master in the small school will only be the superintendent of inefficient pupil-teachers, the large school will support an efficient master and a well-paid staff of assistants. The large-school system will do much to lift the profession of teaching from the dead dreary level which it now occupies, and give the country the services of a body of teachers made doubly efficient by the prospect of promotion. He advocated also the giving of scholarships and exhibitions in the national schools to carry the deserving boy into the secondary schools, and to let him start in the upward race with the self-respect of independence. He stated the object to be to enable any boy or girl, with the requisite ability and perseverance, to work his or her way from the parish school, or even the workhouse school, to the grammar school and the universities.

At the conclusion of the address the various sections assembled in their respective rooms to consider the questions coming before them. In the Education section, papers on the Amalgamation of Schools were read by Mr. Bourne and Mr. Imeson; and in the Health section there were papers on the methods of disposing of sewage and excreta, with a prolonged discussion. The usual Ladies' Conference assembled under the presidency of Lady Bowring. In the evening, Sir William Armstrong entertained a large number of the members of the Association at Jesmond Dene, and after the dinner there was a *soirée* in the Exchange Art Gallery.

On Friday the special question in the Education section was "By what means can a direct connection be established between the elementary and secondary schools and the universities?" Several papers were read on the subject, and in the discussion which followed, Mr. Pears, the General Secretary of the Association, said that Tasmania, with a population of 80,000, gave two scholarships to any British university the winners might select, the value of each scholarship being £200 a year for four years. According to the report of the Endowed Schools Commission, the money required for establishing a direct connection between the schools and the universities was already in existence, and he protested against the application of that money in simply providing education for the middle or upper classes. He suggested the continuation of the fee paid in the primary schools, but that every boy on reaching a certain standard—say, the seventh—should have the opportunity of passing for the same fee to the secondary or endowed school. After passing the necessary examination there, he should have the privilege of free admission to the university.

At the close of the discussion, Mr. R. S. Watson read a paper on the "Best Method of providing Higher Education in Boroughs." He pointed out that there is a great demand and need in large towns for opportunities of higher education. Most boys leave school at 16, and their education is supposed to finish, where it should, in any high sense, be beginning. If they go on with it afterwards, they do so alone and at great disadvantage. In all large towns professors should be provided, with sufficient salaries to admit of the class fees being very low, and classes for both sexes should be held in the evening, where those engaged throughout the day might carry out their studies in a systematic manner without reference to their position in life. A fund from which retaining fees could be paid, a greater number of highly trained teachers, and a connection with some recognized teaching body were required. Every large town should have an institution like Owens College, at Manchester. To the old universities, as the heads of education in this country, he looked for help in this matter. College fellowships might be converted into country lectureships, or the universities or individual colleges might contribute an annual sum towards the salaries of the professors, the borough to be benefited contributing an equal amount, and the professors being appointed by the university or college.

In the Health Department, Mr. Phillips Bevan, editor of the *Food Journal*, read a paper on "The Legislation to prevent Adulteration of Food and Drink." He said, that although it is one of our most important social questions, the apathy and ignorance of the public on the subject of adulteration is astonishing. As each person thinks that all others are mortal except himself, so he imagines that adulteration affects any class but his own; and although we acknowledge its prevalence, and cry shame when we read of any particularly bad case, the sensation is but momentary, and we go on our way as before. What is adulteration, and what does it mean? It means the lowering of the *physique* of the nation, the poisoning of the people, the deterioration of our constitution; and, morally, a fraud practised by the seller on the buyer, a cheating, to which we have become so callous that it has hardened our conscience for honesty in other and bigger things. The great difficulty in dealing with it is that the Government is so slow to move, and even men in high places practically defend it by declaring that it is not so bad as it might be, that the buyer must look to himself, and so on. It is also a very common argument that people bring adulteration on themselves by buying such very cheap articles—so cheap that they cannot be good for the money. But they do so in ignorance, and if the seller were compelled to label his goods with the names of the real ingredients, such as 'best butter mixed with starch, mashed potatoes, and horse-bone oil;' 'coffee, with bread-crumbs and sand;' 'tea, with iron-filings;' 'sugar, with chromate of lead;' 'beer, with salt and cocculus indicus,' it is not the least likely that their cheapness would tempt the buyer; and if a certainty of detection and punishment followed, we should find that the sellers would think twice before they offered such articles. It is strange that, in all our sanitary machinery, the food question and its purity have been so overlooked; but pure food is as necessary as pure air, good drainage, or wholesome water; and it ought not to be left to the philanthropist to remedy the evil, with the tolerable certainty that he will only get snubbed for his pains. It is a Government question, and it ought not to be the duty of a private member of the House of Commons to bring in a Bill. With a view to arouse public interest he had established the *Food Journal*, in conjunction with Messrs. Johnson, feeling that there was a great want of some public organ to discuss these matters; and so convinced was he that no Bill could properly be passed without the knowledge of the legislation which prevailed in other countries, that he applied to the late Earl of Clarendon for permission to address the various consuls on the subject. His lordship not only gave the permission, but evinced his great interest in the matter by requesting him to draw up a circular, embodying all the inquiries on food matters that he wished to make. A thousand of these were sent out by the Foreign Office to all the Consulates and Legations; and Earl Granville, who has taken up the subject in the same warm and earnest spirit as evinced by his predecessor, has forwarded for publication in the *Food Journal* a mass of valuable information, which has never before reached this country. To detail even an epitome of these answers would take up far too much of the time of the meeting. He would, therefore, only briefly touch on some of the main points of the first question of the circular, viz.:—'What legislative enactments at present exist in the country to which you are accredited respecting the adulteration of food and drink? Are these laws actively enforced, and how far do they appear to meet the evil?' Very valuable information came to us from the United States, in Mr. Thornton's report, which adverts to the difficulty of getting systematic information, even through the well-arranged machinery of official correspondence. The State legislation varies very much in the different States, some possessing no legislation at all, and others inflicting very severe penalties. Each State legislates independently, and, in so doing, often delegates the regulation of these matters to the various town or county authorities within its borders. As a general rule, the adulteration of alcoholic liquor is almost universal. The paper then sketched the punishments meted out to those who adulterate food and drink in Rhode Island, Vermont, Ohio, Indiana, Illinois, Missouri, Mississippi, Cincinnati, Georgia, and Texas, as well as in Prussia and Holland. It showed that severe fines and long periods of imprisonment are commonly enforced, and that there are places in which the penalties are whipping, and even death, if fatal results ensue. In Holland punishment is also provided for persons who manufacture or sell ingredients for adulteration; so that the flourishing business known in England as that of a brewer's or distillers' druggist must be there pursued under considerable disadvantage. It proceeded:—"Any fresh legislation on this subject should be compulsory in its character, and not permissive. All articles of consumption which are manufactured should have their ingredients declared, for there is a feeling prevalent among manufacturers, as for instance cocoa-makers, that as long as their articles contain nothing hurtful, they are at liberty to call them by the general name of cocoa. Still, a sophistication is, to a certain extent, a fraud, and every purchaser has a right to know what he is purchasing; and, although we might be safe in the hands of the largest and most respectable manufacturers, there is a considerable class of unprincipled makers who are not above taking advantage." Differences of opinion sometimes occur as to the relative hurtfulness of certain common adulterants, and an eminent authority had assured him that he had grave doubts as to whether alum was not a good thing instead of a bad one. He suggested that there should be a Food Sub-department formed, which should take cognizance of all food legislation and supplies. To it a board of two or three of the most eminent analytical chemists should be attached, who should examine and pronounce upon all disputed chemical questions, and whose opinion should be law. The sub-department should have the election of, and a certain amount of control over the county and borough analysts, whose appointment should be compulsory and not permissive; neither should it rest with vestries or corporations, many of the members of which are often largely concerned in adulteration. Inspectors should have power to visit and take samples from all dealers in articles of food, subject to certain checks, so as to prevent any risk of tyrannical domiciliary visits. They should also have the power of testing the supplies furnished to public bodies, such as union contracts, for guardians have frequently a habit of accepting tenders for food at a price at which the real article cannot possibly be supplied, as a London Union Board did the other day in the case of butter. In cases where a petty dealer declares his ignorance that the goods which he sells are adulterated he would make the onus of proving this fall upon him, and then it would be for the Food Sub-department to take the matter up and prosecute the manufacturer. In adulteration before importation, as in the case of the Maloo tea mixture, the department might well provide the machinery for setting consular and other influence to work to prevent it, and might also step in as the proper arbiter between conflicting interests. In this very case a great fraud on the public was allowed to go unpunished because the Customs could not legally forego the duty. As to offences, when proved, he was no believer in either a very small or a very large fine, but he would have no sliding scale at the option of the magistrate. For the first offence the penalty should be sufficient to make the offender smart in his pocket; for the second, he would double it, and have an *affiche* detailing the offence put outside his door, as also outside the door of the church, police-station and town-hall for a month. The case should also be advertised in the local papers at the offender's expense. For the third offence there should be imprisonment for one month, with hard labour. Adulteration is either a fraud or it is not, and it should be punished like any other cheating.

An interesting debate followed, in which Mr. Rawlinson, Mr. Godwin, Mr. Serjeant Cox, Dr. Farr and other gentlemen took part. The facts and arguments brought forward by Mr. Bevan were generally admitted and assented to, and resolutions were passed recommending local authorities to appoint analysts, whose duty it should be to examine food and drink at the instance of purchasers, and recommending the Council to take steps to secure an amendment of the law.

A paper was afterwards read by Mr. Daglish on "Local Boards of Health," and one by the Rev. H. Moule on "Earth Closets."

On Saturday the members of the Association assembled in the morning to hear an address from Dr. Lyon Playfair, the President of the Education Department. He expressed his opinion that with all its defects the Act of last session is an enormous stride in advance of the old system of contributory help under which schools multiplied but education slipped backwards. He complained, however, that it dealt with the quantity of education, but not with its quality. The improvement which was gradually being developed in the village schools had been thrown back by the State, which had made them mechanical manufactories, turning out no end of yards of the three R's, in standards one, two, and three, but very few in standards four, five, and six, because the latter do not pay. Dr. Playfair proceeded: even in the least productive of arts, that of war, a State is served by the universal education of her soldiers. The educational principle of Continental nations is to link on primary schools to secondary improvement schools. The links are always composed of higher subjects; the three R's being in all cases the mere basis. Elementary science, and even some of its applications are encouraged or enforced. Our primary schools do not teach higher instruction than a child eight years of age may learn. No armour-plate of knowledge is given to our future artisan, but a mere thin veneer of the three R's, so thin as to rub off completely in three or four years of the wear and tear of life. So, under our present system, no knowledge bearing on the work in life of the people reaches them as a result of State education. And yet we are surprised at the consequences of their ignorance. A thousand men perish yearly in our coal mines, but no schoolmaster tells the poor miner the nature of the gas which scorches him, or of the after-damp which chokes him. Boilers of steam-engines blow up so constantly that a Committee of the House of Commons has been engaged in trying to diminish the frequency of such explosions, but the stokers who are scalded to death or blown to pieces were never instructed in the nature and properties of steam. In Great Britain alone more than 100,000 people perish annually, and at least five times as many sicken grievously, out of pure ignorance of the laws of health, which are never imparted to them at school, and which, as they pass into no secondary schools, they have no chance of learning afterwards. Our pauperism, our crime and the misery they produce, increase terribly; and our panacea for their cure is teaching the three R's up to standard 3. Our large faith in our little doings will not remove mountains. Our low quality of education is impoverishing the land. It is disgracefully behind the age in which we live and the civilization of which we boast. In the schools prior to the Revised Code words instead of ideas were worshipped. The teaching of science is the reverse of all this, and will go far to remedy its defects. The whole yearnings of a child are for the natural phenomena around until they are smothered by the ignorance of the parent. Do not suppose that I wish the primary school to be a lecture-theatre for all or any of the "ologies." While I advocate the introduction of higher subjects into our schools I wish them to be of immediate interest and applicability to the working classes. Six months spent in teaching future labourers the wanderings of the children of Israel is sheer waste of time, as regards either their temporal or their eternal interests. If you bring up a ploughman in utter ignorance of everything relating to the food of plants, of every mechanical principle, of farm implements, of the weather to which he is exposed, of the sun that shines upon him and makes the plants to grow, of the rain which, while it drenches him, refreshes the crops around, is that ignorance conducive to his functions as an intelligent being made after the image of Him who has done all things wisely? In all the operations of the field, from the breaking-up and manuring of the soil to the harvesting of the grain, which of the two men would feel that he had the most noble education—the ignorant clodhopper knowing nothing that he is doing, the mere tool or slave of his master, or the worker, intelligent, and knowing his occupation, aiding nature to fulfil her wise laws, and by doing so feeling himself like St. Paul, and with his humility also, to be "a fellow-worker with God?" I have selected for illustration the occupation in which the working-man is now the least cultured and intelligent, but there is not a single craft which could not be dignified in a similar way. Let me, then, refer you to an example, scarcely known, as it is separated from us by stormy seas, but singularly instructive and significant. Those of us who have passed middle life recollect the chronic state of misery and poverty in the Scilly Islands, off the coast of Cornwall. In such a wretched condition were they that the inhabitants were only preserved from starvation during the winter months by constant contributions from the mainland. Now we never hear cries of distress from these islands, and for what reason? In 1834, Mr. Smith, who became their proprietor, undertook their improvement. He abolished the cottar system, consolidated holdings, founded good schools under a compulsory system of his own, and kept them up to the mark by constant inspection. He did not content himself with the three R's, but directed the instruction towards the occupations of an insular people. History, geography, the rudiments of mathematics, and navigation were taught to the children. And with what result? So much esteemed are the youths of the Scilly Islands as sailors that vessels sometimes stop there to procure them, and very frequently they rise to be mates and masters. Pauperism has vanished from the islands, so that it is difficult to find any of its population poor enough to accept the alms offered in the Communion Service. The well-educated population show a disposition to pass to the mainland, for they are much appreciated there, and receive high wages.

BRITISH PHARMACEUTICAL CONFERENCE.

Tuesday, September 13th.

Notes on the Cultivation of the Opium Poppy in Australia.

BY JOHN W. HOOD, CHEMIST, MELBOURNE.

This paper was communicated by Mr. T. N. R. Morson, together with the following letter addressed to the Chairman of the Liverpool Local Committee:—

"38, *Queen's Square, W.C.*,
"*September 10th*, 1870.

"My dear Mr. Abraham,—I this day send you the paper on Opium received last mail from Melbourne; it is a highly interesting paper, and at the present time a very important one. I have no doubt that very good opium can be produced in Australia, and at a reasonable price. To the inhabitants of this part of the globe its home culture is very important, on account of the heavy duty on that imported from Europe. I have examined several samples sent me at various times, and although they varied very considerably in the quantity of morphia they contained, I considered them all to be *genuine opiums.*

"I also send you the specimens I received per post with the paper, please exhibit them. I should like to have them returned to me after the Conference is over. I wish to test some of them, and afterwards to send them to the Museum in Bloomsbury Square, in Mr. Hood's name. "T. N. R. Morson."

The farmers in Victoria, for a good many years, have been touched with a desire to try new crops and new industries. Among the many ventures, suitable or unsuitable, was the cultivation of the poppy and the production of opium, which has been tried with varying success for the past four or five years.

I have felt some interest in this subject and have collected many samples from various districts, and also performed some rather crude experiments myself on the growth of the poppy, which I beg to submit. I feel that, perhaps, my conclusions may be of little value, but as I propose extending my investigations annually, I hope eventually to arrive at the best means of producing the greatest amount of opium together with richness in morphia, from a given quantity of poppy plants.

The first opium produced in any quantity in Victoria was at Sunbury, a village about twenty-two miles from Melbourne. Soil strong, rich, volcanic. It* was a good-looking opium; on analysis it only yielded some 2 per cent. of morphia, but contained an abnormal amount of other opium constituents, notably narcotine, of which there was about 8 per cent. I sent samples of this, and other opium from about the same locality, to T. N. R. Morson, Esq., who, as reported in the Pharmaceutical Journal for January, 1869, stated, "It was of great

* Sample 1.

beauty as far as external characters were concerned, it had the perfect odour of good opium, and it dissolved with the Persian character, but singular to say it contained very little morphia, but a great abundance of the other principles known to exist in opium."

This opinion, from so well known an authority on all concerned with opium, of course reached Melbourne, and was published here with the effect of greatly discouraging the industry. However, a few did continue to plant and produce, and this last season probably a hundredweight and a half were brought into the market here, where it realized about thirty shillings (30*s.*) per lb., as it proved to be a very good opium, containing from 8 per cent. to 10 per cent. of morphia.

Mr. Morson's opinion being so much thought of, I sent him samples. His report being a favourable one, I had it published in the agricultural papers, and now some attention is again given to the opium culture, and I expect that sufficient will shortly be made to enable a trial shipment to be made to London, as from the high price ruling for opium and its preparations it is very desirable that new sources of supply be discovered. With the beautiful climate and fine soil of Australia eminently adapted for poppy-growing, enough opium should be produced to make a marked influence on the price in the European markets, as the growers here will be well paid at from ten to twelve shillings per pound; but as our consumption here is enormous, owing to the great number of Chinese colonists, it will probably be some years before the supply greatly exceeds the local demand.

I send herewith samples of opium from various localities, produced in 1867–8, 1868–9 and 1869–70.

The poppy is sown here in the months of June, July and early part of August, the opium being collected in the summer months of January, February and March. Most of the seed was obtained from Smyrna, and produces plants from five to seven feet high, each bearing three or four flowers of four large white petals. There is also some East Indian variety cultivated with double purple or black flowers, but it is not popular, as it only has one flower on each plant and yields but little opium.

In 1868 I was desirous of ascertaining whether special manures or manner of culture had any influence on the amount of opium yielded and its richness in morphia, and, to determine it, made the following experiments:—

I took six plots of virgin ground and treated them as follows:—

Nos. 1 and 4 were manured with well-decayed stable manure.

Nos. 2 and 5 were entirely without manure.

Nos. 3 and 6 were manured with spent lime from soft-soap works, containing about 3 per cent. of potash and with Peruvian guano.

Each plot was the same size, and was drill-sown with the same lot of seeds on the following dates:—

Nos. 1 and 2, sown on June 13th.
Nos. 3 and 4 ,, July 1st.
No. 5 ,, ,, 12th.
No. 6 ,, ,, 20th.

The plants were all above ground about ten days after each sowing, and about a fortnight after I thinned them out, leaving 150 plants on each plot. Plots 1, 3, 4 and 6 received no artificial irrigation, but depended for moisture entirely on the rainfall, while Nos. 2 and 5 were watered well every week until just before flowering. When ripe, I carefully cut the heads and collected the opium, obtaining the following yields:—

No.	Yield of Opium in Grains.
1	153
2	177
3	159
4	171
5	189
6	203

The greatest yields were from Nos. 5 and 6, the last planted. Nos. 2 and 5, which were without manure, but with plenty of moisture, yielded much more than Nos. 1 and 4, those manured with stable manure. The opium was of the ordinary consistence, and, as far as possible, free from leaves or accidental impurities. Now, as to the richness of the samples in morphia.

On assay from *one hundred* grains of each sample, well dried, I obtained:—

No.	Grains of Morphia.
1	$4\frac{2}{10}$
2	$6\frac{3}{10}$
3	$6\frac{9}{10}$
4	$4\frac{6}{10}$
5	$6\frac{5}{10}$
6	$7\frac{1}{10}$

I also obtained a notable quantity of morphia from the aqueous extract of the bruised green heads from which the opium had previously been as far as possible extracted.

As the same seed, differently treated, gives plants which yielded opium of different values, I naturally infer that manures, nature of soil, want of moisture, or excessive supply of water, and general manner of cultivation, have a great influence on the value of the opium produced. Last season (1869–70) I performed the same experiments with relatively the same results. This year I hope to extend my operations and try many other manures, and have requested all who are growing opium to favour me with all particulars respecting manures, soil, mode of culture and collection and yield, and, if possible, a sample of the opium.

I cannot imagine my experiments as at all conclusive, as the differences might have occurred on different parts of the same ground; but if I find that treatment with stable manure, as a rule throughout the colony, gives a worse yield than if manured with guano, I may then reasonably think that Peruvian guano is more fit for manuring poppies than stable manure; and so on, until I arrive at the best manure and best method of cultivation of the poppy, so as to obtain the greatest and most valuable yield of opium.

Samples of opium accompanying this paper:—

No. 1. Produced in 1867–8, from 80 poppies, at Sunbury, twenty-two miles from Melbourne.

No. 2. Produced in 1869–70, near Gisborne, thirty-two miles from Melbourne, on a river-flat of rich alluvial soil; yield 84 lbs. per acre.

No. 3. From near Bairnsdale, Gipp's Land, in a very cold climate, yield over 60 lbs. per acre.

No. 4. From near Gisborne, 1867–8; yield 50 lbs. per acre.

No. 5. Grown in 1868–9, at Soh Yarra, near Melbourne, collected and dried on tin-plates, so that it is the pure juice dried.

No. 6. Grown in 1868–9, at Dromana, on the shores of Port Phillip Bay, in very sandy soil; the produce of 420 plants.

Mr. Dymond (Birmingham) observed that the plan adopted by the author of cutting off the poppy capsules, and then extracting the opium from them, was not that practised in the East. He had made experiments with garden poppies.

Mr. Sutton (Norwich) said that some years ago a medical gentleman in his neighbourhood grew a considerable number of poppies, and extracted opium by incision from day to day, but the air-dried gum contained less than 2 per cent. of morphia. The season, however, was damp and somewhat cold, and this he (Mr. Sutton) believed was detrimental to the production of any large proportion of morphia. The question was really very little understood, but from experiments in various parts of the world it seemed an undoubted fact that fine, dry, warm weather produced, in any tolerable climate, a fair quality of opium; whereas, in a contrary season, the other and less valuable constituents (narcotine, etc.) were predominant. It was therefore probable that the effect of sunlight and warmth would be to convert a portion of these constituents into the more valuable form of morphia. He also stated that it was his intention to grow some poppies in his own district, should he able to procure good seed, and also forward some to Australia, for the purpose of investigating the matter more fully.

Mr. Dymond remarked that in his opinion we ought to go to Smyrna for seed.

Mr. Brady said he understood some of the Norfolk specimens of opium contained a very large percentage of morphia. He believed it was considered impossible to produce opium on a large estate with a large staff of labourers; and in Asiatic Turkey poppies are grown for the purpose only by small farmers. The French had tried the growth of poppies in Algeria, but with little success, so that other conditions besides climate seemed to be requisite. The extract of poppy capsules had been found by Mr. Deane and himself to differ entirely from true opium in microscopic characters.

Mr. Groves (Weymouth) expressed his belief that the production of opium was a continuous process of the incised poppy, and, therefore, that the proposal to obtain opium, or anything resembling it in strength, by expressing the unripe capsules, would prove delusive. He had himself, on two occasions, examined carefully the ripe capsules. On the first occasion, he had recovered sufficient alkaloids to justify further experiment. The second experiment was conducted upon 50 lbs. of crushed capsules. From that large quantity was obtained, narceia 23 grs., morphia 75 grs., narcotine 36 grs., codeia 33 grs. He had a decided impression that the "crushed" capsules were inferior in quality to the "poppy-heads."

Analysis of Bitter Cassava Juice, and Experiments in Elucidation of its Supposed Antiseptic Properties.

BY PROFESSOR ATTFIELD, PH.D., F.C.S.,

Professor of Practical Chemistry to the Pharmaceutical Society.

The bitter cassava (*Manihot utilissima*, Pohl) is a plant whose tuberous roots yield the starch which, when granulated, is known as tapioca. The juice of the root is said to be somewhat poisonous, but, when heated, the noxious principle disappears, and the concentrated fluid is used as the basis of various sauces (cassareep). This juice, freed from starch and boiled, is commonly believed to be a powerful antiseptic. (Shier, 'Report on the Starch-producing Plants of the Colony of British Guiana,' Demerara, 1847; Hamilton, Pharmaceutical Journal, 1st series, Vol. V. p. 30.)

A specimen of the "boiled juice of the bitter cassava," having a dark brown colour and a consistency of thick cream, was recently sent to me from Jamaica (through Mr. Shepherd, of Chester), with a request that it should be analysed and otherwise examined, with the view of ascertaining whether or not its stated power of preventing decay in meat rendered it worthy of application as a preserving agent on a large scale. The following analytical and other experiments were conducted:—

One hundred parts of the juice contain

Water		39·2
Vegetable matter:		
Albuminoid substance	9·0	
Alkaloidal bodies	none	
Volatile oil	trace	
Cane or grape sugar	none	
Starch	none	
Mucilaginous and other inert matter	37·7	
	——	46 7
Mineral constituents:		
Iron (as peroxide)	2·8	
Other inorganic salts	11·3	
	——	14·1

Experiments.

First Series.—Several cooked mutton chops were well rubbed with various quantities of the juice, and others lightly rubbed, and some smeared or covered. These and a raw chop were set aside in separate cupboards. In two days the raw chop was tainted, and in three putrid. In three days one chop gave evidence of mould; in four days more mould, on the others also: in five to eight days, all more or less mouldy; on the seventh day one chop tainted; on the eighth to twelfth, all were tainted and some putrid.

Second Series.—Some cutlets cooked in water containing small and large quantities of cassava juice, and one cooked without juice, were set aside in separate cupboards. In seven days, the cutlet without juice was putrid; in fourteen days, the others had become mouldy and putrid, more or less quickly, and to a greater or less extent.

Third Series.—Beef was affected in a similar manner, and to about the same extent, as mutton.

Fourth Series.—Extract of meat was diluted with warm water, and three portions set aside.

a. Unflavoured.
b. Flavoured with salt and pepper.
c. Flavoured with cassava juice.

In four days, *a*, the simple diluted extract, was tainted, and in five putrid. In five days, *b* and *c* were slightly mouldy; in nine days tainted, and in fifteen putrid,—each to about the same extent.

Remarks.

The analysis and other experiments show that cassava juice contains nothing that imparts to it antiseptic powers of great value. Its property of slightly retarding the decomposition of raw or cooked animal matter is not greater than that possessed by such common aromatics as pepper; and wholly inadequate to warrant its employment in preserving meat on any large or important scale.

The foregoing experiments were conducted at temperatures of atmosphere varying from 60° to 80° F., in different places, and under other varying conditions. The sample of juice was apparently of average quality, though containing a larger proportion of iron than is present in a specimen in the Museum of the Pharmaceutical Society. Nothing was wanting to make the examination fair and crucial.

I am of opinion that the slight antiseptic character of bitter cassava juice is due to the presence of a very small quantity of aromatic oil, and that the juice is of no practical value as an agent for preserving meat.

Since these experiments were made, larger trials of the juice have been conducted in Jamaica, with similar results to those now described.

On the so-called "Citrate of Magnesia" of Pharmacy.

BY MR. F. M. RIMMINGTON.

There appeared in the Pharmaceutical Journal for June 15th a letter by me on a mode of estimating the value of the so-called citrate of magnesia by estimating the amount of carbonic acid; and I then stated that the amount of acid was influenced by two causes, either by bad management, thereby driving off by heat too much of the carbonic acid, or, by the diminution of the proportion of the bicarbonate of soda, and also, as a matter of course, that of the tartaric acid by increasing the proportion of sugar; for it follows as a natural consequence, that if one of the constituents be increased, the others will be diminished in the same ratio in 100 parts. Now, the goodness of the article depends upon its agreeableness as a beverage, and this again depends upon the amount of carbonic acid given off at the time of mixture.

Since writing that letter I have examined several samples, and tabulated the results below.

The letters A, B, C distinguish samples from three different makers. Those not marked are miscellaneous samples.

One sample of "A," on analysis, gave 44 per cent. of bicarbonate of soda, but only yielded 15 per cent. of carbonic acid, being only two-thirds of the quantity that had been present originally.

A sample of "C" contained 32 per cent. of bicarbonate of soda, and yielded 8·2 per cent. of carbonic acid, being only one-half the amount that must have been in combination with the soda.

Table of Analytical Results.

No. 1	contained	12	per cent.	CO_2
2	,,	9	,,	,,
3	,,	8	,,	,,
A 4	,,	15	,,	,,
B 5	,,	16	,,	,,
6	,,	12·5	,,	,,
C 7	,,	10·5	,,	,,
B 8	,,	13	,,	,,
A 9	,,	16·7	,,	,,
10	,,	9·3	,,	,,
C 11	,,	8·0	,,	,,
B 12	,,	12·5	,,	,,
A 13	,,	14·8	,,	,,
B 14	,,	14	,,	,,
A 15	,,	15	,,	,,
C 16	,,	8·6	,,	,,

The average of four samples marked A is 15·4.
,, four ,, ,, B ,, 13·9.
,, three ,, ,, C ,, 8·9.

The difference between the highest and the lowest being double the amount of carbonic acid, and, as a consequence, one-half the quantity of A would make as good an effervescing draught as double the quantity of C,—a difference too great not to be perceptible.

Mr. Groves remarked that the antiseptic properties attributed to cassareep were perhaps suggested by the little tendency to decomposition shown by the fluid from which it was manufactured. But this fluid contained a notable quantity of prussic acid, the influence of which in retarding fermentation was very remarkable. Of course cassareep would contain none of this volatile body; it must necessarily be dissipated during evaporation.

Mr. Sutton (Norwich) said that the preservative properties of the "cassareep" must be very considerable, as he believed it was the custom of families in Jamaica and other places in the West Indies, to keep a large pot of the prepared juice in the house, into which were thrown odd pieces of cooked meat, bones, etc., where they were preserved for almost any length of time. So long as they were kept under the surface no decomposition occurred.

Mr. Dymond (Birmingham) protested against the Conference officially recognizing the application of the term "citrate of magnesia of pharmacy" (which was the title adopted for this paper) to this preparation, inasmuch as it was a complete misnomer. He had formerly objected to it, and thought the preparation should at most be termed citrate of magnesia of commerce. It was in reality a mixture of tartaric acid, sugar and carbonate of soda. He thought this Conference, as representing and expressing the highest aims of pharmacy, ought to maintain a scientific purity and exactness in its nomenclature.

Mr. Sumner endorsed this opinion, and thought it derogatory to the pharmaceutical body that the practice should exist; and this was not the only misnomer the Conference ought to denounce. Similarly improper names were continually creeping in from time to time.

Mr. Abraham asked how this material was to be labelled when sold?

Mr. Dymond replied that he always labelled it "citrate of magnesia so-called."

Mr. Sutton considered it should be labelled "granulated tartrate of soda."

Mr. Williams (London) said citrate of magnesia was easily made, and was very pleasant tasting. For that purpose calcined magnesia and crystallized citric acid should be heated together without any addition of water. Under these conditions they united together, forming a soluble salt.

Mr. Sumner said that he believed that King's was a real citrate of magnesia.

Mr. Abraham said he had not analysed King's, but he believed that it was composed of bicarbonate of soda, tartaric acid, and sulphate of magnesia.

Mr. Sutton, of Norwich, had subsequently examined this medicine, and found it to consist of bicarbonate of soda, tartaric acid, and sulphate of soda.

Mr. Brady, whilst deprecating the use of names conveying a wrong impression as to composition, thought that, to be consistent, those who advocated an abrupt change in this particular case must extend their protest to "seidlitz powders," "salt of lemons," and a number of similar terms for articles in very general demand.

Mr. Sandford (London) was glad this question of misnomer had been brought forward; he had always protested against applying definite chemical names to articles not having the composition thereby designated, and he thought it was specially the duty of this Conference to discountenance such practice. The evil was increasing; we had effervescing "nitrate of potash," of which a drachm would contain 5 grains, but what was the other portion of the powder? It was, too, a matter of importance to dispensers. Physicians sometimes prescribed "effervescing citrate of potash," for which in one shop ordinary "lemon and kali" would be supplied, in the next citrate of potash, throwing doubt into the mind of the patient.

Mr. Phillips (Crewe) had been accustomed to sell this preparation in Paris under the name of "granular effervescent aperient," in bottles with "citrate of magnesia" stamped on them. The French Government would certainly prevent its sale under the false name commonly adopted in this country. Citrate of magnesia is there largely employed in doses of 40 to 60 grams as a saline purgative, and is known under the name of "Limonade Purgative."

Mr. Groves confirmed the statement made by the last speaker as to the dose of true citrate of magnesia given in France being 60 grams, or about 2 ounces. If the alkaline citrate or tartrate were given, they underwent a process of combustion in the organism, and became carbonate before elimination by the kidneys. This should be recollected by prescribers.

Mr. Andrews (London) said that Mr. Albert E. Ebert, of Chicago, had suggested that the term "granular effervescent salt" should be applied to the preparation commonly known as "granular citrate of magnesia."

Mr. Umney (London) said he had never found more than 17 per cent. carbonic acid in the samples of citrate of magnesia he had examined.

It was then moved by Mr. Dymond, seconded by Mr. Sutton,—

> "That this Conference is of opinion that the term 'citrate of magnesia,' as applied to the ordinary granulated preparation of commerce, is a misnomer, and should be discouraged as inconsistent with the true interests of pharmacy; and seeing that a similar compound is already recognized by the British Pharmacopœia of 1867 as 'citro-tartrate of soda,' this name should as rapidly as possible be brought into general use."

Mr. Greenish objected to the special character of the latter part of the resolution, and considered that there was no necessity for alteration of name so long as granular effervescent citrate of magnesia was only a commercial article, and one never prescribed; if difficulties were thrown in the way of its retail sale by chemists, grocers would necessarily take it off their hands.

Professor Attfield thought this a very difficult question to deal with by any formal resolution. Should we not have "soda-water," "seidlitz-powders" and such articles, next brought under similar condemnation?

Mr. Umney considered that the pharmacists were in the hands of the physician for such granular preparations as effervescent "nitrate of potash," and in those of the public for the popular "citrate of magnesia."

Mr. Savage (Brighton) said whilst the discussion was one of some importance, it seemed to him undesirable to make any alteration of a name so well known to the public, and the best course to adopt would be to avoid committing this Conference to any resolution not likely to be generally adopted.

Mr. Reynolds (Leeds) thought that the second part of Mr. Dymond's motion deserved support fully as much as the first, since prescribers were liable to overlook the large quantity of alkaline citrate and tartrate united with the remedy they prescribed, but not indicated by the name employed.

Mr. Abraham (Liverpool) suggested that the term "citro-tartrate of soda," commonly called citrate of magnesia," should be used. He objected to the term "granular effervescent aperient," inasmuch as no pharmaceutical description was comprised in such a name.

Mr. R. M. Atkinson (Leeds) thought it was no secret that the article was entirely wanting in both citric acid and magnesia, as citrate of magnesia could not be made at the price at which this was offered in the market; he therefore considered it an imperative duty of the Conference, if it wished to hold an honourable position and retain the confidence of the public, that not only in the present instance, but for the future, it should condemn all such impositions when brought before it.

Mr. J. H. Richardson (Cork) said he entirely approved of the resolution.

Mr. Mackay (Edinburgh) felt a difficulty about the second part.

Mr. Ince (London) took the same view, and the mover having consented to an alteration, the motion was carried as follows:—

> "That this Conference is of opinion that the term 'citrate of magnesia,' as applied to the ordinary granulated preparation of commerce, is a misnomer, and ought to be discouraged as inconsistent with the true interests of pharmacy."

SOCIETY OF ARTS.*

On Fermentation.

BY PROFESSOR A. W. WILLIAMSON, F.R.S.

Lecture III.

In referring, at our last meeting, to the place in nature which ought to be assigned to these little organisms of which we have been speaking,—the ferments,—I stated one ground which appeared to me conclusive, or very nearly so, in favour of placing them in the animal and not in the vegetable kingdom. That ground was a chemical one, viz. that these organs assimilate, or, to use a homely phrase, they feed upon very complex substances, and they give off, during their vital functions, less complex substances. That circumstance appears chemically conclusive in favour of their being rather animals than plants, for plants build up complex substances, and animals assimilate the products which plants have formed, and break them up into simpler ones. There are, however, two other considerations which I think are of such importance that it would be undesirable to pass them over, which tend in the same direction, and are striking confirmations of the conclusion to which we then came. The one is, that whereas plants require for their growth the light of the sun—in fact, their very growth is a process of absorption of heat by their leaves from the rays of the sun—and plants by doing so render heat latent, as we sometimes express it, that is, they cause an apparent disappearance of heat, and lower the temperature of the surrounding space; animals, on the contrary, give off heat during the exercise of their vital functions, and do not need to be exposed to heat or to continuous light for their growth. Now, in both these respects, as in the other respects, these little cells, the ferments, appear to be distinctly animals. I do not know of one case of a ferment requiring or using for its vital processes the light of the sun; they usually grow, and they seem to thrive quite well in the dark. Again, there are well-known cases in which, during their vital functions, they evolve or give off heat, so that I think these are very overwhelming reasons for not considering them as vegetables in their functions, but rather as animals or animal atoms. I have on the table here three or four liquids, which are in states of fermentation, of which I have already had occasion to speak several times. This first carboy contains an extract of malt, to which common cane sugar has been added, and some brisk, thriving yeast was then introduced. Effervescence is now rapidly going on, as you may hear by the gas—carbonic acid—which is escaping through the bent tube into the vessel containing lime-water. This liquid contains little soft, nearly round particles, which I was just speaking of as animals, though they certainly do not look like animals. The second flask contains another substance, of which I also spoke the other evening. There is here what I might call gastric juice—it is a mixture made for the purpose of getting lactic acid from sugar. Some pepsine was made to digest a certain quantity of white of egg, and that mixture, whilst still acid, I mixed with some common cane sugar, and put into it some alcoholic ferment, or common yeast. A good deal of the yeast was digested, it disappeared and was dissolved. I thereupon put in more and more, until there was an excess of it left in the flask. It was then kept for upwards of a week in a box which I have been using for the purpose of these fermentations—a metallic box, which is kept, by means of a regulated gas-burner, at a temperature of about 30° Centigrade, or a little above blood heat. During that time the substance has been gradually undergoing a change or fermentation. It became strongly acid, and I then added a base, at one time potash, and afterwards powdered marble or carbonate of lime, which was dissolved by the acid, and thus a quantity of lactic acid was formed. Here also there are little cells, which, under the microscope, can be seen to be different from those in the first mixture. They are smaller in their dimensions, but yet they present no very marked individual characteristics by which they can be identified. Indeed the chief, or, I may almost say, the only thing by which we can certainly identify any one of these organisms is by setting it to work, and by seeing what work it performs. In the third carboy I have a mixture which had gone through the phase I have just been speaking of; it contained some sugar with lactic ferment, but when all the sugar had disappeared, and was transformed into lactic acid, I left the carboy in the same warm chamber, and another fermentation has set in, and there is already a considerable quantity of the substance called butyric acid present, and the greater part, if not the whole, of the lactic acid has already passed over into this butyric acid. Here, in this glass dish, there is another ferment still, although, unfortunately, it has got disturbed in coming here. It contained a decoction of yeast, with which was put about 2 per cent. of pure

---

* Cantor Lectures.

vinegar and about 4 per cent. of alcohol, and I then touched the surface of the liquid, which was perfectly clear, with a glass rod which had been in contact with the vinegar-plant, and left some little particles floating on the surface of the liquid. These little particles, in the course of a day or two, spread over the liquid, and when this vessel came from University College this morning it was covered with a perfectly uniform film, consisting of little cells different from each of the others to which I have called your attention, and quite distinguishable under the microscope. I should state that after the mixture was first made, and after the vinegar-cells were put into it and allowed to grow on it, I supplied them with some additional food twice. On one occasion I added a somewhat larger quantity of alcohol than was intended, and the effect was that the cells were most injuriously affected. They constituted a dense, smooth, white film, and this seemed almost to disappear, and on examination under the microscope it was found that they had shrunk—in fact, they had been killed by a too strong dose of alcohol. This was then allowed to evaporate, and the vinegar-cells very soon again spread over the liquid. I will now commence in another dish a similar experiment. I have in this bottle a mixture of yeast-water and alcoh.l, with a few drops of acetic acid in it. I will pour this into the glass dish, and then put on to the surface some of these little ferments which I have here, and I have no doubt that if we allow this mixture to stand we shall find by our next meeting that it will be covered over with a smooth film, consisting of vinegar-cells, which will be transforming the alcohol into acetic acid. I may show you the strength of the acid in this last instance by putting into it a slip of blue test-paper, which you see is immediately coloured a deep red.

With regard to the process by which these cells are propagated some exceedingly interesting experiments have been made under the microscope. Professor Mitscherlich and various others,—Pasteur among them,—have put little alcohol cells under the microscope, putting them first into a liquid upon which they could feed, and they have noticed that the cells, or some of them, gradually swelled out at one side,—that a little wart, if I may use the expression, made its appearance on one side; that this increased in size until it became as large as the original cell, and then it became detached. The propagation of the alcohol cells, the wine ferment, has been seen by several observers to take place by a process of budding. I will show you the growing cells, by throwing on the screen, by means of an oxy-hydrogen lantern, a photograph of the wine ferment, some of which will, I believe, show a little excrescence at the side, and the general arrangement of the cells will be easily detected. This is a photograph from a plate of M. Pasteur's, and conveys an exact representation of the appearance which the alcohol cells ordinarily present. I will now show you the photograph of the acetic ferments, and the difference in the general appearance is very striking. When examined carefully it will be found that these little vinegar cells are in couples, little masses about twice as long as they are broad, and by degrees they become strangulated at the waist, and ultimately separate. With a considerable magnifying power, it has been found that the wine cells contain granulated particles, but exceedingly little is yet known of their structure. Certainly one of the most promising directions for investigation in the phenomena of life is presented by the study of these various little organisms, which we have so completely under our control.

With regard to the processes by which these cells are propagated, I have mentioned already, that when certain liquids, capable of undergoing decomposition, are exposed to the air, some little cells gradually make their appearance in what was at first quite an unaccountable manner. It was long supposed, and on very good authority, that the oxygen of the air was the active agent in transforming a fermentable substance into these little cells; and Gay-Lussac, one of the ablest of French chemists, who died a short time ago, made some very careful experiments with a view to decide that point. They led him to the conclusion that oxygen was all that was needed in order to initiate the process of fermentation in the juice of grapes, which by itself does not ferment. It is worth while to state, in general terms, the nature of these experiments. He put into a glass vessel, closed by mercury, a small quantity of grape juice, which was expressed under mercury, so that it did not come in contact with air on its way into the glass jar intended to receive it. This was then kept closed for some time without change. He then introduced oxygen, sometimes from the atmosphere—I am now giving you an account partly of what was done by Gay-Lussac, and partly what was done by others—and sometimes the oxygen was derived from potassic chlorate. Air was used which had been passed through red-hot tubes, so that any vital organisms in it must have been destroyed before reaching the grape-juice; and it was found that, in these cases, the access of the air to the substance did induce the formation of yeast-cells, and did induce a process of alcoholic fermentation in the liquid by their growth. The conclusion, therefore, appeared to be established that oxygen was all that was needed for the process. Since that time, however, other experiments have been made, with precautions which were not observed by Gay-Lussac; and I must especially quote a truly masterly investigator, Pasteur, whose extraordinary researches in this subject have certainly constituted an important era in our knowledge of it. Pasteur has made a great number of experiments, partly such as those which had been made before, and partly fresh ones, of which I will describe a few characteristic samples. For instance, he took little glass bulbs, with a long neck bent in several places, like the one I hold in my hand. This little bulb contains some yeast-water, and also about 10 per cent. of sugar, a mixture which is peculiarly susceptible of undergoing fermentation and decompositions of various kinds. When this was introduced into such a bulb, Pasteur boiled the liquid for some time, so that any little living particles which might have entered the bulb with the liquid, by being exposed to the temperature of boiling water, might be killed, and also that any particles which might be lodged in the neck of the flask would be similarly treated and killed. Some of these bulbs he closed, sealing up the tubes whilst still full of steam, and he then put them by in a warm chamber, similar to that which I just now alluded to as being of the temperature of 30° Centigrade, so that they should be under the conditions most favourable to the development of any little living organisms, if such could develope themselves. He so kept them for days, weeks, and months, and I am not sure that he did not keep some for years, and at the end of the whole time he found that in no case was there the production of these vital organisms. I told you that when the tube was closed the vessel was full of steam; of course that steam was condensed on cooling, and left a partial vacuum above the liquid, and when Pasteur opened the tube by breaking off the point, the air rushed in violently to fill the vacant space. He found that in almost every case, although not in all, after this air had rushed in, a process of decomposition commenced, and in some cases he found little animalcules, and various kinds of mould in others, and he has described a considerable number of different organisms which he got in different bulbs in that manner. It so happened, also, that in one case the tube, I think accidentally, at first remained unsealed, that it was not kept from contact with the air as the others were; still, to his amazement, Pasteur found that even in this one which remained open there were no organisms, that it remained as unchanged as those which were sealed up. Finding this, he repeated the experiment many times, making a great number of bulbs similar to the first, putting some of that same liquid into them, and boiling the liquid for some time, so as to destroy any organisms; but, when they had been killed, he left the bulbs open, and he found that the contents were as effectually protected by the conditions there present as if the tubes had been sealed. He submitted the results to several members of the French Academy; the experiment was repeated by other persons, and the results showed—if there were any exceptions I do not remember hearing of them—that no organisms were produced. You will notice that the liquid which had been boiled was separated by a long, thin tube from the outer air, and the air only had access to it through this long, narrow, tortuous passage, which, moreover, was at first wet inside, because of the condensed steam. Pasteur then cut off some of the tubes, so as to allow free access of air to the contents, without having to pass through this long, narrow tube, and soon after that was done the process of decomposition set in, and he got various organisms formed in his mixture, which developed themselves in the way yeast, mould, and such-like organisms generally do.

(*To be continued.*)

Mortality from Snake-Poisoning.—The *Lancet* quoting a letter, dated the 11th August, from T. D. Beighton, Esq., of the Bengal Civil Service, magistrate of the subdivision of the Culna district of the Burduan province of Bengal, remarks, "The Culna district comprises, we presume, 80 or 100 square miles, and has a population of about 300,000. Mr. Beighton says that deaths from snake-bite are singularly common in the subdivision. An average of one per day is reported through the police. The actual deaths are probably double the number reported. If this daily average is meant to apply the whole year round, we should thus get, in a comparatively small district, the frightful result of 700 deaths from snake-bite. It is lamentable to think that, despite the supposed remedial discoveries in this direction, we still seem to be without an agent to neutralize the effects of the bites of poisonous snakes."

Disinfectants used in the International Society's Hospitals.—A correspondent of the *British Medical Journal* says, that in these hospitals the sick and wounded are most rigorously kept apart; the wounded on the lower, the sick on the higher floors of the hospitals. A space of 1500 cubic feet is allowed for each bed. Carbolic acid powder is strewed on the floors of the rooms twice a week. Chloride of lime or sulphate of iron is used for the privies. Chloride of zinc in solution is added to the water used for washing the bandages, sheets, and shirts of the wounded. The compresses, lint, etc., are put into a solution of carbolic acid, and afterwards poured out into a hole dug in the ground, and covered with earth. Sponges are used only to wash the patients, each of whom has a sponge for himself. The wounds are syringed with warm water, to which permanganate of potash is added. The lint and the compresses are moistened before being placed on the wounds, sometimes with carbolic acid solution, or with a mixture of carbolic acid and olive-oil.

Impure Acetic Acid.—Dr. Bruckner, of Philadelphia, reports in the *American Journal of Pharmacy*, that he has found acetic acid to contain phosphate of lime. This is a fact of importance in reference to the use of acetic acid in the analysis of phosphatic materials. The author suggests that the phosphate may have been derived from bone black, used for decolorizing the acid.

The following journals have been received:—The 'British Medical Journal,' Sept. 24; the 'Medical Times and Gazette,' Sept. 24; the 'Lancet,' Sept. 24; 'Nature,' Sept. 22; the 'Chemical News,' Sept. 23; 'Journal of the Society of Arts,' Sept. 23; 'Gardeners' Chronicle,' Sept. 24; the 'Grocer,' Sept. 24; the 'English Mechanic,' Sept. 23; the 'American Chemist.'

Correspondence.

"FREE TRADE IN SURGICAL INSTRUMENTS."

Sir,—As discussion on the above subject appears to be invited, we, the undersigned chemists and druggists in Newbury, desire to express our entire concurrence in the opinions and statements of facts contained in Mr. Magg's letter of the 24th instant.

We consider that Messrs. Maw have not acted in a fair and generous spirit towards the trade, after the many years that their interests have been united; and by their present mode of doing business with surgeons, boards of guardians and others not connected with the profession in any way, and also by an indiscriminate distribution of their priced catalogue they are alienating their best friends, as they term chemists, though we doubt if the latter can conscientiously reciprocate the flattering compliment.

We are, yours faithfully,

PHILIP CHILDS, *Local Sec.*
HICKMAN AND SON.
DAVIS AND SON.
N. W. RYOTT.
F. G. HALL.
J. B. PRATT.
HENRY TAYLOR.
THO. W. AND B. FIELDER.

Newbury, September 26th, 1870.

Sir,—Several letters having appeared on this subject, perhaps you will kindly allow me a small space for remark.

I cannot join your correspondents in considering it a grievance that surgeons should prefer obtaining goods direct from the manufacturers and paying cash instead of encumbering the books of retail chemists with unprofitable, long-winded accounts. The fact alone is on the broad principle an advantage, tending to the improvement of trade in the aggregate.

As for supplying surgeons with any drug or other article, it is generally found unsatisfactory and unprofitable. I lately sold a general practitioner some Howard's citrate of iron and quinine, charging him 25 per cent. on the cost. He complained that the price was excessive, at the same time producing a drug list from a no less respectable firm than Messrs. Evans, Sons and Co., quoting a price considerably lower than I had given, but, while acknowledging that the preparation might be considerably better, said the low-priced drug "would answer his purpose."

An experience of more than thirty years assures me that no house is better disposed toward the legitimate retailer than that of Messrs. Maw, Son and Thompson, who do not supply articles to private customers, as is the known practice of several wholesale druggists and co-operative storekeepers, —a direct injury to retail trade for which there is no remedy. An instance occurred the other day which is more to the point than pages of complaints. A person applied to Messrs. Maw, Son and Thompson for an instrument, value one guinea, and in reply received the enclosed note:—

"Dear Sir,—We are in receipt of your favour of the 17th inst. We only supply the trade and medical profession, therefore must ask you to obtain the articles wanted through one of the chemists in your neighbourhood.

"We are, dear Sir,
"Very respectfully yours,
"S. MAW, SON AND THOMPSON."

(The following post brought me a credit note for 7*s*. commission on the sale.)

I hope it will be understood that my object in writing is not with a view to prolonging an unprofitable correspondence, but rather to express an opinion that the majority will endorse, namely, the right of every house of business, be it large or small, to conduct its own affairs in a manner most conducive to its own interests and to those of its supporters of every grade.

I am, Sir, (in haste) yours obediently,

DEPRECATOR.

THE BRIGHTON CHEMISTS' ASSOCIATION.

Sir,—Your correspondent "Veritas" is entitled to know that this Association was formed some years ago, and actively promoted by a few of the old members of the trade; but by reason of the apathy of the younger branches,—the meetings became stereotyped,—the same half-dozen gentlemen meeting month after month without any addition to their numbers; and, although the trade subscribed readily to meet current expenses, they failed by their absence to give the necessary impetus to secure success, the consequence was the meetings took place at longer intervals, and at last ceased altogether, until last month, when as there seemed a probability of the British Association visiting the town and with it the Pharmaceutical Conference, a meeting was called to consider the subject and to appoint another Secretary in the place of our much-esteemed friend Mr. Gwatkin, who resigned from ill-health. Mr. Julius Schweitzer was appointed Secretary, whilst our Mayor, Mr. Cox and myself were appointed to represent the trade (as duly convened by circular) at the Conference. The necessary qualification to become associated with the trade and an infusion of younger blood into the Association, are favourable circumstances to reinvigorate the institution, and as there is a fund to begin with, the *young men* should now avail themselves of the opportunity of arousing the latent energies of their compeers, and I am quite certain of this, that their older brethren will not shrink from any exertions to aid them. I am, Sir, yours,

W. D. SAVAGE.

DRUGGISTS' PRICES.

Sir,—The *Lancet* pursues a self-constituted censorship of pharmaceutical affairs. We are informed that "one great objection to practitioners handing over the dispensing of their medicines to chemists is to be found in the high prices charged by chemists for medicines," and also that "the dispensing of an ordinary prescription easily costs 2*s*. 6*d*. or 3*s*." Our profits are said to be "monstrously excessive." Let us look into the matter. In the first place, I may safely say that mixtures are more generally dispensed for 1*s*. 6*d*. and 1*s*. 8*d*. than for 1*s*. 8*d*. and 2*s*.; certainly for less in the provinces. A dozen doses of pills may be had for 6*d*. or 8*d*., and medicine enough for a fortnight at an outlay of 2*s*. 6*d*. to 3*s*. In saying that the chemist is "paid at once over the counter" the *Lancet* makes a random assertion. The generality of druggists do a large booking trade, and allow their customers to run accounts, not from choice but of necessity.

It appears that in one town the medical men gave up dispensing. Mark the effect of that act! The druggists have become familiar with prescriptions,—had they seen so little of those ungrammatical productions before?—and now they feel pulses, even those of affluent ladies, before the very eyes of the doctors themselves. What audacity, what effrontery! Here, indeed, is a heavy indictment; here the head and front of our offending. A doctor, finding himself forestalled by a druggist, who had told a lady that she had a weak pulse, evidently feels poignantly upon the subject, for he rushes into print, and declares that "this kind of thing must be put a stop to."

Here are two charges to meet. We are excessive in our charges, and we meddle with the practice of medicine. I say that our prices are not exorbitant, that they are perfectly legitimate, and in no way more than due return for our labour and time, especially in the face of the qualifications which are now to be required of those practising pharmacy. It is an egregious error to imagine that chemists will lower their charges to suit the fancy of the medical practitioner, so that he may obtain full remuneration, whilst the druggist is left to compound medicines at a maximum of trouble and a minimum of profit.

And as to prescribing, what is to be said? Are not the public their own masters? They come of their own accord to us for advice, they are perfectly aware of our status. They do not choose to call in a doctor for every minute ailment, every spasm or ache. We render them what service we can, and I think it may be truly said that we do not interfere with difficult and urgent cases. I have heard it frequently said that the doctor, once called in is, like some parasites, very difficult to get rid of; and I have known many who, after vainly hinting to their medical adviser that his persistent visits were superfluous, have been compelled to give him an outspoken dismissal. This is a reason why we are often consulted. We force physic down no one's throat.

It would be better for the *Lancet* to be a little less partial to its own order, for it might then discern medical shortcomings and abuses more clearly than it now appears to do. It has taken upon itself the unenviable task of attacking chemists and druggists, and in doing so has employed language and epithets of a most offensive character. We leave our case to the discrimination of the public in perfect confidence, assured that they will not cavil at a body of hard-working and painstaking men. Whether the *Lancet's* strictures have been composed in a fit of jealousy or hate I neither know nor care, but to the writer I may say,—

"Of your antipathy
If I am the Narcissus, you are free
To pine into a sound with hating me."

Yours truly

MINOR ASSOCIATE.

PHARMACISTS AND MEDICAL PRACTITIONERS.

Sir,—*Quelle horreur!* to think that a common, vulgar druggist should have the impudence to come "betwixt the wind and the nobility" of a medical man! Sit in the same room, forsooth, certainly not! We who, after heavily feeing a grinder, have passed with difficulty the "Hall," and subsequently received a diploma from the "College,"—shall the "elect" associate with the vulgar herd of pharmaceutists who have really passed a stringent examination? Never! The idea of a professional man, a gentleman, at a public exhibition coming in contact with a shopkeeper! Faugh! The smell of fœnugrec, cubebs, assafœtida would be overpowering. Really, it is too absurd to be entertained for a moment!

Malefactors! oh, the polish, the culture, the amenities of modern journalism! If the editor of the *Lancet* will refer to the police reports, he will soon discover who are the real malefactors. He may possibly find half-a-dozen unfortunate druggists who have caused death by accident or sheer carelessness, but he will find a vast number of cases where *bonâ fide* medical men have been found guilty of criminal practices. There is a wide difference between a druggist who causes the death of a child by selling its mother a pennyworth of Godfrey, and the man with a diploma, who devotes the chief part of his attention to a vile practice which eventually lands him in the hulks. There are very few of the former, unfortunately for society very many of the latter. Who is it that defile our newspapers by inserting disgusting advertisements? Medical men, who may have received diplomas in England, America, Germany, but still medical men. I am not aware that I ever saw a specimen of this obscenity with the name of a pharmaceutist attached.

If a child die by the carelessness of a druggist there is an inquest, and the druggist generally gets severely reprimanded by the coroner, if nothing worse; but how many mistakes are made by medical men which never come to light? In the latter case it is "hum! ha!" "unfavourable symptoms set in," "death," "certificate," "fee pocketed," and there it ends. Who, then, is the malefactor here?

Can the editor of the *Lancet* see nothing reprehensible in the "reciprocity treaties" now so much in vogue, where the physician compels his patient to go to a particular druggist, the two worthies subsequently dividing the spoil? Both are utterly despicable, but as the proposition invariably comes from the medical man he is therefore the most to blame. Confirmatory evidence of this is given in the current number of the journal in an advertisement emanating from an M.D.

According to the *Lancet*, then, a general practitioner (a fusion of doctor and druggist, forcibly reminding one of Barnum's celebrated mermaid, half monkey, half codfish) is a gentleman; but nevertheless he is not too much of a gentleman, not too proud, to take the bread out of the mouth of the poor druggist he so much despises, by retailing his medicines. Why does he, then, if he really be a professional man and a gentleman, play at keeping shop, dishonestly cheating the druggist out of the most profitable part of his business?

Would it not be better if the editor of the *Lancet* were to employ his literary talents in endeavouring to reclaim his erring brethren to the path of rectitude instead of casting aspersions on men who are in respect of education and position fully his equals, and who, as a class, not nearly so criminally-disposed as his own body? Yours obediently,

A COUNTRY M.P.S.

Sir,—"Non-Malefactor" appears little to understand his own interest or position, and still less that of medical men.

These latter must either be of service or the contrary; common consent will admit the necessity; if so, medical men deserve to be protected in their interest, otherwise there is little chance of the high standard being attained among us which "Non-Malefactor" seems to expect. It certainly will not mend matters for Pharmaceutical Chemists to do the work for us, —they are not educated for the purpose, so, to say the least, it is hardly honest on their part.

Both doctors and chemists must look forward to the day when their relative position and duties shall be defined by law, as is the case in many Continental countries.

September 20th. PERCY LESLIE, M.D.

Dear Sir,—In the *Lancet* of Saturday the 17th ult. appeared a somewhat more decent, temperate, and logical article on chemists than it has been accustomed to publish of late. The basis of the article is a letter from a correspondent with the appropriate signature of "Reformer," and he well deserves that title, since in the latter part of his communication he says, in reference to prescribing by chemists, "that this kind of thing should be put a stop to, for I can clearly see, as time advances, that it will get worse. Is it not possible, in this Medical Bill which will be again shortly before Parliament, to get a clause inserted to somewhat restrict this kind of thing? The only other remedy I can see will be for all general practitioners to supply their own medicines, as in former days (which certainly is rather *infra dig.*), and thus to wrench back from druggists that of which evidently they are depriving the profession." It would be quite as fair for druggists to agitate for a prohibition of doctors doing their own dispensing, as for chemists being prohibited from prescribing; and it seems nothing more than is to be expected, that as long as "the profession" dispense their own physic, so long will chemists do a little pulse-feeling, tongue-scrutinizing, counter-prescribing, which at least has been of some use to "the profession;" for "Reformer" says in the letter already quoted, "that in the town in which he resides he was one day greatly amused" (by the tenour of his letter he does not seem greatly amused, but possibly some time has passed, so the amusing effects have worn off) "at seeing the people, one after the other, come in to be doctored, the druggist actually in *my* presence feeling their pulses, etc." It certainly was not a pleasant sight for one of "the profession" to witness "people, one after another, come to be doctored," while his time and services were not in such great requisition; and then he and the other doctors of the town had generously given up dispensing their own physic, an act which I am sure you will coincide with me in saying deserved a better retaliation and which perhaps accounts for the rather bitter epistle of "Reformer."

But there must be something in the people flocking to the chemists and leaving the doctors. Is it on account of "the profession's" excessive charges or in their desire for keeping on with their patients, for both of these are complaints often urged against them by the people; or is it, as the *Lancet* says in the article referred to, that the price charged by druggists for dispensing doctors' prescriptions is high and of itself "a heavy and exhaustive bill to people in humble means, so that they can ill afford to pay the doctor's fee in addition. Mixtures they say are charged at the rate of 1*s.* 8*d.* to 2*s.* each, and other medicines correspondingly; so that the dispensing of an ordinary prescription easily amounts to 2*s.* 6*d.* or 3*s.*" This is really an immense amount to obtain for twenty minutes' work, and the drugs, chemicals, bottles and labels employed, and the risk of making a mistake, for which one might be mulcted in a penalty of £1000, as was Mr. Abraham; for when a mistake is made by chemists it is always found out and generally published, whereas if any mistake is made in writing in doctors' prescriptions, the chemists, as a body, are most scrupulous in keeping it from the knowledge of the patient and the public. And this amount, which in the majority of prescriptions, does not reach 2*s.*, is grudged by "the profession," after taking of the "person in humble means" a sovereign for a fee. Whether chemists, or even the people, see as "the profession" see, may be doubted. If the doctor dispensed his own physic, would the charge be much less than 1*s.* 8*d.* or 2*s.* for dispensing, or is not the doctor's usual price from 2*s.* 6*d.* to 3*s.* for the 8 oz. mixture of six doses, with other things in the same proportion? that is, nearly double what the *Lancet* calls heavy and exhaustive prices charged by the chemist to the "person in humble means." This price is not warranted by the extra skill used by the doctors in dispensing, seeing that the majority use ready-made mixtures and pills, which do for a large proportion of patients, and the dispensing is generally done by assistants whose pharmaceutical knowledge a very modified examination would "pluck." Nor is it the greater cost of the drugs employed, as those who supply dispensing members of "the profession" know, nor a more concentrated form, as those who take them know.

It would have looked much more becoming a learned profession if they had treated a newly State-recognized Society with some amount of generosity, and encouraged it in its laudable efforts to raise the standard of pharmaceutical education in the country, instead of throwing cold water on its well-meant, if at present weak efforts, or entering on a new crusade "to wrench back from the druggist" the small modicum of dispensing they have granted him. Apologizing for the length of this letter,

I remain, yours very obediently,

"AUDI ALTERAM PARTEM."

"IMPROVEMENT IN STOPPERED BOTTLES."

Sir,—Mr. Mayhew's letter in the Journal last week is a very sensible one; but I, however, also suggest that a small groove be made in the neck of the bottle to correspond with the groove at the top of the stopper, so as to keep the string in its place. There would be less danger of the string slipping from its position. Mr. Mayhew is an experienced man; I was a fellow-assistant with him in Cheltenham in 1838.

Louth, September 26th, 1870. JOHN HURST.

Thomas Day (Manchester).—Persons desiring to present themselves for the Minor and Major examinations must have passed the Preliminary examination, unless they, being twenty-one years of age, had been in business three years before the passing of the Pharmacy Act, 1868, and have also applied before 31st December, 1868, to be allowed to pass the Modified examination.

B. K. Earnshaw (Putney).—Yes.

"*Amor Justitiæ.*"—Such a person can be registered without examination upon making the statutory declaration, a form of which will be supplied by the Secretary on application.

"*Inquirer.*"—The Apothecaries' Hall certificate would be accepted by the Board of Examiners in lieu of the Preliminary Examination.

"*Inquisitive*" (Morecambe).—*Vide* 32 & 33 Vict. s. 1.

"*Spes*" writes, saying that in the Conspectus of the Examinations of the Pharmaceutical Society, for the Minor Examinations in Chemistry, the candidate is requested to give a description of the processes by which acids, oxides, salts, etc., of the Pharmacopœia are produced, and to state the composition of such as are *compound.* "Spes" would be greatly obliged if any of our correspondents would give one or more examples of the above compounds.

"*Quærens*" (Greenwich) (1) wishes to be informed what Oil of Kermes is. (2.) Tourmaline is the name of a group of double silicates, usually found in granite, gneiss or mica slate. The term artificial tourmalines has been applied to crystals of sulphate of iodoquinine on account of their optical properties. An article in which formulæ are given for the preparation of these crystals will be found in PHARM. JOURN., 1st ser., Vol. XIII. p. 449. (3.) Pimpernel water is distilled from the root. It is acrid, and of a blue colour.

Y. G. (Notting Hill.)—Sulphide of arsenic and unslaked lime are sometimes used for the purpose in combination with starch. Another method is to use a strong solution of sulphide of barium made into a paste with powdered starch.

"*Ink Pot.*"—(1.) Bloom of Roses is a solution of carmine in ammonia. You will find forms for its preparation in any work on cosmetics. (2.) PHARM. JOURN., 2nd ser., Vol. IX. p. 434. (4.) See the schedule to the "Petroleum Act," and numerous articles in the PHARMACEUTICAL JOURNAL. (5.) The rule for anonymous communications is that no notice can be taken of them.

G. H. H. will find a recipe for Glycerine and Lime Cream in PHARM. JOURN., 2nd ser., Vol. VIII. p. 679.

Instructions from Members and Associates respecting the transmission of the Journal should be sent to ELIAS BREMRIDGE, *Secretary,* 17, *Bloomsbury Square, W.C.*

THE PROCESS OF NUTRITION.

BY BARON LIEBIG.

Sensation and exertion are things fundamentally different, though it may be a long while before the physiological intellect succeeds in drawing a sharp distinction between them.

The plant is a magazine of sun-force which has been accumulated in its parts during their development, and this force stored up in the food material of animals is again manifested in the animal body; it is the manifold action of this force which comprises and determines all phenomena of animal life. Hence the elucidation of the laws obtaining in regard to that force should, above all things, engage the attention of investigators.

In a complex machine it constantly happens that interruptions of the work to be done are caused by the mere action of the mechanism itself: the driving bands stretch, or a screw gets loose, or there is a loss of power in consequence of friction between certain parts of the machine, and for this reason we find in large factories some one continually occupied either in finding out the causes of such impediments, or in providing a remedy for them according to the means at his disposal.

This case presents a very slender and scarcely accurate representation of the problems with which the physician and surgeon are jointly concerned in dealing with the infinitely more complicated human machine; but their ultimate object is in all cases that of maintaining this machine in regular work and in good condition, so that out of the power generated in the machine, there may be a maximum amount remaining available for the performance of intellectual and corporeal work.

I have already mentioned the very remarkable fact that in feeding a dog with a mixture of fat and meat (the latter being in larger amount than requisite for the animal's support), the excess of meat which is not accumulated in the body undergoes metamorphosis, its decomposition not being hindered by the fat given with it in the food.

This fact proves the existence of a cause which definitely limits the accumulation of those blood-constituents which are not applicable for increase of flesh, and it may be a question for the investigations of physiologists to decide whether this cause operates directly upon the colloidal albuminates of the blood, or whether its operation is restricted to those flesh-constituents which have passed into the circulation before assuming the colloidal condition. The opinion that the cause here referred to operates directly upon the albuminates of the blood, as such, can scarcely be reconciled with the phenomena observed during a state of hunger.

According to what we know respecting the processes going on in the muscles, urea is not a direct product from muscle-constituents within the muscle itself, and the question as to the origin of urea, or as to the part of the body in which it is formed, is still one of great interest.

Stokvis and Heynsius found urea in the liver of the mammalia, and they have expressed the opinion that it is formed in the liver from uric acid. Meissner has also established by a very comprehensive investigation the fact that urea does occur in the liver.

For appreciating the processes going on in the liver, which is in animals of the higher classes the most powerful apparatus in the whole body for splitting up material, it is essential to take into account the remarkable observation by Schmulewitsche* as to the formation of bile. Uric acid and the acids of the bile are nitrogenous compounds, and they must be regarded as derivatives of albumen; the same with regard to hippuric acid, creatin, glycocol, etc. Moreover, sugar is formed in the liver.

From the chemical point of view, which is alone to be considered here, a comparison of the composition of blood-albumen, the acids of bile and other nitrogenous products, leads to a recognition of some very interesting relations of these substances amongst each other, and to blood-albumen: as purely calculated relations they possess no real value, but they may nevertheless be of some utility in suggesting problems for investigation.

If to the formula which I have adopted for albumen of blood,† there be added 20 equivalents of oxygen, we obtain exactly the elements of 12 atoms of uric acid, 2 atoms of cholic acid, 1 atom choleic acid, and 14 atoms of water.

Blood-albumen . . .	$C_{216} H_{169} N_{27} S_2 O_{68}$
20 Oxygen	O_{20}
	$C_{216} H_{169} N_{27} S_2 O_{88}$
= 2 uric acid	$C_{60} H_{24} N_{24} O_{36}$
2 cholic acid	$C_{104} H_{86} N_2 O_{24}$
1 choleic acid	$C_{52} H_{45} N S_2 O_{14}$
14 water	$H_{14} O_{14}$
	$C_{216} H_{169} N_{27} S_2 O_{88}$

In like manner cholic acid contains the elements of hippuric acid, margaric acid, and a hydrate of carbon; by adding 2 equivalents of oxygen to 2 of choleic acid, we obtain the elements of cystin, cholesterin, margarin and carbolic acid.

By the association of 4 equivalents of water with cholic acid, there may be produced leucin, oleic acid and carbonic acid.

In 2 atoms of uric acid and 12 equivalents of water, there are the elements of 2 glycocol, 3 urea and 6 carbonic acid.

From 4 equivalents uric acid and 22 equivalents water, there might be produced 2 creatin, 5 urea and 14 carbonic acid.

There would be no object in multiplying these calculations, but I do not regard them as absolutely valueless, because a knowledge of *possible* relations of this kind awakens attention to those which are *actual*, and in that way it may contribute towards paving the way to a comprehension of normal and pathological processes. In connection with the foregoing formulæ the occurrence of cystin in the urine involuntarily calls to mind the formation of cholesterin and the reverse, while the occurrence of leucin suggests the formation of oleic acid.

In recent times several physiologists have occupied themselves with the question as to the origin of fat in the animal body.

Fat being non-nitrogenous, I believe that its formation must be in some way connected with the non-nitrogenous constituents of the food, though I do not dispute the possibility of its being produced from albuminates.

According to the investigations of Voit, it appears

* See *ante*, p. 143. † See *Chemical Letters*.

on the contrary to be tolerably well made out that fat is a product of the breaking up of albuminates, and Voit regards it as probable that the milk sugar in milk originates from the fat as the result of an oxidation, so that both fat and milk sugar would be derivatives of albuminates in the food.

But in my opinion the investigations conducted by Voit in reference to the origin of fat and milk sugar in the milk of cows, lead to entirely opposite conclusions, and it may not be uninteresting to examine somewhat closely the basis of his experiments and opinions.

The most important argument adduced by Voit in favour of the probable formation of fat from albuminates is based upon some experiments made, together with Pettenkofer, by which Voit believes he has proved that, in the body of a dog fed on meat, fat was formed from flesh, or might have been so formed.

Comparing the quantity of carbon in the meat-food taken, with the quantity given off as carbonic acid and in the other excretions, Voit found there was a deficiency of 3·8 grams carbon in the excretions, and, from considerations as to what may have become of that carbon, he is inclined to think that it was converted into fat and remained in that form in the body of the dog.

Although the deficiency of 3·8 grams is but small, Voit, nevertheless, does not think it can be due to experimental error.

Examining more closely the data employed in this calculation, it is, in the first place, noticeable that the daily excretion of urea varied between 100·41 and 115·02 grams, while the fæcal excretion also varied between 18·1 and 53·6 grams.

The quantity of carbon in the urine was calculated from the mean of ten experiments; the quantity in the fæces from the mean of seven experiments; but on the other hand, only three respiration experiments were taken into account for the determination of the carbon in the expired carbonic acid.

It appears to me that this circumstance involves an error, though it may be a small one, inasmuch as a correct balance could be expected only when the determination of the carbon eliminated in the urine and fæces referred to the same day on which the carbon in the expired carbonic acid was determined; but on that day the dog did not pass any fæces, so that the numbers given could only represent estimated quantities, and though they are astonishingly accurate when not differing more than 3·8 grams in the carbon, they are not absolutely accurate, nor would any one acquainted with experiments of this kind regard them as sufficiently accurate to serve as a basis for a theory of fat production.

But even if the accuracy of the deficit be not disputed, there is a further reason for refusing to attach any weight to Voit's inference that the 3·8 grams of carbon wanting in the excretions had been converted into fat, because he forgot that the meat on which he fed the dog contained some portion of fat. In his previous experiments with Bischoff, he says, "the meat was good fresh cow-beef, always *very carefully* deprived of fat, bones, etc. Several analyses showed that it contained at the utmost only 1 per cent. of fat."*

I have myself determined the fat in a piece of very lean beef that had been selected by Professor Bischoff for this purpose, and, by dissolving the meat with hydrochloric acid, I obtained ⅓ per cent. fat.

Then considering that in the experiments made by Voit and Pettenkofer, the dog was fed daily with 1500 grams of meat, and assuming this to contain ⅓ per cent. of fat, the dog would receive 5 grams of fat daily in the meat; moreover, if there was really, as observed, a deficiency of 3·8 grams carbon, corresponding exactly to 5 grams of fat, it is infinitely more probable that this quantity of fat, taken in the food, had simply remained in the dog's body, than is the assumption that this 5 grams of fat was consumed in the respiration, while another 5 grams was produced out of the albuminates of the meat. Such an assumption is indeed incompatible with the economic laws of the animal body.

Besides this, Voit did not take into account the fact that in his earlier experiments together with Bischoff,* a dog fed with 1800 grams of meat (or 300 grams more than in the case above referred to) lost, within seven days, 230 grams, or nearly half a pound of body-weight.

This fact is as little in favour of the production of fat from flesh, as the more recent experiments. It may indeed be said that the loss of weight in an animal fed with meat does not at all disprove the production of fat from flesh, since the fat must displace a certain quantity of water, and thus give rise to loss of weight; but such an objection as this would not have any significance, unless the production of fat from flesh were indubitably proved, and that is not the case.

In Voit's investigation there is the same kind of error that Pasteur committed when, from the loss in his determination of the ammonia in fermented liquors, he inferred a positive fact, without knowing the source of that loss—thus adopting a procedure inadmissible in scientific investigation.

As may be gathered from what has already been said, Voit's experiments with the dog cannot any longer be admitted as arguments in the question as to the production of fat.

In regard to Voit's experiments with the milch cow, his exposition of them, just as in Thomson's investigations, is based upon the erroneous idea that a diet rich in albuminates exercises an influence on the production of butter, and increases the quantity of it, while existing experience only goes to show that a *strong diet* (Kraftfutter) increases the *yield of milk*.

The experiments made in this direction by Kühn show that the composition of cow's milk is very constant with different animals and kinds of food; milk varies in the amount of water, but during long periods of observation there is scarcely any alteration in the relative proportions of its constituents. "The greatest differences were observed in the fat, next to those in sugar. On the average of all the animals this amounted to 0·09 per cent. in favour of food that was itself superior to the extent of about 17 or 18 per cent." This is a remarkably small difference.†

It is evident that it would only then be possible to speak of any influence of albuminates upon the yield of butter if, on the addition of albuminates to the fodder, the amount of butter in milk were sensibly and permanently augmented; however, observation shows nothing beyond the fact that the yield of milk

* 'Die Gesetze der Ernährung des Fleischfressers,' p. 56.

* *Ibid.*, p. 79.

† Landwirth. Versuchs-Station, Dr. Nobbe, 1869, xii. 154.

is increased by adding meal to the ordinary hay fodder.

The conclusion at which Voit arrives is the following. He says, "As regards the main question, it appears that, on the whole, the cow took up into the circulation from the fodder, 1658 grams of fat, or four-fifths of the fat contained in the milk; the 562·35 grams nitrogen in the urine corresponds to 3602 grams albumen, which, according to our views, yields 1851 grams fat (100 albumen = 51 fat)."

"Therefore, we have in all 3509 grams fat available from the food and the albumen. However, the milk contained only 2024 grams of fat, so that there remains over and above that 1485 grams fat, which is nearly sufficient for the formation of the milk sugar in such a manner that, in the foregoing case at least, there is no necessity for having recourse to the hydrates of carbon for the wanting fifth of the fat, or probably for the milk sugar either."

This calculation is as clear as possibly can be; all the albumen of the fodder passing into the circulation is supposed to be converted, in the body of the cow, into casein, urea and fat; any deficiency of fat in the milk is made up by albumen, and whatever fat remains over is converted into milk sugar.

But in regard to the validity of this calculation, there are very important objections.

It is, in the first place, a thoroughly well-established fact that, for keeping up a given condition, an animal requires a certain quantity of albuminates and non-nitrogenous substances for the performance of its internal work; the nitrogen of the albuminates is eliminated in the urine and fæces, in the former as urea and hippuric acid, etc.

A cow producing milk requires a larger quantity of fodder than a working ox, and the fodder must contain the same proportion of albuminates as in the latter case,—for 100 pounds live weight 0·23 pounds albuminates, and from 1·25 to 1·4 pounds non-nitrogenous substances, according to Settegast. In both animals the quantity of nitrogen taken up is the same; in the cow, a part of the nitrogen passes into the milk as casein, and the remainder into the urine and fæces. Deducting from the nitrogen in the urine of the ox that quantity of nitrogen which is contained in the milk of the cow, the remaining nitrogen in the urine of both animals will be the same. The weight of both animals remains unaltered, and it is clear that the albuminate which becomes casein in the cow is expended for work in the body of the ox. On the whole, the secreted quantity of nitrogen is the same in both cases, but the quantity in the urine of the ox is larger than in that of the cow.

Consequently, if *all* the albumen corresponding to the nitrogen in the urine were, as Voit thinks, together with the fat from the fodder, converted into urea and milk in the body of the cow, much as corn is converted in a mill into bran and meal, there would not be any albumen left for the vital economy of the animal. This leads obviously to the assumption that the cow had lived solely at the cost of the non-nitrogenous constituents of the fodder, and had thereby performed its internal work.

But, assuming on the contrary that the albumen corresponding to the nitrogen in the urine has served for internal work and for replacing material eliminated from the body by metamorphosis, it would then follow that the products of this metamorphosis had been applied for the production of milk, and that 85 per cent. of these products consisted of urea and fat.

Then, if we seek for the reasons by which, regardless of all that we know as to the products of metamorphosis in the animal body, we are to be induced to regard such conclusions as valid, we find them thus stated by Voit:—*

"Since I do not at present know any better, I take it for granted that from 100 albumen there are produced 33·5 urea and 51·4 fat."

This is, indeed, the actual basis of Voit's theory respecting the production of milk, a purely supposititious breaking up of albumen into fat and urea in proportions that suit his calculation, adopted solely to serve, in the absence of facts, as the foundation for an imaginary explanation. Consistent with this is Voit's procedure in dealing with ascertained facts concerning the production of milk, so as to make them agree with his views; in his hands, such facts are like wax, to which the wished-for form is given by kneading it.

In scientific investigation such a mode of proceeding does not convince any one; it is always a sign that facts are wanting which would speak for themselves.

After all the laborious work and all the multiplicity of analyses that have been made, we are not one step further advanced in our knowledge as to the origin of fat and milk-sugar in the milk of the cow; and, as I believe, the reason of this is, that the question has not been properly stated. Let us only suppose that Voit had in his experiments selected another cow,—one that gave little milk instead of one that gave much; it is highly probable that his calculation would then have come out still more favourably for his theory than was actually the case; it might have happened that the quantity of urea excreted by this cow should have been just as large as in the experimental case, and then by calculating the urea as albumen, there would have been enough of this substance available for the production of *all* the constituents of the smaller quantity of milk, the casein, the fat and the milk-sugar together, and, in such a case, it would not have been at all necessary to regard the fat of the fodder as taking part in the production of milk. It must be evident that as Voit puts the question at issue, its decision would, in any case, have been in favour of his preconceived view; the more unfavourable the conditions, the better would the calculation have suited.

In the treatment of physiological problems there is only too often an opportunity of observing the absence of that strict method which does not permit of data being applied for drawing conclusions before their sufficiency for this purpose has been fully established; thus, for instance, Voit calculates the nitrogen in the urine of his experimental cow as albumen, although he knows that a considerable portion of that nitrogen belongs not to urea, but to hippuric acid, which contains, relatively to nitrogen, eighteen times as much carbon, which then figures in the calculation as fat. In doing this, Voit relies upon Meissner, who thinks himself justified in concluding from his experiments that the non-nitrogenous product of hippuric acid must be derived from non-nitrogenous constituents of the food. However, the facts ascertained by Meissner are susceptible of an entirely different elucidation, and, in particular, we know that benzoic acid as well as bitter-almond oil,

* *Op. cit.* p. 116.

are constant products of the oxidation of albuminates.

The production of benzoic acid from the non-nitrogenous constituents of hay appears to me much more difficult to explain than the production of margaric acid from hydrates of carbon; still these are things that are in no way connected with the question here under consideration.

Our experience in reference to the chemistry of fermentation teaches us that from sugar, alcohols may be produced, which have many characters in common with the fats; and there is little reason for regarding as inappropriate the opinion that in organic processes alcohols of a higher order may be produced from non-nitrogenous substances, or that from those alcohols the corresponding acids may originate. It is sufficiently well known that butyric acid may be produced from lactic acid.

Quite recently it has been asserted that by the aid of the microscope, the conversion of the plasma of the cells into fat in the lacteal glands may be observed, inasmuch as its breaking up is accompanied by the appearance of fat in the form of milk corpuscles. But independently of the fact that we cannot actually see such a transformation of the constituents of cells, and indeed only perceive one thing in the place of another, Voit's experiments appear to me in this respect unfavourable to the idea of a conversion of nitrogenous constituents of the lacteal glands into fat, since he is compelled to adopt the assumption that at least four-fifths of the fat in cow's milk must have been furnished by the fodder.

The fat in milk contains, as is well known, several glycerine compounds of volatile acids,—butyric, caprylic, and caproic acids, which may very well be derived either from ordinary sugar or from milk sugar.

The question as to the production of fat does not appear to me to be susceptible of determination by experiments with herbivorous animals: what we do know with certainty is that in the case of these animals, albuminates and hydrates of carbon must act together, in order to produce fat; but we do not know at all whether the non-nitrogenous product that becomes fat originates from albumen or from hydrate of carbon, and I do not think it would easily be possible to ascertain this with certainty.

In researches of this kind I believe it to be necessary to take into account the nature of the animal, and that we should not, without good reason, assume the processes taking place in an herbivorous animal to be the same as those going on in the body of a carnivorous animal.

There is a large number of observations which appear to prove that in certain pathological processes fat originates from nitrogenous tissues, and therefore I regard it as probable that in the bodies of carnivorous mammalia albumen is concerned in the formation of fat and milk sugar, perhaps also under some conditions in the bodies of herbivorous animals. At least there are no chemical reasons that are opposed to such a view.

I have already mentioned that cholic acid, a product of the splitting up of albumen, contains exactly the elements of hippuric acid, margaric acid, and a hydrate of carbon:—

$$\underset{\text{Cholic acid.}}{C_{52}H_{43}NO_{12}} = \underset{\text{Hippuric acid.}}{C_{18}H_{9}NO_{6}} + \underset{\text{Margaric acid.}}{C_{32}H_{32}O_{4}} + \underset{\text{Hydrate of carbon.}}{C_{2}H_{2}O_{2}}$$

And in like manner glycocol, another product of the splitting up of albumen, contains the elements of urea and sugar:—

$$\underset{\text{2 Glycocol.}}{C_{8}H_{10}N_{2}O_{8}} = \underset{\text{Urea.}}{C_{2}H_{4}N_{2}O_{2}} + \underset{\text{Sugar.}}{C_{6}H_{6}O_{6}}.$$

Chemically, therefore, we may regard as possible the production of milk sugar and of a part of the fat in milk of carnivorous mammalia, from albumen.

The formation of hippuric acid from benzoic acid in the bodies of animals demonstrates the existence of glycocol, and its presence admits of the belief that this substance serves certain purposes in the organism.

The fact that, in the case of men fed on a diet consisting chiefly of meat, there is a reduction of the amount of fat in the body, is in no way opposed to the opinion that fat may be produced from albuminates.

To explain this fact it has been assumed that, owing to an excess of albuminous substances in the food, there is an increase in the number of blood-corpuscles and that, thereby, the absorption of oxygen by the blood is augmented, so that the oxidation within the body, especially of fat, is increased; but the absorption of oxygen is solely dependent upon the rapidity with which air and blood come in contact within the organs of respiration; in the higher animals it stands in proportion to the number of the heart's pulsations and of the inspirations within a given time; it is not even dependent upon the amount of oxygen in the respired air.

In compressed air the number of inspirations is diminished; in expanded air the number of inspirations is increased; while in both cases the quantities of expired carbonic acid, and the temperatures, vary only within narrow limits. In the ascent of Mont Blanc, Lordet observed that, from Chamouni up to the summit, the pulsations of his heart increased from 80 to 136, while the temperature decreased during the ascent, but after resting at the same height it remained constant at 36·5° C.

The diminution of the fat accumulated in the body when the diet contains a preponderance of meat is readily explicable from the slight respiratory value of meat as compared with fat and the hydrates of carbon.

A dog weighing 34 kilograms requires for the maintenance of its weight a daily supply of 3 pounds or 1500 grams of meat; and it is intelligible that a man weighing twice as much (for whom it would be almost impossible that he should consume, with a little bread, 3 pounds of meat daily) would not find this diet sufficient for the requirements of respiration. According to Voit, a working man consumes daily, for instance, under normal conditions of diet 137 grams of albuminates = 549 grams meat; also 117 grams fat, and 352 grams hydrates of carbon. Therefore, deducting from the 1500 grams of meat the above 549 grams, there remains for replacing the fat and starch 951 grams of meat, which would barely suffice to make up for the starch (97·2 parts starch = 309·7 parts meat); and even assuming that a man had consumed 1500 grams of meat, it is evident his body must furnish the 117 grams of fat that would be deficient. This sufficiently accounts for his becoming lean.

In all the processes of the animal body,—in digestion, formation of blood, respiration and metamorphosis,—some part is taken by those inorganic constituents, or salts, which are constant constituents of the blood, muscles, tissues, as well as of all organs, and, in the latter form, of the food. Sometimes the part they take is very decided; it is only by their aid that the nutritive substances in the food of man, and in the fodder of animals, acquire the capability of serving for the maintenance of organic processes and, consequently, these salts should always be taken into account in the explanation of those processes.

However, the length to which these papers have now extended precludes any more detailed consideration of the chemical relations of salts to the organic processes for the present, and I must reserve this subject for a future opportunity.—*Proceedings of the Roy. Bavarian Academy of Sciences*, 1869, ii. 4.

PREPARATION OF CANTHARIDATE OF POTASH.

The following directions are given by MM. Delpech and Guicard:—Dissolve with a gentle heat 2 grams of cantharidine in 150 grams of alcohol; add 1·6 grams caustic potash dissolved in a little distilled water. The liquid immediately assumes the form of magma, and the alcohol is to be separated by filtration and pressure. Ninety-eight parts of cantharidine give 163 parts cantharidate.

To prepare vesicating taffetas, make a solution consisting of gelatin 2 parts, water 10 parts, alcohol 10 parts, cantharidate of potash 0·2 part, and glycerine as much as may be required. This mixture is to be spread over thin sheets of gutta-percha with a brush, so that each square decimetre may contain one centigram of cantharidate. These taffetas must be moistened with water before being applied. Vesication will be produced in about six hours.—*Journ. de Pharm. et de Chim.*

THE PRODUCTION OF IODINE AND BROMINE.

BY W. H. CHANDLER.

To Scheele the world is indebted for the first intimation of the elementary existence of fluorine and chlorine, he having in 1771 referred the action of sulphuric acid upon fluor-spar to the freeing of a distinct acid from the mineral, though whether fluorine has, even up to the present day, been isolated, is a matter of great doubt. In 1774 the same chemist isolated chlorine. In 1811 Courtois separated iodine from the waste liquor in the manufacture of soda ash from seaweed. This was followed by the discovery of bromine in the bittern of sea-water by Balard in 1826. The isolation of these four closely-allied elements from their compounds was thus included in a century, and the application of them to economical purposes, to any extent, has been accomplished since the beginning of the present century. Their close relationship, their physical properties and their chemical affinities, which are nearly in an inverse proportion to their chemical equivalents, induce the supposition that they are modifications of the same element.

The isolation of chlorine, bromine and iodine from their compounds with the alkalies, is accomplished with equal facility. But the abundant store of the former in the enormous deposits of salt throughout the world and in solution in the ocean and inland seas, forms a striking contrast to the rarity of the two latter halogens. In combination with silver, bromine and iodine are found in some rare ores in Mexico and South America. Chatin claims to have detected iodine in rain-water, though in very minute quantities, and even in the atmosphere. In sea-water traces of it have been uniformly detected though not in quantities sufficient for quantitative estimation. Bromine exists in slightly larger quantities and, associated with iodine and chlorine, is found in the water of the ocean and inland seas, the various mineral and saline springs and in salt deposits throughout the world.

According to Von Bibra, the amount of bromine in the Atlantic Ocean, in one United States gallon, is 24 grains; in the Dead Sea, examined by Herapath, 121·5 grains; in the dried residue of the Mediterranean, 1·15 per cent.; in the mineral springs of Kreutznach, Ure found 10·8 grains; in Kissingen water, determined by Kastner, 0·44 grains; at Tenbury, in Worcestershire, examined by Dr. Ure, as much as 12·5 grains; and at Arnstadt, according to Hartung, 13·6 grains. Iodine occurs in far less quantities, from mere traces to 2·2 grains per gallon, this latter quantity being found in the iodine spring at Halle.

In the United States, both bromine and iodine have been detected in the various saline and mineral springs. Iodine was first detected in this country, in the Saratoga Spring waters, by Drs. Usher and Steel, in 1830, and bromine in the same waters by Dr. A. A. Hayes, and in the salines of Onondaga by Professor B. Silliman, in the same year. The quantity of bromine in the spring waters of Saratoga county, determined by Professor Chandler, reaches 3·63 grains per gallon in the water of one of the artesian wells, the largest amount of iodine found being 0·2 grain; but in America, as in Europe, it is in the salines that the quantity of these substances becomes of economical importance, and in a brine of the Saginaw valley, Dr. Chilton found 7·65 grains of bromine; at Tarentum, Pa., 6 grains bromine and 4 grains iodine were reported by Stieren; in the Salina brine analysed by Professor Goessmann, however, only 1·36 grains of bromine per gallon are reported.

Besides these various sources, iodine has been detected in the soda deposits of Peru, in the ashes of sponges, and in the ashes of the Spanish barilla plants. Cod-liver oil is said to owe some of its medicinal properties to a trace of iodine. Though the distribution of bromine and iodine is thus very general, yet owing to their existence in such comparatively minute quantities, the sources of our commercial supply are much more restricted.

Up to the beginning of this century the alkalies of commerce were derived from the ashes of plants, and the burning of sea-weeds was an important industry, especially in Great Britain and Ireland.

The amount of ashes of sea-weed, the so-called kelp, reached its maximum production in 1800, when 20,000 tons were collected. To produce this, 400,000 tons of wet weed were burned. From this time, owing to the removal of the import duty and to the introduction of the manufacture of soda-ash from common salt, the trade declined. But the discovery of iodine in the mother-liquors of kelp salts, somewhat revived the manufacture,—and it is to this source alone that the total supply of iodine in commerce is due. The high price stimulated the business, and, in a few places in New England, iodine factories were established. These latter, however, were soon abandoned, the weed upon our coast being of poor quality. The process of separating the iodine is exceedingly simple, being nearly analogous to that for the isolation of chlorine. The ashes are leached with water, and the various crystallizable salts of potash and soda are separated by concentration. Carbonates, sulphates and chlorides of potash and soda are thus removed, leaving in solution, sulphite, hyposulphite and some carbonate of soda, together with the iodides and bromides. By the addition of sulphuric acid the first three salts are decomposed, and the sulphate of soda produced is removed by crystallization. The concentrated mother-liquor is acidulated with sulphuric acid, and after the addition of binoxide of manganese, the iodine and bromine distilled off. The reaction may be represented thus:—

$$NaI + MnO_2 + 2(HO,SO_3)$$
$$= NaO,SO_3 + MnO,SO_3 + 2HO + I.$$

The bromine of commerce was derived mostly from salines until the salt mines of Stassfurt were opened; the Schoenebeck salt springs, near Magdeburg, producing the greater part of the supply for Germany. The method of manufacture is similar to that followed in the separation of iodine.

Upon opening the mines of Stassfurt, bromine was found in the mother-liquors in considerable quantities, and at present the principal part of the European product is derived from this source; as much as 300 grains per gallon having been obtained from these mother-liquors. Although but two or three of the manufactories have economized this substance, the price of bromine has greatly decreased during the last five years. This decrease has been hastened by the large production of bromine in the United States.

Although the amount of bromides in the Saratoga waters is considerable, yet the comparatively limited flow of water there, and the large consumption of the waters for medicinal purposes, precludes the manufacture. But from the strong salines it is derived in large quantities. At Tarentum, Sligo and Natrona, in Western Pennsylvania, Pomeroy, Ohio and Kanawha, West Virginia, the manufacture of bromine has become of considerable importance. The production of 1870 will reach 125,000 lb., a quantity probably in excess of the United States consumption. In 1867 the Stassfurt production of bromine was nearly 20,000 lb.

The total production of iodine in Great Britain and France is about 200,000 lb. annually, and outside these two countries very little is produced. As the average production of iodine is about 10 lb. to the ton of kelp, and it requires 20 tons of wet weed to produce one ton of kelp, this total quantity represents the burning of 400,000 tons of sea-weed. At the present price, the iodine produced is of more value than the alkaline salts, which were the original object of the industry.

As previously stated, iodine is not produced in the United States. Since its use was first established there the price has fallen from \$16·00 to about \$5·00 per lb. At present, bromine is furnished for less than \$1·50 per lb.

The chief consumption of bromine and iodine is for medicinal purposes in the form of iodides and bromides of potash, soda, or ammonium. A small proportion is consumed in photography. Bromine has been proposed as a discharge in calico printing, and during the late war was to some extent employed as a disinfectant. As yet, but a small proportion of the bromine of the saline mother-liquors is economized; but should manufacturers turn their attention to this important substance, the consequent reduction in price would render its economical employment in other directions possible.—*Amer. Chemist.*

MISTURA CRETÆ.

In the *American Journal of Pharmacy*, Mr. H. P. Reynolds, of Plainfield, New Jersey, recommends the following formula for mistura cretae, which, he says, will yield a mixture that does not ferment in the warmest weather:—

℞ Cretæ Præp.,
Pulv. Gum. Acac.,
Glycerinæ (pur.), āā ℥j
Aquæ Cinnamomi ℥xv

Mix in the usual manner.

With the same object, Mr. W. Ranstead, of Mount Airy, Philadelphi, prepares a powder as follows:—

Cretæ Præp. ℥ss
Pulv. Sacch. Alb.,
Pulv. Gum. Acac. āā ʒij

Mix well by rubbing in a mortar, and keep well stopped from the air in a bottle.

When the chalk mixture is needed he uses ʒj of the powder with f℥ss each of water and cinnamon water for each f℥ required.

It is also suggested by Mr. Reynolds that in the next revision of the United States Pharmacopœia glycerine should be substituted for syrup and sugar in very many of the official preparations. He says, "Glycerine preparations, made by cold percolation direct from the crude drugs, may advantageously take the place of nearly all the present official syrups, possessing, if desired, the same density, better representing their respective bases, and being of a far more stable character. Of this I am satisfied by actual experiment."

Suicide by Poisoning.—On Tuesday, September 17th, an inquest was held by Dr. Lankester upon the body of Mr. Walter Killick, twenty-one years of age, lately a clerk in a mercantile house. It appeared that the deceased having shown signs of mental aberration, his friends had taken steps to place him in a lunatic asylum. It is probable that he heard of this design, for he suddenly left his friends in the country, and came up to town. After partaking of refreshment at an hotel, he retired to rest. The next morning, as he made no appearance, his room was entered, and he was found lying on the bed quite dead. There were bottles about the room which had contained chloroform, beetle poison and laudanum. The laudanum, it was shown, was purchased at the shop of Mr. Mason, chemist, Old Street, St. Luke's, Mr. Mason's daughter, a girl only fourteen years of age, selling it. The deceased had represented that he was a surgeon, and wanted the poison to destroy a dog. The jury returned a verdict "That the deceased committed suicide while in an unsound state of mind," coupling with it a reflection upon Mr. Mason for permitting a child to vend poisons.

Death under the Influence of Chloroform.—A few days since, a man thirty-four years of age received a severe wound on the finger from the kick of a horse. He was admitted into the Royal Free Hospital the following evening with symptoms of tetanus. The next day, it having been decided to amputate the finger, chloroform was administered on a piece of lint. After two or three inhalations the patient struggled violently, and shortly afterwards expired. At the inquest which was held, a verdict of "Death from tetanus, accelerated by chloroform," was recorded.

Poisoning by the Leaves of the Yew.—*L'Imparziale*, of Florence, mentions the case of a girl who took a decoction of the leaves of the *Taxus baccata* to bring on catamenia. She repeated the dose every morning for three days, but on the fourth she took an increased dose of eight ounces. Severe vomiting ensued, a medical man was called in, and the vomiting was encouraged by the use of tepid water. In spite of every effort, however, the patient died delirious, eight hours after taking the last dose of the decoction. Nothing of importance was revealed by a post-mortem examination.

Poisoning by Locock's Pulmonic Wafers.—It is reported that a child has recently been killed at Kilmarnock by swallowing some of Locock's pulmonic wafers. Medical help was obtained, but it was of no avail, the child dying in twelve hours. The basis of these wafers is probably some form of opiate, but the public are not generally aware that they are so dangerous as this case would seem to prove them to be.—*Medical Times and Gazette.*

Adulterated Beeswax.—Dr. Hager has met with a substance, sold in the Continental market as beeswax, which consists of equal parts of beeswax, paraffin and Japan wax.—*Pharm. Cent. Halle.*

Radway's Ready Relief.—According to Dr. Hager, this nostrum is an alcoholic solution of camphor, oleoresin of capsicum, and ammonia.—*Pharm. Cent. Halle.*

The Pharmaceutical Journal.

SATURDAY, OCTOBER 8, 1870.

METROPOLITAN LABORATORIES.

The Pharmaceutical Society no longer stands almost alone in having, as a part of its educational department, a chemical laboratory for students which would bear comparison with the laboratories of the Continent. Other institutions have long since seen the value of this means of study, and, recognizing the special necessity for practical work in the study of chemistry, they have applied their resources in the establishment of suitable laboratories.

In the matter of chemical laboratories, however, we are yet shockingly behind Germany. Still we are improving. At St. Bartholomew's there is the fine new laboratory, presided over by Dr. MATTHIESSEN. The Charing Cross Hospital has also recently enlarged its laboratory. But the laboratory of the Pharmaceutical Society will still bear advantageous comparison with those of other metropolitan institutions, and the attendance of students at it seems to show that its beneficial assistance is well appreciated.

Since last Session considerable changes have taken place in the chemical lectures at the medical schools. At Guy's Hospital, in the room of Dr. TAYLOR, there is Dr. DEBUS. King's College, as our readers will perceive, has just lost Dr. MILLER.

St. Thomas's, on the other hand, which was to have removed to its new quarters, opposite the Houses of Parliament, is still in its temporary lodgings in the Surrey Zoological Gardens.

Probably before long we may have provincial laboratories in no way inferior to those in London.

In a recent article upon the Art of Prescribing, the *Lancet* expresses an opinion that, as understood by our fathers, it is certainly dying out if not already dead. Prescriptions are simplified, and single drugs are often given, but the teachers of the present day err in paying no attention to the instruction of their pupils in the art of writing such prescriptions as would be given to a private patient to be compounded by an ordinary druggist. Time may be saved in hospital practice by using formulæ for mixtures and pills, or referring to their number in the hospital Pharmacopœia, but by so doing the student misses teaching to which he is fairly entitled.

It also points out that although there is a general consent that the "directions" should be in the vernacular, but the drugs and their quantities in Latin, —teachers seldom dictate the drugs in Latin, much less the quantities; and asserts that if an ordinary abbreviated prescription were put into the hands of many advanced pupils, they could not put it into Latin without committing various solecisms.

CHEMISTS AND DRUGGISTS' FUND FOR THE SICK AND WOUNDED.

The following contributions have been received since the publication of our last:—

	£.	s.	d.
J. B. Bailey, Reading	1	0	0
John Mitchell, 254, Upper Street, N.	1	1	0
J. Smart, Scarborough	1	0	0

Collections per Michael Rogerson, Local Secretary at Bradford, Yorks:—

	£.	s.	d.
M. Rogerson and Son	5	0	0
Joseph Hick	2	2	0
Harrison and Parkinson	5	0	0
John Boast	1	0	0
William Cockshott	1	0	0
John Walker	0	5	0
William Newsholme	0	10	0
John Tankard	0	5	0
James Foster	0	5	0
James Roper	0	4	0
Joseph Cookson	0	2	6
Samuel Parker	0	2	6
Samuel Beanland	0	5	0
J. Rhodes	0	5	0
John Priestley	0	1	6
	£16	7	6

	£.	s.	d.
T. Ackerman, Bristol	1	1	0

3 oz. bottles of sulphate of quinine.

Edward Constance, 37, Leadenhall Street.
1 doz. 2 oz. liq. opii sedat.
½ ,, 2 ,, cinchon. cordifol.

J. Bell and Co., Hastings.
2 lb. methylated chloroform.
4 oz. chloral.
4 lb. lint.

Charles Jones, Hanley.
6 gross 1 gr. opium pills, in bottles of 4 doz. each.
6 ,, 2 ,, quinine pills ,, ,,
6 ,, ¼ ,, morphia pills ,, ,,
3 lb. lint.

R. H. Davis, Harrogate.
400 pil. opii, gr. i, in bottles of 50 each.
400 pil. morphiæ acet., gr. ¼, ditto.
1 oz. muriate cinchonine.
4 ,, pot ext. carnis.
1 lb. chocolate powder.
1 ,, arrowroot.
2 woven vests.
4 bandages.

S. A. Keyworth, Hastings.
2 ½-lb. bottles pure carbolic acid.
2 lb. lint.

The following letter has been received in reference to this Fund:—

Dear Sir,—Will you kindly allow an explanation in reference to the Chemists and Druggists' Fund for the Sick and Wounded?

It ought to be known that our esteemed friend Mr. Alderman Gould, J.P., of Kingston, among many other places visited Richmond, and by his disinterested exertions succeeded in arranging two public meetings, at which he delivered interesting and stirring addresses; a committee was formed, and the chemists on being called upon liberally responded, by supplying considerable quantities of the most useful medicines, etc.

In addition to this effort public collections were made at the various churches and chapels of the town; these facts will, I hope, be accepted as a sufficient reason why our names did not appear in your subscription list.

I remain, dear Sir, faithfully yours,
R. GOODWIN MUMBRAY.

14A, *Hill Rise, Richmond, S.W*

Meeting of the Pharmaceutical Society.

The Inaugural Meeting of the session 1870–71 was held on Wednesday evening, Mr. Sandford in the chair, when there was a more than usually large attendance of members, probably owing to the interest felt in the presentation of the Sandford testimonial portrait, which had been announced to take place on this occasion. Several ladies graced the proceedings by their presence.

The Secretary read the list of donations to the Library and Museum as follows:—

University College Calendar, 1870–71: from the College,—Edinburgh University Calendar, 1870–71: from the University,—Smithsonian Report, 1868; The Indians of Cape Flattery, by Mr. J. G. Swan: from the Smithsonian Institution,—Proceedings of the Newcastle-on-Tyne Chemical Society: from the Society,—Pisciculture dans les Neilgherries; Belanger's Essai de Culture du Quinquina: from M. le Dr. J. L. Soubeiran,—Report on the Specimens of Chinchona in the Herbaria at Madrid, by C. R. Markham; Planchon on Peruvian Barks; Botanical Exchange Club—Report of the Curator and List of Desiderata for 1870: from Mr. James Collins,—Remarks on the Generic name Cascarilla; Notes sur les Quinquinas: from Dr. H. A. Weddell,—On Medical Reform: from Dr. Edwards Crisp,—Address Delivered at the opening of the Botanical Society of Edinburgh, Session 1869–70: from Dr. Cleghorn,—Science et Nature, 2 vols.; De la Bière: from Professor Attfield,—On a Species of *Ipomœa*, affording Tampico Jalap: from Mr. Daniel Hanbury,—Old Manuscript Receipt Book: from Mr. James Baynes,—The Practice of Perfumery: from Mr. R. J. Owen,—43 Specimens of the Educts and Products obtained in working Seaweeds by the Process of R. C. C. Stanford, Esq., of Glasgow: presented by Mr. Stanford,—Specimen of Cape Saffron: presented by Mr. J. R. Reeler, of Cape Town,—Tail of the Musk-rat (*Mygale Muscovitica*), bought at Damascus in April, 1870, by Professor Schwarzenbach, of Berne: presented by Professor Dr. Flückiger,—Bark of *Cinchona Calisaya*, grown in Cordova, Mexico, by M. Nieto: presented by Professor Soubeiran, of Paris,—Specimen of true African Elemi, collected from a tree of *Canarium edule*, Hook. f., growing in the Angola district, Pungo Andongo, by Dr. Friedrich Welwitsch: presented by James Collins (Curator).
