**Helmitol, a New Urinary Antiseptic.**—It is generally conceded that urotropin is one of the most valuable if not the most powerful urinary antiseptic we have. It owes its value to its decomposition with the liberation of free formaldehyd. Unfortunately, however, this decomposition is exceedingly slow in alkaline urine, so that the remedy fails in precisely those cases in which its action is most needed. Goldschmidt<sup>1</sup> describes a new form of this remedy which is constructed with the idea of overcoming the difficulty just named. Chemically it is a methylene citronate of urotropin, and is marketed under the name of helmitol. The addition of an alkali to its solution in a test-tube brings about the liberation of formaldehyd. The presence of free formaldehyd was also demonstrated in the urine after its internal administration. Goldschmidt found that beside the free formaldehyd a certain proportion of the antiseptic occurred in the urine still in chemical combination. It is very possible that this union possesses antiseptic properties. Helmitol has the advantage over urotropin of being more soluble, while its price is not excessive. In a large series of cases of cystitis, prostatitis, and similar diseases, especially in those cases with a tendency toward alkaline decomposition, Goldschmidt found the remedy in doses of one gram two or three times a day of great value. He was unable to observe any effect from the remedy in cases of phosphaturia. The same is true of infectious diseases of the urethra. [H.C.W.]

**Treatment of Puerperal Insanity.**—E. W. White<sup>2</sup> thinks that as soon as premonitory symptoms of puerperal insanity are observed extreme quietude of surroundings should be ensured and careful, skilled supervision of the patient enforced. The child should be weaned at once. Give liberal and sustaining diet and keep the bowels regular. Thorough examination of uterus and surroundings should be made, lochial discharges dealt with, and urine examined. Avoid any free use or abuse of sedatives and hypnotics. If there is acute maniacal excitement with insomnia, opium and all its preparations should be avoided and proper doses of potassium bromid and chloral given, subsequently sulfonal and trional. But if the mental symptoms are of the melancholy type the preparations of opium and diffusible stimulants are indicated. Other medical treatment is outlined, and as soon as strength will permit fresh air out of doors, gentle exercise, amusements, and light occupations should be encouraged. Recovery in all cases is gradual and protracted, but the final results satisfactory, as about 80% recover. [W.K.]

**The Gelatin Treatment of Melena Neonatorum.**—Oswald<sup>3</sup> has seen among 6,500 newborn children, 5 with true melena neonatorum. Two were treated with 2% solution of gelatin hypodermically, 2 with ergotin and ice, 1 with ice only. One of the 2 patients treated with ergotin left the hospital before termination, the other 4 recovered. It is therefore a question whether gelatin saved the 2 patients, or whether they would not have recovered without it. On account of the rapid results, however, he believes himself justified in continuing the treatment with gelatin, should other cases present themselves. [E.L.]

**The Treatment of Diphtheria by the Intravenous Administration of Antidiphtheric Serum.**—Cairns<sup>4</sup> advocates the intravenous injection of antidiphtheric serum in (1) the malignant forms of the disease—those characterized by hemorrhage from the nose or into the skin, by great glandular enlargement with marked cellular infiltration, and by extreme blanching of the skin; (2) any marked involvement of the lungs, either at the time of admission or subsequently; (3) a moribund condition of the patient on admission; and (4) profoundly toxic condition of the patient. In all such cases an initial dose of from 20,000 to 25,000 units is perhaps not exces-

sive, and if in 24 hours the patient fails to respond to the treatment by continued rise of temperature and increased frequency of pulse-rate and respiration-rate, and by an extension of the membrane, the dose may be safely repeated. A series of 50 illustrative cases is reported. [A.O.J.K.]

**Results of the Tuberculin Treatment According to Goetsch's Method.**—Roemisch<sup>1</sup> has treated 17 patients in various stages of pulmonary tuberculosis with tuberculin, following the method of Goetsch, with favorable results in incipient cases, and in some more advanced instances, which, in spite of conscientious carrying out of the proper hygiene and diet, and under favorable conditions, had not shown any progress for a long time. He does not recommend it in highly nervous patients, in cases with a temperature curve, and in individuals already affected with such extensive lung changes as to produce considerable tissue destruction during the reaction. To obviate the latter it is better, therefore, to choose only such cases for the treatment which, through prolonged suitable measures, have begun to cicatrize, and when associated with such measures, he believes the tuberculin treatment indicated. The method is applied as follows: He begins by injecting the active substances of tuberculin "R" in doses of  $\frac{30}{1000}$  grain (.002 milligram), and increases it gradually to  $\frac{1}{1000}$  grain (.1 milligram). He then substitutes the entire tuberculin in doses, gradually increasing from  $\frac{1}{1000}$  to 15 grains (.1 milligram to 1 gram), repeating the last dose several times in intervals of a week. The intervals between the other injections were usually two days. The temperature was taken five times daily, and whenever an elevation occurred he returned to the next lowest dose, which was endured without reaction. [E.L.]

**The Treatment of Glycosuria and Diabetes Mellitus with Aspirin.**—Williamson<sup>2</sup> recommends the use of aspirin (acetyl-salicylic acid) in the treatment of glycosuria and diabetes mellitus, his observations being made on 40 patients. In 11 cases which were carefully observed for a long time the results were as follow: 1. In four very severe cases the drug did not produce any decided effect on the sugar excretion. 2. In three cases of chronic glycosuria the sugar excretion ceased when aspirin was given, the diet being kept unchanged. 3. In four cases of diabetes mellitus of the milder form the sugar excretion appeared to be clearly diminished by the aspirin. [A.O.J.K.]

**Beer Yeast in the Treatment of Eruptive Fevers and of Erysipelas.**—Following the discovery of the good effects obtained by the use of beer yeast in the treatment of furunculosis a number of investigators have been led to experiment with yeast in the treatment of divers affections. Among these Piétri, of Nice, and Conche, of Lyons, secured interesting results in the treatment of variola, though it appears that they had been forestalled in the use of beer yeast by Presta and Taruella, who report having employed it in June, 1901, with success in varioloid, scarlatina, rubeola and erysipelas. The results of these experiments are given, whereby it appears that beer yeast exercises in eruptive fevers and erysipelas a quasi specific action, which is attributed not to the soluble products secreted by the yeast, but to the action of the yeast protoplasm itself.<sup>3</sup> [C.S.D.]

**Intravascular Antiseptics.**—Fortescue Brackdale,<sup>4</sup> as a result of a series of experimental investigations, concludes (1) that rabbits injected daily with nontoxic doses of mercury oxy-cyanid, formaldehyd, chinolol, protargol, or sodium taurocholate are not thereby protected from the usual effects of a previous inoculation of virulent anthrax; and (2) that chinolol and formaldehyd in large doses (toxic) so depress rabbits infected with pneumococcus that they die sooner than an untreated animal. Generally, then, it may be said that at present there is no experimental evidence which would warrant the assumption that the course of septicemia in animals can be favorably influenced by the intravenous injection of antiseptic substances and that the only result to be obtained by pressing such a treatment beyond the maximum nontoxic dose is to hasten the death of the animal. In view of the results obtained, as well as those

<sup>1</sup> Therapeutische Monatshefte, 1903, xvii, p. 36.<sup>2</sup> British Medical Journal, February 7, 1903.<sup>3</sup> Münchener medicinische Wochenschrift, November 25, 1902.<sup>4</sup> Lancet, 1902, ii, 1685.<sup>1</sup> Münchener medicinische Wochenschrift, November 18-25, 1902.<sup>2</sup> British Medical Journal, 1902, ii, 1946.<sup>3</sup> La Semaine Médicale, October 29, 1902.<sup>4</sup> Lancet, 1903, i, 98.

obtained by other investigators, it seems useless to continue trying to apply clinically a method which, while by no means free from special dangers and difficulties, is at present unsupported by any experimental evidence either as to its present advantages or future prospects. [A.O.J.K.]

**FORMULAS, ORIGINAL AND SELECTED.**

**For Toothache.<sup>1</sup>—**

Orthoform	1 part
Carbolic acid, crystallized	1 part
Camphor	4 parts
Chloral hydrate	4 parts

Mix and dissolve.

Clean out the cavity, if possible, and dry it with a pledget of absorbent cotton wrapped around a toothpick or sharpened match end; then introduce a little wad of cotton saturated with the liquid into the cavity. A thin strip of bibulous paper may sometimes be used for drying the cavity with better advantage than cotton.

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 14, 1903:

**SMALLPOX—UNITED STATES.**

---------	----------------------	---	--

**Changes in the Medical Corps of the U. S. Army for the week ended March 14, 1903:**

BARTLETT, First Lieutenant COSAM J., assistant surgeon, is granted leave for one month.

RAFFERTY, Major OGDON, surgeon, is granted leave for two months from April 1, or as soon thereafter as his services can be spared.

GRANER, CARL, hospital steward, company of instruction No. 2, hospital corps, Fort McDowell, will proceed to Benicia Barracks to relieve Hospital Steward Wilfred H. Schuyler. Steward Schuyler will be sent to Manila, P. I.

**Changes in the Medical Corps of the U. S. Navy for the week ended March 14, 1903:**

LUMSDEN, G. P., surgeon, detached from the Hancock and ordered home to wait orders—March 9.

WAGGENER, J. R., medical director, commissioned medical director from January 20, 1903—March 10.

HAAS, H. H., passed assistant surgeon, and W. H. Bucher, commissioned passed assistant surgeons from January 10, 1903—March 10.

HUNTINGTON, E. O., DENNIS, J. B., and THOMPSON E., passed assistant surgeons, commissioned passed assistant surgeons from February 10, 1903—March 10.

DORSEY, B. H., assistant surgeon, appointed assistant surgeon, March 2, 1903—March 10.

HURD, I. N., pharmacist, detached from the Navy Yard, Portsmouth, N. H., and ordered to Washington, D. C., for examination for retirement, and thence home to wait orders—March 11.

BOGERT, E. S., JR., detached from the naval recruiting station, Buffalo, N. Y., and ordered home to wait orders—March 12.

MCMURDO, P. F., acting assistant surgeon, ordered to the Gloucester—March 12.

GROVE, W. P., passed assistant surgeon, detached from duty with marine detachment, Culabra, P. R., and ordered to Naval Hospital, New York, for treatment—March 12.

**Changes in the Public Health and Marine-Hospital Service for the week ended March 12, 1903:**

THOMAS, A. R., passed assistant surgeon, granted leave of absence for two months from February 25—March 5, 1903.

KERR, J. W., assistant surgeon, leave of absence granted by department letter of September 20, 1902, amended so that said leave shall be for one month and fifteen days—March 2, 1903.

FOSTER, A. D., assistant surgeon, upon return of medical officer in command, relieved from duty at Wilmington, N. C., and directed to proceed to Charleston, S. C., and assume command of the service, relieving acting assistant surgeon F. F. Sams—March 6, 1903.

BEAN, L. C., acting assistant surgeon, granted leave of absence for two days—March 9, 1903.

GOLDSBORO, B. W., acting assistant surgeon, granted leave of absence for one day—March 9, 1903.

PATRIE, W. E., acting assistant surgeon, granted leave of absence for fourteen days from February 27—March 10, 1903.

RODMAN, J. C., acting assistant surgeon, granted leave of absence for three days—March 7, 1903.

ACHENBACH, J., pharmacist, relieved from duty at Port Townsend quarantine, Washington, and directed to proceed to Port Townsend, Washington, and report to medical officer in command for duty and assignment to quarters, relieving pharmacist R. F. Troxler—March 6, 1903.

THURSTON, E. J., pharmacist, to proceed to Gulf Quarantine and report to medical officer in command for duty—March 6, 1903.

WOODS, C. H., pharmacist, granted leave of absence for twenty days from March 21—March 9, 1903.

DAVIS, H. E., pharmacist, relieved from duty at Louisville, Ky., and directed to proceed to Memphis, Tenn., and report to medical officer in command for duty and assignment to quarters, relieving pharmacist E. M. Holt—March 6, 1903.

TROXLER, R. F., pharmacist, upon being relieved from duty at Port Townsend, Washington, to proceed to Port Townsend Quarantine and report to medical officer in command for duty—March 6, 1903.

HOLT, E. M., pharmacist, upon being relieved from duty at Memphis, Tenn., directed to proceed to Louisville, Ky., and report to medical officer in command for duty and assignment to quarters—March 6, 1903.

*Promotion.*

PARKER, H. B., assistant surgeon, commissioned as passed assistant surgeon, to rank as such from March 3, 1903.

*Resignation.*

THOMAS, A. R., passed assistant surgeon, resigned to take effect April 25, 1903.

**Relation of the Physician to the Illegitimate Child, Its Mother, Etc.**—We regret extremely that the engagements of our space are such that we cannot reproduce in our pages the noble article by Hastings H. Hart, LL.D., on "The Illegitimate Child in Chicago," published in the March number of the *Chicago Medical Recorder*. Dr. Hart's description of Chicago as "the great dumping ground for the social wreckage of the interior," is of course applicable to every large city. The personal aspect of the question is inevitably bound up with the function of the physician, and every general physician must have realized many times the poignant fact described in the following quotations:

When one contemplates the multitude of young women, timid, inexperienced, shamefaced, driven into the maelstrom of a great city by the coldness of their friends and the hostility of their native communities; when one considers the suffering through which they pass, alone and unprotected; the perils to which they are exposed with no sufficient counselor, the perpetual stream of these poor creatures pouring into the houses of prostitution to become bondwomen, doomed to a brief life of misery and an early and forgotten grave, his heart is stirred with a desire to do some small part in redeeming them from their sad fate and restoring them to a happy and womanly life.

The physician more than any other public servant is the guardian of the sexual morals of the community. His relation to his patient is such that he is able to exercise a potent influence at the time when it is most needed. Many a man has been saved to honor and rectitude; many a young woman has been rescued from dire peril and has become a good wife and mother, through the wise and timely intervention of a faithful physician. He can do what neither parents, clergymen nor friend can do. He is invariably consulted, sooner or later, and his advice is usually followed. A great responsibility rests upon him, therefore, because he practically controls the policy of the community in dealing with this important social question.

Four parties are concerned in the illegitimate child, says Dr. Hart—the child, the mother, the father, and the community, including relatives and friends. Concerning the child we are delighted to learn that it is not necessary to allow it to be killed in Chicago. It is not necessary to sell it to be killed; not necessary to deny it the mother's breast and care in order for the mother to become a wetnurse. It is not necessary for the mother to give it up in order to earn her living. As to the young mother, the physician can help to reform her, help her to meet her maternal obligations; often the parents can be prevailed upon to take her back; if not, places can be found for both mother and child

whereby lives of decency and morality and even honor may be led. As to the father, he that suffers least of all, he can often be brought to face his obligation, and either to marry or support the mother and child, and especially if the effort is made before the birth of the child. To fail to bring him to account is often to fail lamentably in the physician's duty and in the whole problem. If he cannot be brought to book, the law with all its sternness should be called in. As to the community and the relatives, every counsel urges that the saving of both mother and child for future lives of service and respectability is the one rule that must govern all action. Dr. Hart says:

I desire to say in behalf of the Illinois Children's Home and Aid Society that the services of the society are freely offered to every physician who may desire counsel or assistance in dealing with any case of illegitimacy. We do not lay down any fixed rules for dealing with such cases. We employ trained agents and we endeavor first to find out just what ought to be done in the particular case before us, and then, if possible, to do that thing. It may be to take the child from the mother and place it in a family home; it may be to secure a situation for the mother where she can nurse her baby and keep it with her; it may be to secure a boarding place where the mother can pay board for the child; it may be to care for the mother and child together in a suitable institution for six months or a year; it may be to induce the grandparents to adopt the child as their own; or it may be to bring about a marriage between the parents.

Are there such institutions and helpers in other cities to whom the physician may turn for aid when these pitiable victims come under his care and appeal to him for advice?

**Doctor or Patient—The Point of View?**—When a book, an article, or a discovery of possible medical value appears, the medical journals, reviewers, critics, and, generally speaking, the judges at once take up an attitude toward it. The attitude taken to the new proposal may be good, or indifferent, or bad, but we wish today to fix in mind one habit that exists, and which seems to be both dangerous and increasing. This is the tendency of the judges to take the point of view of the doctor and of the profession rather than that of the patient and of the world of patients. It is most natural, often inevitable, that this should be so, because the alleged discovery or proposal is of course at first viewed from the scientific or the professional standpoint. But

it should be viewed not only and not always from that position! For there is no more stale truism than that doctor and profession exist for the benefit of the patient. If we are not here finally to cure and prevent his diseases we have no right to be here at all. It is not only conceivable but it is actually true that the professional attitude, the frame of mind that looks at a book or proposal purely from the point of view of the doctor and of medical truth may not coincide, may even be opposed to the practical curing and preventing of the patient's disease. The doctor who is interested in diagnosis alone, not in therapeutics, is an illustration, and both he and other numerous examples do in fact exist.

**An Illustration of a Bad Point of View.**—Let us suppose that one person in a hundred in the United States has or has had a severe disease that, if not fatal, at least renders life intensely miserable. Let us suppose that of these 700,000 patients 70,000 have been cured of this disease, that they can testify to the fact, and that hundreds of reputable physicians will also testify that it is their treatment which has given the relief. Let us suppose further that 200,000 other physicians have unconsciously drifted into the habit of ignoring the fact and the philosophy of these cures, and that most of these disbelievers are scoffers of the theory. Of those who ignore and do not scorn a number have come in some measure to see that the disease in question may be curable by the method advised. They indeed admit it and, in a way, urge it, but they add and emphasize the addition until it is the only result left in the mind that the advocates of the new truth are great exaggerators and hobby-riders. It is a truth, but, but, but, and but, again, until there is nothing but but, nothing except exceptions, left in the attention of the bewildered seeker of advice. He, indeed, if he is more interested in his patient and less in the personal, competitive, or professional standpoint of the critic, he will ask, How am I to know how far to go in the theory, when to try it or not in the cases of Mrs. Jones, Mr. Brown, and the Robinsons?

The patient's point of view may be entirely ignored through the exaggerating clamor against exaggeration and the passionate attack on hobbyriding by the critic and the evidence-weigher. He, indeed, is always more interested in the exception and the critical attitude than in the cure of a patient. He admits perhaps the limited truth, but kills it by harping on the danger of "over-enthusiasm," and buries it very deep by a hint that the specialist's interest in the matter is at bottom self-interest. "Typhoid fever may, of course, be due to contaminated city water, scarlet fever to milk, but not always, and then the sanitary cranks are not the only doctors in the world." "Headaches and sick headaches and biliousness are sometimes due to eye-troubles, but these oculists—really, you know, we can not accept the broad conclusions and extravagant statements, etc." "Disorders of digestion are sometimes due to dental troubles, but we shall hardly turn our practice over to the dentists, and go out of business, etc." And for a generation the deaths go on from pol-

luted water, one in ten continues to suffer for a lifetime with the daily agonies of headache, sick headache and biliousness, and every second child is still left with teeth unattended to. The point of the matter is that this neglect is by the leave and encouragement of the conservative and critical sneerer, until some "over-enthusiast" immolates himself on the critic's altar and by iteration does at last get the neglected truth attended to. Then the critic turns over in his grave and with the old murderous self-satisfaction he softly whispers to the over-enthusiast, his next-door neighbor, "*I told you so; I always said that this was a great truth!*"

**The Patient Who is Not Advised, and if Advised Cannot Get Treatment.**—Is it possible in these days of an overcrowded profession and an over-bedrugged world of patients, is it possible, one asks, that any patient cannot get medical advice and scientific treatment? Strange as it may seem, that is a fact, one over-neglected—one tremendously important. It is also a fact that the critic of specialists and hobby-riders, the weigher of evidence, the represser of over-enthusiasm needs to ponder for a few years, perhaps for the rest of his life. He thinks only of the well-to-do of the great city, or of the well-to-do of the small cities and country. He ignores the greater mass of the lower middle classes, and the yet vaster masses of the poor. These in the country—far removed from the city—frequently find it impossible to secure that expert advice which will relieve them of the original sources of their miseries. There are millions of people who are unadvised or incapable of consulting the specialist who only is capable of scientifically treating them. The self-chosen represser of "the specialist's exuberance" should put himself in their place. The general physician is the only adviser whom these millions can reach. The skill and learning necessary to cure certain affections of the ear, of the teeth, of the eye especially, of the nose and larynx and other organs, cannot be expected of the country physician, and often the patients could not pay for it if such skill were obtainable. Least of all can they consult the city specialist, especially if they have heard from the judges that these over-zealous specialists greatly exaggerate the power of abnormal dentition, eyes, ears, etc., to produce systemic disease.

**"Cleaning by Vacuum."**—We are slow to learn that the prevention of disease may consist in some small easily overlooked matter. When we reach a scientific conclusion, *e. g.*, as to the germ-origin of disease, we still for years neglect some simple little practical application needed to make the discovery of real use. In illustration, the *Lancet* and the Health Department of Chicago are wise in urging the great hygienic significance of a new device for cleaning carpets, furniture, etc. The broom and dust brush stir the dust up, spread it through the atmosphere for better inhalation, the residue then being left to settle where it was. The compressed air method is no better, but is even worse. The "vacuum cleaner" is a method of sucking the dust out of carpets, curtains, etc., as they lie or hang, and conveying it through rubber tubes to an exhaust cylinder

and thence to the furnace. Not only is the dust taken away, but fresh air is drawn into the rooms by the process itself. If it works as described it should be used in every household. But if of use in the home it is of course of greater service in the sick-room, in hospitals, etc., where the germs of infectious diseases are more numerous.

**Homes for the Homeless Children.**—The Children's Aid Society of Pennsylvania does not believe in the institutional care of homeless and destitute children. For 21 years it has been carrying on its work of finding individual homes for them, and its "Well done" will be seconded by all. New York and Boston also have similar societies, but there should be one in every city of the land. From the Pennsylvania Society's latest report we notice that of 1,076 overseen in 1902 there were:

Orphans . . . . .	24
Half orphans . . . . .	145
Deserted . . . . .	29
Of dissolute parents . . . . .	78
Of parents unmarried . . . . .	47
Of invalid and insane parents . . . . .	37
Of cruel parents, through S. P. C. C. . . . .	41
Of parents separated . . . . .	95
Of parents unable to control . . . . .	15
Vagrancy . . . . .	5
From Court and Magistrates previous to passage of Juvenile Court Act . . . . .	55
From almshouse authorities . . . . .	317
Foundlings . . . . .	4
Committed by Juvenile Court . . . . .	161
From police station . . . . .	3
From other sources . . . . .	19
From the street . . . . .	1
Total . . . . .	1,076

The application of the home principle to young law-breakers is of especial interest to the public this year through the accumulation of cases of that class committed to the Society by the Juvenile Court. Since June 14, 1901, on which date the Juvenile Court Act went into effect, the Society has received by commitment from the Judges 161 children. These children were received under the following charges: Burglary, 3; larceny, 28; till-tapping, 1; malicious mischief, 2; vagrancy, 4; assault and battery, 2; incorrigible, 34; runaway, 6; abandoned, 3; delinquency, 1; homeless child, 1; neglected, 76—total, 161. They were all placed immediately, with one exception, in separate homes in the country, put into school, and were made subject to the rules of the Society; 149 of these are doing well; 2 are still on trial with but slight improvement; 3 were returned to parents by order of the Court; 7 failed to be benefited.

The result of the work in New York was that whereas in the year before the Children's Aid Society's plan was adopted, hardly one foundling in a hundred had survived in the barracks; the deathrate fell to 50% in the first year of the change, 30% in the second year, and a trifle over 10% in the fourth year; this is lower than the average foundling deathrate throughout the country.

**The Barbarism of the Poorhouse Treatment of the Insane.**—We have several times referred to the horrors of the system of confining the insane in poor-

houses, but the conditions in the State of Missouri are probably worse than those elsewhere in the civilized world. According to the 1901 report of the State Board of Charities (quoted in *Charities*), there are 1,260 insane persons confined in the poorhouses of the State. Dr. Charles A. Ellwood, head of the Sociological Department of the State University, writes of these insane inmates of poorhouses:

"In many cases they are kept in chains for months and years. In one poorhouse in this State are confined in chains 3 violently insane persons. One has been in chains for 15 years, one for 7 and one for 3 years. These persons live in filth and are deprived of almost every comfort. Doubtless such cases of 'barbarity,' though sufficiently frequent to make one shudder, are exceptional, but the barbarity of mere neglect is found everywhere where the insane are permitted to remain in the poorhouses, and instances of this I can report from seeing with my own eyes. Unfortunately I have had opportunity to visit only a very few almshouses in this State. But even with my limited experience I have seen an insane paralytic left lying in his own filth, shut up in a steel cell. I have seen an insane old man, dying of cancer, shut up in a steel cell and left uncared for and unattended. I have seen others half naked in their cells, 'because no clothing could be kept upon them.' Reports by my students from almshouses I have not seen have confirmed my belief that such neglect as this is common in all almshouses in the State in which the insane are kept."

**The Tragedy of the Homeless and Friendless.**—In the year 1902, in the Borough of Manhattan, there died of tuberculosis, chiefly in the various hospitals of the city, 1,787 patients. Of these 950 were "not known" at the addresses given; 456 gave no address; 275 gave the address of a lodging house; and 106 gave an address outside of the city. It must be remembered that these deaths constitute only about one-seventh of all the deaths that took place. Moreover, for every death there are, according to Dr. Farr, about two years of illness endured. When one thinks how much our happiness, even in health, depends upon home and love and friendship, and that in illness and death the blessedness of these things is vastly increased; and then when one realizes that there are so many thousands of the sick and dying in our cities utterly homeless and friendless, the pity of it all becomes, indeed, terrible. The tragedy of obviably disease and needless death kindles our zeal to stop the spread of infection, to discover the means of preventing the suffering, and when this is not possible, to surround the lonely sick and dying with the best medical skill, attention, and kindness that is possible. The desolation of their appalling loneliness is often doubtless greater than that of their illness and oncoming death combined.

**The Financial Argument For and Against Sec-tarianism.**—The same mail brings us two sorry evidences of pitiable bigotry. The first is from a "regular" who, by grammar and spelling that would make a fonetik reformer laf, and by arguments that would make a logician grin, fights vociferously against the attempt of the American Medical Association to unite the profession in some kind of effective organization. The source of the movement is traced to the desire of the editor of the Association journal to increase the circulation of the journal, and also his "selera"

(salary), and he will have no reform "tainted with homeopathy." The specialists also aid, he says, in order to get consultations with the hated irregulars. His printed circulars, letterheads, etc., seem to show that he has some following. His earnestness is quite equal to his ignorance. The second proof comes from the other side, and is as silly and wrongheaded. We can do no better than to quote from the *Medical Century* of March, 1903:

"Getting right down to the milk in the cocoanut, the whole scheme of union of the schools, as promulgated by the American Medical Association, is simply to get us out of the way. Our success has staggered them; they know that wherever there is a homeopathic physician there is a prosperous practitioner; that wherever a homeopathic physician is employed there is wealth, intelligence and culture; they know that in communities where there are ten allopaths to one homeopath, the latter has the cream of the business and is pulling the silver door-knobs. Why? Because we are trading on a name? By no means; simply because we have the success. It is our success, our growth, our progress that is making inroads upon our brethren of the old school. We are getting some of the plums in municipal, State and national institutions; our colleges are growing, and our threatened movement along the line to strengthen our fortifications has excited an unrest among our enemies. It is more their own financial interests that are involved than ours; it has ever been a thorn in their flesh that they could not perfect a medical monopoly. . . . It is the homeopathic scalp that is wanted. When that is obtained the financial interests of the sectarian schools and journals will be out of the way, and their own financial horizon cleared. . . . We prefer to hold to our 'invested interests' a while longer."

Except the last sentence there is not a word or glimmer of truth in the contention of either contender. If either of these malignant dunderheads had a spark of true professional feeling he would welcome every attempt to extinguish sectarianism in medicine.

**The Notification of Chickenpox.**—Iowa is the Massachusetts of the west, and, like her eastern prototype, is in the vanguard of sanitary progress. The latest regulation put into force is the notifying and placarding of chickenpox. At present this is confined to Des Moines, but no doubt it will soon be adopted by other cities in the State. There is a possibility that boards of health may go to extremes in the matter of notification, and we must confess that we scarcely think it necessary to placard the house in which there is a case of chickenpox. During the prevalence of an epidemic of smallpox we should favor having all cases of chickenpox reported to the authorities, because many cases of variola are then likely to be treated, either wilfully or unintentionally, as chickenpox. Anything more than this, however, is probably too drastic. There is just as much, or just as little, reason for reporting and quarantining all cases of sore throat, because some of them might turn out to be diphtheria.

**Vacuum Apparatus for House Cleaning.**—The Chicago Department of Public Health advocates the vacuum method for house cleaning. This consists of a mechanical apparatus consisting of tubes of varying lengths, which are conveyed to different apartments. The dust and dirt particles are picked up and carried to a central receiver by a suction force, which eliminates all dirt and dust and does away with the necessity of taking up carpets, the removal of upholstery, furniture, etc. It is said to be especially applicable for the sick-room, from which the ever gathering dust can be removed without fear of contamination.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**The American Urological Association** will hold its annual meeting in New Orleans, La., May 8 and 9.

**Smallpox**, as officially reported in the United States from December 27, 1902, to March 20, 1903, amounts to 12,281 cases and 369 deaths, as against 24,157 cases and 707 deaths for the corresponding period of last year.

**The National Confederation of State Medical Examining and Licensing Boards** will meet in New Orleans, La., May 4, 1903. Members and ex-members of State Medical Examining Boards, physicians and educators who are interested in higher medical education are cordially invited to attend.

**Deaths Due to Accidents.**—According to the United States census a person is twice as liable to die from accident as from old age, and people die more frequently from accidents in the mountainous regions of the country than on the coast. It appears on the whole that nearly 6% of all deaths in the country are due to accidental injuries, the average age of death from accidents being about 33½ years.

**Lepers to be Colonized in the Philippine Islands.**—It has been decided that the proper method of treating lepers in the Philippine Islands is to colonize them at a central point, and the island of Camalin has been selected for this purpose. The colony will be to a certain extent self-governing, since a number of the lepers are persons of high intelligence and ability and capable of participating in the governmental affairs of the colony. All recent cases will be segregated from those which are chronic in character and marriages will not be permitted. Near relatives and friends will be permitted to visit the patients at certain times under restrictions. Plots of ground will be assigned to the various patients and implements given them. Vegetables and fruit may be grown to assist in sustaining the members of the colony.

**Contagious and Infectious Diseases Among Animals.**—The Department of Agriculture has announced a new code of regulations for the suppression and eradication of contagious and infectious diseases among domestic animals. It is required that all persons owning, managing, or transporting animals must ascertain that they are not affected with nor exposed in any manner to contagious or infectious disease. Persons having charge of affected or exposed animals must keep them segregated from other animals, and premises or vehicles where diseased or exposed animals have been shall not be occupied by healthy animals until thoroughly disinfected. Any place where there exists contagious or infectious disease among animals is to be considered an infected locality and the conveyance of susceptible animals into or through an infected locality will be governed by these regulations and any subsequent orders of the Secretary of Agriculture; vehicles used for their transportation must be cleaned or disinfected according to the Secretary's orders. The shipment or removal of hay, straw, fodder, or other similar materials, or of meats, hides, or other animal products, through an infected locality is prohibited. Shipments of live stock and products may be stopped in transportation for inspection and disposed of if found liable to disseminate contagion. Violations of these regulations are made punishable by a fine of \$100 to \$1,000, or by imprisonment not exceeding one year, or both fine and imprisonment.

**Hospital Benefactions.**—BALTIMORE, MD.: Under the will of the late Lavinia E. Frey, of this city, the Presbyterian Eye, Ear, and Throat Charity Hospital will receive \$500. PHILADELPHIA, PA.: Under the will of the late William McClary, which was recently adjudicated, many bequests are left to charities and other institutions. Among these is \$5,000 to the Protestant Episcopal Hospital to endow a bed in memory of the testator's dead wife, Esther J. McClary, the Church of the Nativity to name occupants. Sums of \$5,000 each are also left to endow beds in the Presbyterian, German, St. Joseph's, and Samaritan Hospitals.—Under the will of the late J. Alfred Kay, \$5,000 each is allowed to the Pennsylvania, Germantown, University, Jefferson, Orthopedic and Polyclinic Hospitals. St. Agnes', St. Joseph's, German, Gynecean, Howard, Medico-Chirurgical, Jewish, Hahnemann, and Presbyterian Hospitals will each receive \$1,000. A similar amount was given to the Pennsylvania Institution for the Instruction of the Blind, Philadelphia Dispensary, and the Howard Hospital and Infirmary for Incurables. One-sixth of the residuary estate not named is divided among the Pennsylvania, Germantown, University, Jefferson, Orthopedic and Polyclinic Hospitals. PATERSON, N. J.: The Paterson General Hospital, St. Joseph's Hospital, Paterson Orphan Asylum, and the Catholic Orphan Asylum will each benefit \$25,000 by the death of William D. Laverack, of this city, which occurred recently. These are bequests from the late Mary Laverack, who left all her estate, which amounted to over \$100,000, to Mr. Laverack during his life. At his death, if he had no children, it was to be equally

divided among the two orphan asylums and the two hospitals. Mr. Laverack married, but had no children. DOVER, N. H.: The late Aricoh Wentworth, of Swampscott, Mass., has bequeathed \$100,000 to the town of Dover, N. H., for the erection of a hospital to be called the "Wentworth Hospital."

**Typhoid Fever and Its Mortality.**—From the Registrar of Vital Statistics of the New York Health Department are obtained statistics which give us some idea of the relative prevalence of typhoid fever and its mortality in the various large cities of the United States and in foreign countries. From these it will be seen that the capital city of the United States, whose municipal administration is practically under the control of Congress, has the highest mortality of any other American city, while among foreign countries the comparative rarity of the disease and its mortality are strikingly different. The rigid administration of sanitary law and the careful supervision of the water-supply are doubtless the most important factors in these strikingly divergent figures:

AMERICAN CITIES.

	Population.	Deaths.	Deathrate per 10,000.
Washington.....	278,718	161	5.78
Chicago.....	1,698,575	509	3.00
Boston.....	573,579	142	2.48
Philadelphia.....	1,321,408	444	3.36
Providence.....	178,000	47	2.64
New York.....	3,536,517	727	2.06
St. Louis.....	598,000	198	3.31
San Francisco.....	369,000	70	1.94

FOREIGN CITIES.

Belfast.....	351,083	349	9.94
St. Petersburg.....	1,248,643	1,060	8.49
Cairo.....	608,910	485	7.96
Glasgow.....	764,467	198	2.59
Liverpool.....	686,451	165	2.41

Vienna.....	1,735,740	76	0.44
Munich.....	503,000	24	0.48

NEW YORK.

**Deaf to Hear.**—It is reported that a device resembling an ordinary telephone has been invented by an electrician of New York, which when placed in the vicinity of the ear of a deaf person will enable him to hear distinctly. The outcome of this reported discovery will be awaited with interest.

**Coroner's Bill Passed.**—The bill abolishing the Board of Coroners in New York City has passed the Senate. The act authorizes the Board of Health of New York City to appoint a chief medical examiner at \$6,000, and medical examiners at \$3,500, to take the place of the coroners at present in office, and whose terms do not expire for three years to come. The investigations of crime are to be made by the city magistrates and by the district attorney.

**Registered Nurses.**—The bill before the New York Legislature, which requires nurses to appear before a board of examiners to receive the degree of Trained Nurse before they can follow their vocation in that State, is likely to be amended. The proposed amendment provides that any nurse who has been practising her profession in the State to the exclusion of all other business for five years prior to the passage of the act and whose character and qualifications are endorsed by three licensed physicians of the State may be registered and entitled to the distinguishing mark of R. N. (registered nurse), provided the application therefor be made prior to July next.

PHILADELPHIA, PENNSYLVANIA, ETC.

**Joined Twins.**—Dr. J. H. Sargent, of Philadelphia, was attending physician at the birth of male twins united in exactly the same manner as were the famous Siamese brothers. The mother was a young married woman in the southern portion of the city. A band of flesh about seven inches long united the thorax of one child to that of the other. Neither child lived.

**German Hospital.**—The forty-third annual report of the medical board of the German Hospital has just been issued. During the year there were 2,715 patients admitted to the hospital proper and 355 patients were received in the Marine Hospital department. There were 1,615 surgical operations performed and in the various clinics of the dispensary service 41,909 patients were treated.

**Health of Philadelphia.**—A slight decrease has been noted in the number of cases of typhoid fever reported for the week ended March 21. In all 247 cases were reported with 27 deaths, as against 272 cases and 38 deaths for the preceding week. There were 26 new cases of smallpox and 1 death, as against 44 cases and 5 deaths in the previous week. The whole number of deaths from all causes was 535, showing a falling off of 42 as compared with the foregoing week and an increase of 59 as compared with a report of the corresponding week of last year.

**Preparing for Bids on New Hospitals.**—It is stated that within the next few days proposals will be received for the erection of the hospital for the insane and for the indigent on the sites selected adjoining the House of Correction at Holmsburg. Those in authority state that contracts for the work will be awarded by the end of the present month. The administration building and the new wards for the Hospital for the Insane are to be pushed as rapidly as possible to provide sufficient accommodations for the nearly 1,500 insane patients now in the old hospital in West Philadelphia. When completed the new Hospital for the Insane will accommodate 3,000.

**State Bacteriologic Laboratory.**—A bill was recently introduced into the Pennsylvania Legislature appropriating \$25,000 for the establishment of a bacteriologic laboratory at Harrisburg. It also provides for the appointment of a chief by the Governor, at an annual salary of \$5,000. The urgent need of such an institution is clearly set forth in the preamble of the bill, which states "there are many acute specific diseases prevalent in the State which are caused by certain known germs, such as tuberculosis, diphtheria, typhoid fever, etc., and whereas, our seaports are subject to an invasion of bubonic plague, cholera and other infectious diseases; and whereas, the State Board of Health is often called upon to make an analysis of water for the typhoid fever bacilli by many boroughs and townships throughout the State, and has not the facilities for so doing; and whereas, such a laboratory would be a sure means of determining the nature of such infectious and contagious diseases, thereby preventing epidemics and the useless sacrifice of human life. . . ."

**New Jefferson Hospital.**—It is announced that the demolition of the old buildings, at present occupying the site upon which the new hospital is to be erected, will be started at once, and that so soon as the appropriation expected from the Legislature is received work will be begun on the superstructure. The proposed new hospital will be an absolutely fireproof structure six stories in height with a basement and roof-garden. The basement will contain the power plant, x-ray-room, incinerating plant, and postmortem and disinfecting rooms. The administration office, eye department, men's receiving ward, surgical, and out-patient departments will be on the first floor, while on the second floor will be the men's department, with a semicircular surgical ward, operating-rooms, medical ward, dining-rooms, quiet-rooms, baths, etc. The women's department, similarly arranged, will occupy the third floor. On the fourth floor will be the children's ward, while on the fifth there will be 29 bed-rooms, drug-rooms, diet kitchens, etc. The sixth floor will contain dining-rooms, private wards, storage-rooms, etc. The cost will aggregate \$700,000.

**The Philadelphia Polyclinic** has established a phototherapeutic department and is prepared to treat patients with concentrated chemical rays of light and with the Röntgen rays. The installation of a new and powerful electric coil also offers increased facilities for radiography. A limited number of poor and deserving patients will be treated without charge, but from those who are able to pay, a moderate charge will be made for the treatment. The professor of diseases of the skin will examine each patient and determine the character of the treatment to be employed. The department is prepared to undertake the examination of patients referred to it for Röntgen ray diagnosis. Each application should be accompanied by a statement of the nature of the case, an outline of the history and a careful explanation of the diagnosis desired. No patient will be examined unless referred by a physician. A graded fee will be charged according to the nature of the part to be examined. The lamp to be used for the Finsen light treatment was made in England and is said to be a marked improvement upon the original. The Polyclinic is the first medical institution of Philadelphia to procure from Europe such an apparatus.

**Higher Requirements for Doctors.**—A bill has been introduced into the Pennsylvania Legislature which is intended to elevate the medical profession from the standpoint of preliminary education. It is also intended to amend the Medical Council Act of 1893, which establishes three State Boards of Medical Examiners. Under the present law the Council selects the questions to be submitted at each examination. The bill proposes to so amend the present law as to permit only the medical members of the Council to pass upon the questions submitted, and also that a certificate granted shall have inscribed upon it the name of the particular board under which the licentiate was examined. The educational test requires from candidates for license to practise medicine a diploma of graduation from a reputable college or university, or a diploma of graduation after a four years' course at a State normal, a high school, or academy, or a certificate of having passed the examinations for admission to the freshman class of a reputable literary or scientific college or university. After January 1, 1907, the bill provides that applicants for license must furnish proof that they have pursued the study of medicine "for four years, for at least eight months in each year in four different calendar years in some legally incorporated reputable medical college." At a meeting of physicians held recently in Philadelphia it was declared that the welfare of citizens would be much advanced by the passage of this bill, and it was therefore heartily

endorsed by the members of the profession present, and it was resolved to petition the authorities for its enactment into a law.

#### SOUTHERN STATES.

**Röntgen Rays in Trachoma.**—It is asserted that a patient with trachoma has been successfully treated at the Maryland General Hospital by exposing the eyelids to the Röntgen rays. The treatments were given three times a week, the duration of each being from 7 to 10 minutes. It is stated that a cure was effected in about two months.

#### WESTERN STATES.

**Compulsory Vaccination for Waiters.**—The Bulletin of the Health Department of Chicago for the week ended March 14, 1903, states that a prominent club in the city, which frequently employs from 40 to 60 colored waiters and attendants, has adopted a standard rule requiring satisfactory evidence of recent successful vaccination as a condition of employment in any capacity about the club-rooms. The example should be followed by every club in the city.

**Persons Suffering from Tuberculosis to be Excluded from California.**—It is announced that the committee appointed to investigate conditions concerning the ingress of the tuberculous into California from other States will recommend to the Legislature measures restricting such persons from coming to the coast. It was also decided not to advise the establishment of a State Sanatorium for the treatment of tuberculosis as it is believed such a project would encourage the tuberculous to come to the State.

**Hydrophobia in Chicago.**—The death by hydrophobia of a son of Dr. Henry P. Loomis, of Chicago, has called attention to the unusual prevalence of rabies in the city. It is reported that the Pasteur Institute is receiving many more than its usual quota of patients at this season of the year. The Health Department, which has also under its care patients whose cases may eventuate in rabies, likewise reports unusual activity. The seriousness of the condition is probably overestimated from newspaper reports, but there still probably remains some ground for the manifest interest taken.

**To Restrict Practice of State Employes.**—The following is taken from the *Journal American Medical Association*: The resolutions recently adopted by the San Joaquin Medical Society, directed against private practice by the physicians at the State hospitals, have been crystallized into a bill which has the following provisions:

The medical superintendents and assistant physicians of the several State hospitals for insane persons must not engage in the private practice of medicine, but must devote their whole time to the performance of their duties, unless granted leave of absence by the board of directors. If any of such physicians shall engage in the private practice of medicine his office shall thereon become vacant, and the board of directors, or other appointing power, shall immediately appoint some qualified person, other than the officer whose office shall have become so vacant, to fill such vacancy.

**Physicians Again Duped.**—From Indianapolis (Ind.) comes the news that two young men, who represented themselves as agents of the "Medical Alliance of America," victimized about 100 physicians and business men in that city. The doctors were to pay an initiation fee of \$10 and \$1 a year dues and furnish a list of patrons to the "Alliance," which was incorporated by one of the young men in question. The agents then went among the patrons of the physicians and induced a number to become members of the alliance by paying an initiation fee of \$1, in lieu of which they were promised free medical attention. Others joined at \$2 a head. The alliance was to issue policies for the payment of death benefits, etc. They secured about \$5,000 in money. The young men disappeared, leaving their victims wiser, somewhat poorer and with the "alliance" on their hands.

**To Eradicate Plague in San Francisco.**—According to the Public Health Reports active measures for the eradication of plague are being enforced daily. Overcrowding in tenement and lodging houses has been prevented and over 200 arrests have been made for a neglect to comply with the cubic air-space ordinance. Scavengers are employed to remove garbage frequently, sweep the streets, and sprinkle them afterward with HgCl<sub>2</sub> solution three times a week. Lining of unsanitary places, such as closets, urinals, cellars, back areas, and unclean alleyways, is progressing rapidly, and at the completion of this form of disinfection the same territory will be covered again, using instead carbolic acid spray. The sick are inspected daily, the dead examined carefully, and necropsies insisted upon in doubtful cases in order that no case of plague escape detection. The extermination of rats by means of traps and poisons continues unabated.

**Increased Birthrate of Chicago.**—The Bulletin of the Health Department, in discussing the increased birthrate of the city, proves conclusively that it cannot be attributed to the

great numbers of immigrants who have settled in the city. It states that of the three principal cities having populations of more than 1,000,000 each in 1900, Chicago had next to the largest proportion of "native born," and a larger proportion even than the typical American city—Boston. The following figures are from the twelfth United States census:

	Native population.	Native born.	Native born, per cent.
New York.....	3,437,202	2,167,122	63 0
Chicago.....	1,698,575	1,111,463	65.4
Philadelphia.....	1,293,697	998,357	73.2
St. Louis.....	575,238	463,882	80.6
Boston.....	560,892	363,763	64.9
Baltimore.....	508,957	440,357	86.5

Philadelphia, St. Louis and Baltimore are out of the immigration wave; immigrants are not attracted and do not settle in these cities—therefore no comparison can be made with them. Eliminate these cities, and it is seen that Chicago has the largest proportion of native born population of the important cities of the country, and that its increasing birthrate cannot properly be attributed to the immigration factor.

#### CANADA.

**New Medical Building for the University of Toronto.**—According to the *Chicago Medical Recorder*, a deputation from the medical faculty of the University of Toronto waited on the Premier of Ontario recently to ask for a further grant of \$50,000 to finish and equip the new medical buildings now nearing completion in the Queen's Park, Toronto. The original sum of \$125,000 has been found inadequate, and the medical faculty seeks to borrow another \$50,000. This building when completed will be the finest type of modern college building on the North American continent. It has been constructed on the "unit system," the standard size of the class-rooms being 23 by 30 feet. The lecture-rooms are supplied by a number of "research" rooms in which students can carry on independent investigations. It is the first university building to be constructed on this unit principle since it was laid down. Toronto University now has the largest number of medical students of any Canadian university, even leading McGill, which for so many years took first place. There are at present 420 medical students on the rolls.

## FOREIGN NEWS AND NOTES

#### GENERAL.

**First Medical College for Women in China.**—A medical college for women was opened with appropriate ceremony in Canton, China, December 17, 1902, by the United States Council. Many missionaries participated in the ceremonies and a high tribute was paid to Doctor Mary Fulton, who has labored long and extensively among the Chinese. It is said that 13 young women are studying medicine in the institution and the applicants for admission for next year already number 60.

#### GREAT BRITAIN.

**Antityphoid Serum.**—Trustworthy information is at hand to the effect that Lord Lister has communicated to the Royal Society a paper by Dr. Allen MacFayden, director of the Jenner Institute of Preventive Medicine. Lord Lister sets forth a prophylactic and curative treatment for typhoid fever, as worked out by Dr. MacFayden, who it is claimed found that the cellular juices obtained by crushing typhoid bacilli in liquid air can be used for the purpose of injection. It acts as a curative agent and as a means of prophylaxis in the treatment of typhoid fever. Practical results from this reported discovery will be awaited before much credence will be placed in this novel theory.

**Measles in London.**—It is stated that measles is very prevalent in London, and while it is not one of the diseases requiring compulsory notification, yet the London County Council are reported to be taking active steps to combat its spread. It appears that the public schools are the particular avenues of dissemination. That death from measles is more common among children than is ordinarily supposed is illustrated by the fact that in London in the year 1901 there were 1,952 deaths reported from the disease, which is equal to a death-rate of 0.43 to each 1,000 persons living, whereas the mortality from scarlet fever the same year was only 0.13, and diphtheria showed 0.20; whoopingcough for the same period, 0.35.

#### CONTINENTAL EUROPE.

**Endowment for Hospital Bed.**—It is asserted that Mrs. Robert Goelet, of New York, has given \$2,500 to endow an American bed in the Victoria Hospital of Nice, France, in memory of her daughter Beatrice. The only other American bed in the hospital was endowed five years ago by Andrew Carnegie.

**Bacteria to Give Light.**—Prof. Hans Molisch, of Prague, believes he has discovered a use for bacteria in a mining lamp. The lamp consists of a glass jar in which there is a lining of potassium nitrate and gelatin previously inoculated with bacteria. The latter multiply enormously in two days, causing the jar to become illuminated with a bluish green light. This lasts brilliantly for several days, gradually dimming until it disappears in from two to three weeks. It is stated that the lamp thus provided is suitable for mines, powder magazines and other places where explosives are likely to be kept.

### OBITUARIES.

**Edward W. Jenks**, of Detroit, Mich., March 19, aged 70. He was graduated from the Bellevue Hospital College, New York City, in 1864. He was a Fellow of the American Gynecological Society and Obstetrical Society of London, Eng.; a member of the American Medical Association and Detroit Academy of Medicine; honorary member of the Ohio State Medical Society, Maine Medical Association, and the Cincinnati Obstetrical Society; and ex-president of the Michigan State Medical Society. He had been a member of the Michigan State Board of Corrections since 1894.

**Major Norton Strong**, a retired army surgeon, died in Baltimore, Md., March 23, aged 51. He was a graduate of Harvard Medical School, and after leaving that institution he went to St. Luke's Hospital, in Chicago, where he earned quite a reputation as a bacteriologist. In 1880 he was appointed to the position of surgeon in the United States Army.

**T. Harper Rice**, at Pottstown, Pa., March 14. He was a graduate of the medical department of the University of Pennsylvania, Philadelphia, and was also a licentiate of the Royal College of Physicians, London, and of the Royal College of Surgeons, Edinburgh. He served as surgeon in the Boer army during the South-African war.

**J. Augustus Carnross**, of Philadelphia, March 19, aged 58. He was graduated from the Jefferson Medical College in 1876. He was connected with the State Hospital for the Insane at Warren, Pa., and the Philadelphia Hospital. He was a member of the Philadelphia County Medical Society and of the Philadelphia Medical Club.

**Charles A. McCall**, of Philadelphia, March 12, aged 67. He was graduated from the medical department of the University of Pennsylvania, Philadelphia, in 1855, and afterward served for several years as chief resident physician in the Pennsylvania Hospital. He served as assistant surgeon in the Civil war.

**John H. B. Browning**, at Smithtown Branch, L. I., March 17. He was graduated from the Columbian University Medical School, New York City, in 1883, and was at times assistant resident physician of the insane asylum on Ward's Island and house physician and surgeon of St. Francis' Hospital.

**Samuel McLean**, of Hillisboro, Ill., March 18, aged 56. He was graduated from the Eclectic Medical Institute, Cincinnati, Ohio, in 1874, and at the time of his death was superintendent of the Illinois Asylum for Feeble-minded Children at Lincoln, Ill.

**James J. Larkin**, of Chicago, Ill., March 12, aged 49. He was graduated from the Chicago Medical College in 1830. He was a member of the Chicago Medical Society and Physicians' Club and was surgeon to the South Chicago Hospital.

**Levi B. Ward**, in Canon City, Colo., February 21, aged 37. He was graduated from the Kentucky School of Medicine, Louisville, in 1896, and was a member of the Colorado State and Fremont County Medical Societies.

**Henry R. Potter**, of Bismarck, N. D., died at Agra, India, March 3, aged 55. He was graduated from the University of Georgetown, Washington, D. C., in 1872. He was an acting assistant surgeon in the Army.

**Walter W. Bunyan**, at Chicago, Ill., March 16. He was graduated from the Northwestern University Medical School in 1901, and at the time of his death was serving as interne in the Cook County Hospital.

**Joseph C. Shepard**, of Wilmington, N. C., March 5, aged 63. He was graduated from the New York University in 1860, and served as a surgeon in the Confederate army during the Civil war.

**Jonathan Cilly**, of Cincinnati, Ohio, March 18, aged 65. He was graduated from the Miami Medical College, Cincinnati, Ohio, in 1866. He served as an army surgeon during the Civil war.

**Rutherford R. Price**, of Toronto, Ohio, died at Phoenix, Arizona, February 26. He was graduated from the Western Pennsylvania Medical College, Pittsburg, in 1900.

**Frank Merritt**, of Charlotte, Mich., March 17. He was graduated from the Detroit Medical College, Detroit, Mich., in 1877. He served two terms as Mayor of Charlotte.

**Benjamin P. Hooke**, of Loysville, Pa., March 11. He was graduated from the medical department of the University of Pennsylvania, Philadelphia, in 1855.

**George W. Smith**, of Monongah, W. Va., at Fairmount, W. Va., February 26, aged 28. He was graduated from the Rush Medical College, Chicago, in 1894.

**William F. G. Noetting**, in East Hampton, Conn., February 28, aged 83. He was graduated from the University of Heidelberg, Germany, in 1842.

**John N. Kendig**, of Akron, Ohio, in Cincinnati, Ohio, February 26, aged 28. He was graduated from the University of Maryland, Baltimore, in 1898.

**John K. Faust**, at Hyndman, Md., March 8, aged 68. He was graduated from the College of Physicians and Surgeons, Baltimore, Md., in 1886.

**Theodore A. Grover**, at Wilmington, Del., March 6, aged 63. He was graduated from the Starling Medical College, Columbus, Ohio, in 1869.

**Henry Edward Newell**, in West Derry, N. H., February 24, aged 51. He was graduated from the Long Island College Hospital, Brooklyn, in 1873.

**William Campbell Goodlett**, in St. Louis, Mo., March 1, aged 80. He was graduated from the University of Pennsylvania, Philadelphia, in 1849.

**Richard D. Greene**, in Lexington, Ky., February 25, aged 63. He was graduated from the Bellevue Hospital Medical College, New York, in 1867.

**James Henry Dugan**, of La Salle, Ill., March 2, aged 30. He was graduated from the College of Physicians and Surgeons, Chicago, in 1899.

**J. R. Simms**, in Linden, Cal., February 27, aged 82. He was graduated from the Medical School of the Valley of Virginia, Winchester, in 1849.

**William H. Baird**, of Oxford, Miss., died at Jackson, Tenn., March 5. He was graduated from the Tulane University, New Orleans, in 1869.

**Daniel C. Dickinson**, in Union Hill, Va., March 6, aged 45. He was graduated from the Medical College of Virginia, Richmond, in 1878.

**Sherburne R. Merrill**, in Paterson, N. J., March 16, aged 81. He was graduated from the Jefferson Medical College, Philadelphia, in 1851.

**Enoch P. Jones**, in Marion, Ind., February 26, aged 75. He was graduated from the Eclectic Medical Institute, Cincinnati, Ohio, in 1854.

**Noyes Barstow**, a retired physician of Springfield, Mass., March 16, aged 82. He was a graduate of the medical school at Woodstock, Vt.

**Elliott W. Leech**, in Shelbyville, Ind., March 5, aged 70. He was graduated from the Kentucky School of Medicine, Louisville, in 1891.

**James C. Patton**, in Francisco, Ind., February 19, aged 76. He was graduated from the Medical College of Evansville, Ind., in 1850.

**George W. Bishop**, in Snow Hill, Md., March 6, aged 76. He was graduated from the Jefferson Medical College, Philadelphia, in 1848.

**H. T. Bass**, at Tarboro, N. C., March 16. He was graduated from the medical department of the University of Pennsylvania in 1874.

**Charles W. Roberts**, of Scranton, Pa., March 21. He was graduated from the Hahnemann Medical College, Philadelphia, in 1889.

**John Graham**, in Plainville, Ill., February 23, aged 65. He was graduated from the Eclectic Medical Institute, Cincinnati, in 1878.

**Francis Rourk**, in Detroit, Mich., February 22, aged 61. He was graduated from the University of Maryland, Baltimore, in 1865.

**Benjamin M. Van Sickle**, at Newark, N. J., March 15, aged 46. He was a graduate of Bellevue Medical College, New York City.

**Albert B. McKee**, of Edwardsville, Ill., March 17, aged 40. He was graduated from the Rush Medical College, Chicago, in 1893.

**David F. Rupp**, in San Diego, Cal., February 25, aged 53. He was graduated from the Kansas City Medical College in 1879.

**John N. Davis**, of Boulder, Colo., February 22. He was graduated from the Eclectic Medical Institute, Cincinnati, in 1880.

**Edward E. McCall**, at Lima, Ohio, March 23, aged 37. He was graduated from the Baltimore Medical College in 1894.

**Samuel C. Hanford**, in Hempstead, L. I., February 24, aged 80. He was graduated from the New York University in 1845.

**Jonathan Baker**, at Des Moines, Iowa, March 15. He was graduated from the Chicago Physio-Medical College in 1888.

**L. W. Bishop**, in Batavia, Ohio, February 27. He was graduated from the Medical School of Ohio, Cincinnati, in 1870.

**Edward R. Kittoe**, in Galena, Ill., February 18, aged 57. He was graduated from the Chicago Medical College in 1869.

**Henry W. Richter**, in Brooklyn, N. Y., March 4, aged 63. He was graduated from the New York University in 1861.

**Lester Joslin**, in Ionia, Mich., February 26. He was graduated from the Cleveland Medical College in 1867.

**T. W. Wright**, in Farmington, Iowa, March 1. He was a graduate of the Keokuk (Iowa) Medical College.

**H. Hungerford Drake**, of Winsted, Conn., March 16, aged 70.

**Hezekiah Henry Bean**, at Baltimore, Md., March 18, aged 83.

**William J. Enders**, in Hamilton, Ohio, March 7, aged 26.

**John McCormick**, of Shubuta, Miss., March 17, aged 29.

**A. D. Griffin**, in Vinton, Iowa, February 25.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## THE STUDY OF DIFFERENTIAL DIAGNOSIS.

BY

JOHN L. BURNHAM, M.D.,  
of Las Cruces, N. M.

The following cases, which have come to me during the year, illustrate the difficulties that must be contended with in an isolated district where cases cannot be referred to the specialist:

CASE I.—A Mexican had been treated for three months by other physicians for dysentery with no relief. The patient coming to me, after one week of fruitless treatment upon ordinary lines I examined a fresh specimen of feces microscopically and found the feces swarming with *Amoeba coli*. Two weeks' use of quinin, 1-1,000 enemas, cleared the feces from amoeba, and the patient made a fair recovery.

CASE II.—A young woman of 17 had been treated a year by several physicians for chronic bronchitis and asthma. Coming to me, my examination showed exophthalmic goiter, two of the cardinal symptoms being present, rapid heart and paroxysmal palpitation with dyspnea, and goiter present. Exophthalmos was wanting. Laryngeal cough, presumably from pressure on recurrent laryngeals, furnished "chronic bronchitis," and paroxysms of tachycardia with dyspnea and the "asthma." Patient was well in six months.

CASE III.—A girl of 12 for six months had been treated by several physicians for "tonsillitis," "wry neck," "neuralgia" of occipital region extending to top of head and down on front of neck. My examination showed head and neck rigid—a case of caries of the upper cervical vertebra. Rest in bed with confinement of joint brought about great amelioration in a month, with subsequent steady improvement. The cause of the symptoms was discovered and the patient treated accordingly.

CASE IV.—For a year a cowboy had noticed a lump in the pit of his stomach, which slowly increased in size and became tender and painful after a day's work in the saddle. His physician diagnosed "chronic abscess," and advised incision. Physician and patient came to my office for advice, and operation if necessary. Examination revealed a boggy tumor, the size of a large hen's egg, in the middle line about midway between the umbilicus and the ensiform cartilage, slight impulse on coughing, not tympanitic. Putting patient on his back with shoulders raised, gentle taxis restored the "abscess" to the abdominal cavity—an omental epigastric hernia. The results of incision can be imagined.

My guiding principles from the beginning of my practice of medicine in the study and treatment of the sick have been two maxims of two of my teachers—Professor P. S. Connor, who said, "Take no man's diagnosis; make up your own mind from your own study of the case;" and Professor C. P. Nancrede, who gave as a definition of skill "A knowledge of what will and may happen, and attention to detail."

## APOMORPHIA HYDROCHLORATE.

BY

EDWIN R. SHANNON, M.D.,  
of Waterloo, Iowa.

Previous to 1896 my knowledge of this drug consisted of its value as an active emetic. In the summer of that year I found myself early one morning with strength and patience nearly exhausted, having been in attendance nearly the whole night upon a young woman suffering (or causing me to suffer) with hysteroepilepsy. The usual antispasmodic treatment had proved futile, and chloroform was finally resorted to, which gave only temporary relief.

Having lost patience and perhaps sympathy because of the obstinacy and character of the case, it occurred to me that a restful change in picture and symptoms might be secured by giving an emetic. Apomorphia was then administered in full emetic dose and my surprise and satisfaction were intense when, after an unnecessarily severe vomiting spell, the patient relaxed and fell into a peaceful sleep, giving me no more trouble for several months, when a recurring attack was quickly relieved by smaller doses of the same drug. I learned later that Gowers had recommended the drug in this form of hysteria.

In 1897 I was called to see a man of 76, who had been hiccupping constantly for six days. He had been under the care of several physicians and on account of his age and extreme debility little hope of recovery was entertained. I gave him 3 mg. ( $\frac{1}{20}$  grain) of apomorphia hydrochlorate; nausea and alarming heart weakness followed in a few minutes, succeeded, however, within 15 minutes by relief from the hiccup. I found it necessary within the next three days to give only two more doses of 2 mg. ( $\frac{1}{20}$  grain), after which the patient made rapid recovery and is still alive.

In June, 1902, I was called to attend a married woman whom I found in a most alarming condition of suffering; nearly every muscle of her body was in spasmodic contraction, so intense about the neck and back as to produce opisthotonos. I could learn nothing from her as she was in a state of delirium from pain. Her husband informed me that she had experienced dozens of these attacks, that a number of physicians had attended her during seizures, that she had contracted the morphin habit from the treatment thereof, and that chloroform had been the only means of giving relief. Now, I had tried that all-night chloroform treatment before, and here was a case with manifestly no inflammatory or organic lesion, and apomorphia occurred to me at once. Three mg. ( $\frac{1}{20}$  grain) were administered, and I left my patient asleep in 20 minutes.

There are two other conditions in which this drug has been quite uniformly useful to me: The insomnia of acute alcoholism and angina pectoris. It is not the purpose of this paper to define the exact diagnostic conditions calling for this remedy or to formulate a theory of its action. The cases cited do both in a practical way.

The dosage should be as light as possible, preferably to secure nausea without emesis. Ordinarily 3 mg. ( $\frac{1}{20}$  grain) hypodermically is about the proper dose, though in old people this may be too much. In the whole domain of medicine no drug has given me so much satisfaction as this, for its results are immediate and positive, and the class of cases calling for its use are usually the most trying that a physician is called upon to attend. If the reported action of this drug will be the means of doing my readers any part of the good it has done some of my colleagues and myself I shall feel well repaid for this effort.

NEVUS OF THE MOUTH.<sup>1</sup>

BY

FREDERIC GRIFFITH, M.D.,  
of New York City.

Surgeon Bellevue Dispensary; Fellow of the New York Academy of Medicine.

The patient, aged 25, is a Jewess, brunet, and single. She consulted me in February, 1903, in regard to a congenital formation. The growth was situated upon the right side of the mouth cavity and consisted externally of the bulged lips and corner of the mouth, extending backward to the anterior border of the masseter muscle. The tumor was purplish-red in color, movable but with a broad base; was painless, pulseless, and while tense to the touch it was readily determined to be made up of congeries of enlarged veins or capillaries. The mass felt not unlike lobes of varicocele. Shot like bodies of a size No. 5 could be felt, which later were found to be spheres of fibrous blood-clot formed probably by attrition during functional activity of the parts.

In spite of the fact that when the mouth was opened the tumor took its place between the teeth the patient affirms that she never had it to catch between her jaws when eating or talking. The truth of this statement was witnessed by the glistening, velvety, unscarred mucous surface which was presented. Four weeks ago with the aid of local anesthesia produced by a .25% cocain solution I was enabled to accomplish the removal of the growth. The patient's desire for active interference rested entirely upon the cosmetic effect which the gradually growing nevus produced. My thought in advising operation rested upon the danger from possible future malignant change or hemorrhage from rupture. As I was unattended the difficulties which were considered at the time of operation were control of the bleeding and the amount of subsequent deformity which would result from nerve or muscular involvement. After injecting the mucous membrane and submucous tissue I passed numerous silk sutures from beyond the lateral limits of the growth through the base and almost to the cheek surface in depth. Left long the ends were clamped and

<sup>1</sup> Presented to the Surgical Section, New York Academy of Medicine.

weighted by hemostats. The anterior sutures were passed from before backward to provide for the formation of the corner of the mouth. Dissection was done with blunt-pointed, curved scissors and forceps, commencing posteriorly, as the blood supply seemed to come from in front and below. Bleeding was free, but was readily controlled by tying the sutures consecutively as I passed over the area covered by each. All of the sutures were removed during the course of the first ten days. The surface was smoothed off and the outline of the mouth rendered as though undisturbed by careful application of silver nitrate at intervals. Home treatment consisted in the daily use of a 20% hydrogen dioxide solution.

The case is presented for interest (as the books give nevoid growth from mucous membrane as being uncommon); for the successful control of the hemorrhage by the method given, and for general result.

## CHLOROFORM IN LABOR: HINTS ON SOME OF ITS USES.<sup>1</sup>

BY

STEPHEN HARNSBERGER, M.D.,

of Catlett, Va.

"As travail upon a woman with child." Thus does sacred history record the fact that woman in labor must suffer; and while this is true, is it a valid reason why we, in this age of anesthetics, should sit idly by and let her suffer? I am, and always have been, an advocate of the rational use of chloroform in labor. I rarely fail to give it during the latter half of the second stage. I give it in properly selected normal labors, and I give it in the aberrant cases. Why should we not give it? Why should we allow any one to suffer pain? Then certainly why should we sit stoically (I had almost said stupidly) by, as many do, and see women suffer the agony of travail, and say, as I have often heard physicians say, "Oh, madam, you are doing all right. Let nature have its way," when all the time nature's way is preparing her for prolonged future suffering, and in not a few instances for an early grave.

I do not believe every physician fully realizes the importance of controlling pain. Pain may be only a symptom, but it is a symptom that not infrequently ends in death, which may occur in a very short time by rapidly overcoming the vital forces. But perhaps the most usual instances in which pain proves fatal is when it so antagonizes the physiologic processes and functions that every tissue and organ is seriously impaired and cannot withstand the encroachment of disease. It seems to be a well recognized fact that patients kept free from pain in peritonitis recover, while those who are allowed to suffer commonly, if not always, die. This is true in other conditions in which pain is a prominent symptom, and is no less true in the lying-in chamber. Here, as elsewhere, pain often determines the life or death of the patient.

I would suggest the use of chloroform during the second stage of labor. I rarely use it during the first stage, because dilation of the cervix is a slow process, and once you begin to use chloroform the patient will not have it discontinued. Its employment, however, is advisable in the first stage in the so-called forced labors. I have rarely ever seen chloroform lessen, and have never seen it suspend, uterine action. Some women have nagging pains in the back or in front, though less frequently, for many hours or even days, before labor properly sets in; they are worn out and irritable from loss of rest and sleep. A suitable anodyne, reinforced by a rational use of chloroform during the first stage, though it should retard somewhat the progress of the case, will give them the encouragement and strength to pass through the inevitable ordeal. In other cases labor sets in suddenly and with unnaturally severe expulsive pains. These should be lessened and the uterine contractions moderated. The use of chloroform here will save the patient probable shock, and the parturient canal much of the imminent danger of threatened and probably permanent injury from lacerations—no less, perhaps, the risks of postpartum hemorrhage and subsequent septic infection. At other times we meet cases in which the pains are excruciating but nonpro-

pulsive. There is little or no progress. In these patients under chloroform anesthesia the obstructive conditions yield and they go promptly on to a happy completion. I was asked to attend a case of this character in 1883—third child. The family physician had been called suddenly but imperatively away. He left word, however, that the patient was not under any circumstances to be given chloroform, on account of organic heart disease. The woman suffered pain after pain. Several hours passed wearily away and yet no progress was noted, and finally when I noted that all symptoms pointed to a sure and as I believed speedy collapse, I awoke her husband, explained the matter as it stood, and plainly told him that she must either have chloroform or die. He reluctantly assented. Her pulse began to improve in rhythm and tone from the moment anesthesia was reached and became steady and regular. In 30 minutes the baby was born. Her puerperium was uneventful. I have attended similar cases since with as satisfactory results, and I am persuaded from this experience that danger lurks not so much in the cardiac condition of the patient as in the quality of chloroform and the manner in which it is administered. Furthermore, in those rarer cases in which we find almost incessant and excruciating girdlelike pains in the lower quadrant of the belly, which furnish our surest sign of threatening rupture of the womb, chloroform anesthesia gives us our strongest hope. General tranquillity may supervene for awhile, and longer than we may wish, but it is the repose that saves.

At other times we meet intensely neurotic women, who cry, toss about, and "are a terror" to family and doctor. These women, I find, quiet down only under chloroform. It is the physician's only reliable means for promptly and successfully managing such patients.

In puerperal eclampsia one can use chloroform as an adjuvant. It helps to mask the hideousness of the condition while pilocarpin hydrochlorate and saline infusion are putting in their curative work.

In labors in which no operation is performed, but in which it is incumbent upon the obstetrician to make manipulative procedures necessary for the welfare of the woman, chloroform should be employed, if she is suffering much pain, in order to quiet her. During obstetric operations, such as version, the use of the forceps, etc., I think chloroform should always be employed. It saves the patient pain; it allays excitement; it minimizes the risks of injury to the uterine structures and those of the other portions of the parturient canal, and the operator is able to work better through knowing that his patient is free from suffering. He is not so inclined to hurry when haste would be hazardous to the best interests of the woman.

Of course, we would naturally expect to employ chloroform or other anesthetics in operations like abdominal sections, etc., and therefore further consideration of this point is not necessary. It has been claimed that inflammations, postpartum hemorrhage, puerperal fever, subinvolution, etc., are more liable to occur when chloroform has been used in labor. The liability to the first of the accidents enumerated can not be increased, unless violence be used during operations, and no operator with average skill should do a bungling operation. The second accident may be a trifle more liable to occur after the use of chloroform, though I have never found this to be true. Still, if recognized as possible, it can be easily guarded against by taking proper precautions. The third accident, I feel sure, is more of an assertion than a fact, for the more comfortable we make the lying-in woman the better care we take of her, and the more we husband her vital forces, the less likely is she to fall a victim to puerperal sepsis. In my own clinical experience chloroform helps to prevent puerperal fever, and any agency that does this also helps to ward off subinvolution and chronic uterine disease.

In all cases when pain is severe we barter time, cause our patient to lose strength and depreciate her chances of recovery by allowing ourselves, as many do, to depend on nature and nature's way.

To employ chloroform intelligently and successfully in obstetric work, good judgment and a thorough knowledge of the action of the drug must be had, especially in those cases

<sup>1</sup>Read, by invitation, at the meeting of the Tri-State (North Carolina, South Carolina and Virginia) Medical Association, Battery Park Hotel, Asheville, N. C., February 25-26, 1902.

in which organic disease of the heart is present. Furthermore, the personal equation, as well as suggestion, cannot wholly be disregarded in the elements of success.

The following are important factors of success in the administration of chloroform:

Be sure to use only a pure preparation.

Go slow—give it drop by drop in an Esmarch or other good inhaler.

Withhold its administration and remove the inhaler unless needed—chloroform acts quickly.

Remember this: in obstetric work it is rarely necessary to force anesthesia beyond the so-called second stage.

Keep the patient's lower jaw pushed well forward.

Watch the patient—the eyes, pulse, respirations, color and muscular movements.

## RAPID REACTION FOR BENCE-JONES ALBUMOSE.

BY

ALEXIUS McGLANNAN, M.D.,  
of Baltimore, Md.

To the Editor of *American Medicine*:—On page 238 of the February 7 number of *American Medicine*, A. O. J. K. gives an abstract of Boston's method for a rapid reaction for Bence-Jones albumose. I respectfully call attention to the following copy of a communication on this method sent by me to the *Maryland Medical Journal*, which appeared in their December, 1902, number:

The method directs the treatment of urine with sodium chlorid, followed by boiling with caustic soda, and then the addition of lead acetate, after several intermediate changes, a final black precipitate of lead sulfid indicating the presence of albumose from which sulfur has been split off by the alkali.

Unquestionably sulfur will be split off from albumose by this treatment, but as a reaction to prove the presence of albumose in urine the method is worthless, because among the normal constituents of urine are certain substances grouped under the name of neutral or reduced sulfur, including thiosulfuric, tauro-carbonic, sulfocyanic acids, cystin, ethylsulfid, etc. All of these substances are characterized by the ease with which they give up sulfur when heated with caustic alkali, and the ordinary reaction to show their presence in urine depends on this property and the subsequent formation of a brown or black precipitate by the action of the resulting alkali sulfid on lead acetate.

For this reason, in order to identify albumose by its loosely combined sulfur it is necessary that the material be salted out of urine, and the above mentioned reaction be made with the well-washed precipitate.

## TETANUS CURED APPARENTLY BY ANTITETANIC SERUM.

BY

J. R. CARE, M.D.,  
of Norristown, Pa.

CASE.—On October 31, 1902, Mrs. J. M., while walking in her yard, stepped on a nail, which penetrated her foot. A physician was called, who applied a sorbefacient and the wound healed promptly, but the foot remained sensitive and became daily more painful. The patient was now treated for rheumatism.

On November 17, I was called and found her suffering with a marked tetanic spasm of the left leg and foot, an effort to move them being followed by painful spasms. There was some induration in the sole of the foot that was more or less sensitive to pressure. On November 18 the patient was etherized and the penetrating wound made by the nail was carefully dissected out. Between the second and third metatarsal bones there was found pus, dirt, and some threads of stocking. After irrigating the wound with 1 to 500 mercuric chlorid solution it was packed with 10% iodoform gauze and the ordinary antiseptic dressing applied. I then gave her one million units of antitetanic serum and the following internal medication:

Potassium bromid.....	5	gm.
Tinct. hyoscyamus.....	10	cc.
Tinct. gelsemium.....	3	cc.
Comp. syrup sarsaparilla, sufficient to make.....	60	cc.
Teaspoonful every three hours.		

On November 19, at 9.45 a.m., I gave her another million units and repeated the dose again at 9.45 p.m. The next morning she was resting easier and her jaws could be moved slightly. As I could not get any serum for 24 hours none was used until November 21 at 9.45 a.m., and again on November 22. She

then seemed to be so much more comfortable that I deferred giving her any more antitoxin until the twenty-fourth. At this time the jaws were rigid and her temperature, which had not gone beyond 100.2°, reached 101°. I gave her a dose at 9.30 a.m. and repeated it again at 9.45 p.m. On November 25 I again repeated the dose, and the jaw being relaxed and the spasms less frequent, I rested the serum for a time to await developments and from this time on she continued to improve. The only untoward effect that could be said to result from the serum was the occurrence of a very severe attack of urticaria. The spasms of the muscle of the leg continued more or less severe for ten days after the last injection of the serum, but gradually relaxed and at this time she is completely cured.

I think we can rightfully claim that the serum had a beneficial or curative action in this case, for the reason that when the serum was omitted the symptoms became aggravated until sufficient serum was used to neutralize the toxins in her system.

## EMANSIO MENSIMUM.

BY

C. W. FENN, M.D.,  
of San Diego, Cal.

Entire absence of the menstrual molimen without appreciable effect upon the general health is infrequent enough to merit mention. After an observation extending over 40 years I recall but two authenticated cases of the anomaly.

Mrs. O. B., a white woman, now approaching 60, has never menstruated, and aside from occasional attacks of epistaxis, which may have been neurosis, has had good health.

More recently a colored woman, over 50, assured me she had never "seed her courses, and meanwhile had been weller than most women."

Both have been married and are robust in appearance.

I regret that opportunity was not afforded me to determine whether absence of uterus or ovaries or atrophy of the fossas, etc., had any causative relation.

## USE OF THE MAGNESIUM RING IN UNITING SEVERED BLOODVESSELS.

BY

THOMAS J. TURPIN, M.D.,  
of Monterey, N. L., Mexico.

To the Editor of *American Medicine*:—Upon reading the letter of Dr. Senn ("Professor Nicoladoni's Clinic," *American Medicine*, page 587, October 11, 1902) I was impressed with his account of the magnesium ring used for the purpose of uniting severed blood vessels. I would suggest that the same ring made a little larger might prove useful in uniting intestines, taking the place of Murphy's button and the bone plates. If I had frequent opportunity for abdominal work I would try the magnesium ring, but as my opportunities in this line are limited, I suggest it for the consideration of those who are more fortunate.

## UNSUCCESSFUL VACCINATIONS.

BY

W. J. PURKHISER, M.D.,  
of Salem, Ind.

To the Editor of *American Medicine*:—I desire to add my experience to your "no-take" vaccination discussion.

Since January, 1882, I have made 14 unsuccessful efforts to vaccinate myself. I have used the ivory points and tube virus in about equal number, and with the same results—"no take." The virus used was the product of the most reputable producers. It is scarcely probable that the virus or the technic could have been at fault in so many vaccinations.

I have also made four unsuccessful efforts to vaccinate Miss Ella P., a healthy girl of 13. Following the second vaccination (?) there appeared an area of exuberant granulations about one-half inch in diameter, and elevated above the surface of the skin about one-fourth of an inch. The granulations were cauterized, and prompt healing followed. No vesicle or pustule appeared, and I regard it as a "no-take" vaccination.

## THE PSYCHIC NATURE OF SOME DISTURBANCES OF THE ACTS OF URINATION AND DEFECACTION.

BY

CHARLES J. ALDRICH, M.D.,  
of Cleveland, Ohio.

Lecturer on Clinical Neurology and Anatomy of the Nervous System, College of Physicians and Surgeons, Cleveland; Neurologist to the Cleveland General Hospital and Dispensary; Neurologist to the City Hospital.

Within the past ten years I have observed a number of patients with nervous or psychic disturbance accompanying or associated with the acts of urination and defecation. Careful notes of these cases have been preserved, and it has occurred to me that a brief consideration with a detailed report of some of the purer types would be both interesting and instructive. Few general practitioners or surgeons of experience will fail to recall some of these peculiar psychoses, but the gynecologist and neurologist meet a far greater number. I will consider the cases under two separate heads, beginning with psychoses of urination.

*Psychoses of Urination.*—Before taking up the psychic and neurosomal phenomena connected with urination it will be well to devote a paragraph to the consideration of the physiology of the act. Considerable uncertainty and differences of opinion as to the physiologic mechanism of micturition have obtained. Goltz's description of the series of events which occur in micturition is given most frequently, and is perhaps the most logical and clear explanation which we possess:

The distention of the bladder by urine finally causes stimulation of the sensory nerves in the muscular coats, thus producing reflex contraction of its musculature, which squeezes a small amount of urine into the urethra. These few drops exert a stimulation upon the sensory fibers and give rise to a conscious desire to urinate. If no obstacle is presented the accessory muscles of urination and the bladder wall itself contract vigorously, while both the inhibition of the will and the automatic center in the spinal cord, which are doubly involved in control of the sphincter, are taken off; it relaxes, and the act of urination is in force. If the bladder is not too full and the sphincter is kept in contraction for some time the contractions of the bladder may cease and the desire to micturate pass away.

The proverbial frequent visits to the urinal by the student up for his final examinations is not always due to polyuria, for not infrequently it is accompanied by tenesmus and the passage of but small amounts of urine. Soldiers in the excitement of battle also frequently lose control of their sphincters. Emotional and hysteric people often complain of polyuria, tenesmus, and even of incontinence or retention of urine.

An able-bodied and not overly nervous physician of my acquaintance cannot urinate in the presence of another person, no matter who it is. He can give no reason for this, but states it is not due to shame. Inquiry among physicians who do a large amount of insurance examinations reveals a large number of like inabilities.

A patient told me recently that his wife, physically vigorous but neurotic, could not urinate in his presence, although the act was accomplished with ease in the presence of women.

A perfectly healthy middle-aged woman informed me that she could not urinate in a public urinal, and that travel was a terror to her because of this fact. Even to urinate in a private bathroom in a hotel was impossible. The use of a night-vase, however, was attended by no difficulty. Defecation was accomplished without the slightest trouble in any of these places, but urination could not be accomplished. Believing this phobia to be a fear of contamination, I suggested her carrying an ordinary glass urinal, which she tells me she uses with the greatest ease when on the cars, steamships, or in public closets.

The mother of an athletic young woman, who is very fond of camping out, consulted me recently because of the great difficulty experienced by her daughter in urinating while in camp. Questioning revealed the curious fact that when a little girl she "could not sit down out of doors," as her mother put it. I have not learned the result of my advice to carry a portable closet into camp with her.

All are acquainted with the reflex effect produced by hearing running water or by allowing cold water to run upon the

hands. A neurasthenic patient once told me that she never dared wash her hands in a stream from the tap without having urinated previously.

A neurotic boy was brought to me for respiratory tic. Among other neurosomal and psychic stigmata it was related that he could not urinate in a dark room. If, however, he was out of doors the darkness did not affect his control of his sphincters.

A hysterical girl of 17, whose attenuated brain held a hundred aberrant notions, could not urinate unless in a darkened room. So firmly fixed was this idea that on one occasion, under circumstances which did not conform to her distorted ideas, she retained her urine so long that she got an overdistended bladder which the catheter alone relieved.

Another case is that of a girl of 16 with hysteric mania whose axial delusion, and around which revolved a dozen others, was that she could not voluntarily pass urine. Acting upon the advice of Drs. W. J. Scott and M. Rosenwasser, the mother was taught the use of a catheter, and the girl was confined to a dark, unfurnished attic. She urinated voluntarily the next day, and later resumed her place in the family, although her mind did not clear for months afterward.

By far the most singular case of this curious collection is that of a little girl of 12, endowed with a neurosomal heredity enhanced by much infantile illness. When she was twelve years of age, it was found that during urination she repeated rapidly throughout the entire act—"number one! number one! number one!" When taken to task for this peculiar reiteration, she declared that it was impossible to urinate without repeating this formula. Threats, rewards, and punishment had no effect upon her. Upon gaining her confidence I found that when a little child she would go to her mother telling her that she wanted to do "number one" when she wanted to urinate, and "number two" for defecation. As is often the case with neurotic children, she seems to have micturated very frequently, and she would run to her mother many times a day, saying, "number one! number one! number one!" She soon found herself repeating this during urination, at first to herself in a whisper, but at last her oblique psychology was satisfied only when the words were repeated aloud. It is a devious route full of much speculation to attempt to establish connection between an evident psychic tic and the loss of power to coordinate the complex combination of nervous impulses supplied by the will and the various spinal and intrinsic bladder centers presiding over normal micturition. When last heard of the child's condition was unchanged, no farther manifestation of a disordered psychology had appeared, but if she lives long enough more will follow.

The following case presents features worthy of careful study:

Miss S., aged 21, a stenographer, was referred to me by Dr. R. E. Skeel. She gives a negative family history. She suffered considerable sickness during childhood, but none since maturity. She gives no history of hysteria or other functional nerve disease. She is a lover of good literature; has had a good education, and is refined and cultured. She is distinctly a neuro-path. In personal appearance she resembles the voluptuous type of hysteric; she has red hair, brown eyes, well rounded figure. She states that one day, at noon, while riding home on a street-car, she felt a sudden and almost irresistible desire to urinate, although she felt sure that her bladder was not unduly full. She suffered considerably in her efforts to control this impulse, and on reaching home was not surprised to note the fact that while comparatively little urine passed the desire at once disappeared. Before starting on her return to the office she visited the closet, but about half-way to her destination the desire to urinate came upon her with such irresistible force that she was compelled to leave the car, when to her surprise the desire quickly disappeared without the passage of urine. She walked to her work for several days and experienced no trouble, but whenever she attempted to ride the impulse became so marked as to force her to the street immediately. For some time she avoided cars, but her distress was complete when one morning, as her employer began to dictate to her, the impulse to urinate came upon her with the same force and imperiousness as when on the street-car. Morning after morning her work was a perfect misery between going to the closet and fighting the now well-nigh irresistible impulse to urinate during the taking of dictation. Careful analysis of her sensations while the impulse was upon her revealed a complexity. The impulse came so quickly and forcibly that the will control of the sphincters was not always sufficient to prevent a slight jet of urine issuing with considerable force. During this time she became confused, was possessed by a nameless fear, her face flushed and burned; fingers and toes tingled, and a degree of mental excitement coupled with an intense desire to go to the urinal became almost uncontrollable. If she retired to the closet a small amount of urine would pass in a natural manner and all her symptoms disappear, but she would be no more than seated at her desk when the impulse would return with all of its terrifying accompaniments. Thinking perhaps it was a manifestation of sexual excitement possibly not understood by the innocent girl, I suggested the wearing of a napkin, which would absorb the few drops of urine that would pass after the first impulse had forced her to the closet. This was tried without benefit; although she would dampen the napkin the impulse remained, nor would it depart until she sat upon the closet. When this impulse

became timed to the hours of dictation it permitted her riding on the street-cars, with constant teasing, however. Although she was vouchsafed this slight measure of relief, the psychosis soon manifested itself whenever she went to church, the theater, to a party, or to any gathering outside her home. Strange as it may seem, she could entertain any number of friends in her own home without the least personal discomfort. This latter observation was made by Oppenheim in a study of a series of these cases. Dr. Skeel treated her for local conditions, and found a spot at the base of the bladder which appeared irritated. Careful systemic treatment failed to aid her. Becoming convinced that he had a neurosomal or psychic ailment to deal with he referred the case to me.

I found in addition to the foregoing manifestations quite a list of the stigmata of degeneration. One hand was larger than the other and one leg was much larger than its fellow, and the seat of a peculiar paresthesia. Belladonna and arsenic carried to toxic limits, suggestion and the pill of three valerianates have produced marked benefit, although the patient is now, at the end of three and a half years, compelled to keep the valerianate pill on hand to aid in maintaining control of her urinary impulses.

Miss J. S., white, aged 22, a dressmaker by occupation. She may be described as an erotic psychopath whose natural tendencies are strongly repressed by great will power and good training. Her previous health has been good, and except for a hernia, she has been perfectly sound up to the beginning of the present ailment. About three months previously she noticed that when she went into society, or to church, or any place where many people were assembled she experienced a distressing desire to empty the bladder, accompanied by a feeling of fear, a rush of blood to the face and head, cold extremities, and a peculiar sinking at the stomach. Unable to find any organic foundation for her distressing condition and discouraged with my ill success in affording her relief, I referred her to Dr. M. Rosenwasser, who returned the patient to me with the following note: "Examination of Miss S. reveals no physical or pathologic condition to account for her symptoms. The urine is normal. There is no pain in the bladder, nor is there any evidence of disease of the urethra. The kidneys are not loose. My conclusion is that the condition is neurotic and I would suggest treatment along that line."

Her condition kept her from the theater, concerts, parties, and church for nearly two years. While she was under my care during that time many medicines and measures were used, but I believe that suggestion and liberal doses of the tincture of time and essence of patience were the only remedies that aided her in obtaining her present fairly comfortable condition.

*Psychoses of Defecation.*—As in the consideration of the peculiar disturbances encountered in urination I will precede the relation of my one case of a psychosis of defecation by a brief reference to the physiology of the act.

From the experiments of physiologists it seems that the whole act of defecation is a complex combination of involuntary reflexes, and while the chief physiologic center for this complex automatism probably lies in the lumbar cord with accessory centers in the organs themselves, yet it has sensory and motor connections with higher centers which make this act largely controlled by voluntary impulses. It is also true that various physiologic states and even the emotions often exert profound effects upon the act. Goltz has shown that in dogs with the spinal cord severed defecation is performed normally. In another experiment, in which the entire spinal cord, except the cervical and upper part of the thoracic region, was removed it was found that after the animal had recovered from the operation normal defecation took place once or twice a day, clearly indicating that the rectum and lower bowel act by virtue of their own intrinsic mechanism. In infants the involuntary character of the act is well known, but higher control is acquired later until the adult, through the action of the will, can almost completely control the operation of both the spinal and intrinsic nerve mechanisms concerned in the complex act of defecation. The chief voluntary factor consists in the "taking off" through action of the will the inhibitory power of the spinal and intrinsic centers controlling the two sphincters. This "taking off" of the inhibition seems to put in motion not only the peristalsis itself, but by an almost imperceptible aid of the will the glottis is closed, the diaphragm fixed, the abdominal muscles powerfully contracted, the intraabdominal pressure raised, and the act accomplished.

I have observed that although the internal sphincter

is said to be involuntary and largely innervated by the sympathetic system, and the external sphincter composed of striate muscle tissue and more directly under control of the will, yet it appears that whenever the feces are sufficiently fluid to pass the internal sphincter successfully and produce irritation of the mucous membrane, the most powerful effort of the will must be exerted to prevent the external sphincter opening and a putting in motion of the powerful impulses which tend to produce an involuntary contraction of the accessory muscles of defecation, combined with the active peristalsis which is a part of the internal sphincteric relaxation.

My experience would indicate that the psychoses of defecation are far less frequently encountered than those of micturition. Indeed the following case is the only one of clearly defined type that I have had opportunity to study and record:

Mr. A., a Hebrew merchant, aged 47, was referred to me by Dr. C. B. Parker. His ancestral history is negative. His wife is an amiable cultured woman. They have two daughters, the eldest of whom has a slight spinal curvature and has had hysteria; the youngest was referred to me by Dr. Rosenwasser because of hysteria and chorea. Mr. A. is a moody man given to worry about his business, and has for years suffered from obstinate constipation. He has run the gamut of laxatives, cathartics, and physiologic and dietetic cures but with no lasting benefit. He was operated upon for hemorrhoids by Dr. T. C. Martin about two years ago. From his piles he was relieved but the constipation remained as obstinate as before.

He came to me 18 months ago complaining of peculiar psychic phenomena following defecation. When he sat down in my office he presented the most perfect picture of dejected hopelessness that I have ever witnessed. It appeared that he would arise in the morning feeling well and go about his work, and if he had no stool would remain in normal condition; if, however, the bowels acted, the most intense mental and psychic dejection followed; to such a degree that thoughts of suicide continually recurred to him in spite of the horror and fear which they excited in his reasoning mind. This condition would last for two or three hours, then slowly recede, leaving behind some worry as to his condition, but no foolish thoughts and but little depression. He was treated by galvanism, the negative pole in the rectum the positive dispersing pole over the lumbar spine, tonics, suggestion and cold baths. He improved and I flattered myself that the psychosis was caused by some local rectal trouble. About two months after his last treatment he again appeared at the office and informed me that following some unusual business worries he had a return of the awful depression, but it now followed urination instead of defecation. The periods of depression were identical in character, but not so deep or prolonged as the former ones. No such trouble followed defecation now, not even if he passed urine at the same time. Careful examination disclosed no local disease nor other evidence of nervous or psychic disturbance. The shifting of the scene had placed the case in the category of a pure psychosis not dependent upon any local lesion. The negative bulbous sound in the urethra instead of the rectum instituted an improvement, which has continued for over a year.

In this rambling relation of a number of cases which have been observed during a long period of time there has been no attempt at classification other than the division observed in their recounting. Possibly it may be of advantage to refer briefly to some of these cases in an analytic way and draw some conclusions as to their origin as well as of their nature.

In the case of the physician, notwithstanding his statement that it is not shame that prevents his urinating in the presence of others, I am positive that ingrained modesty is the origin of this not uncommon inability to harmonize the various complex reflexes associated in the act of normal micturition. Inquiry also revealed the fact that the woman who was unable to urinate in the presence of her husband had neither a brother nor a father who "looked upon her childhood" since infancy. I believe that we are justified in believing that shame or innate modesty was sufficient to disturb her coordination of normal reflexes. In another instance the difficulty in urinating experienced by the young lady while in camp may be explained upon the hypothesis of some fear that developed when a child while attempting to urinate on the ground out of doors. In the case of the woman who was unable to use a public urinal, the idea that it was a fear of contamination which pre-

vented a correlation of the reflexes sufficient to accomplish the act was proved correct by her adopting my suggestion of carrying her own urinal, with subsequent relief. This is analogous to recorded instances of women, apparently sane, who, because of ungovernable pathophobia, are afraid to touch their genitals with an unglowed hand. It is difficult to explain the case of the neurotic boy who could not micturate in a dark room, and more difficult to explain why he was not troubled when out of doors in the darkness. The same remarks apply to the hysteric girl who could urinate only in a dark or darkened room. In the case of the little girl who repeated aloud "number one! number one! number one!" during micturition, we have to deal with a form of convulsive tic, and the occurrence of obsessional ideas connected with one of the common functions of life. It is also a question if the case of Miss S., which was related in detail, is not also another example of a tic of the bladder itself, in which the convulsive movements are entirely confined to its muscular walls, affording contractions of sufficient force to exude a few drops of urine into the urethra already hypersensitive, and thus set in motion not only the intense desire, but the force of the accessory as well as the intrinsic muscles of micturition. Her disturbed mentality, flushing, etc., are all understood in the light of her emotional nature and refined and modest character. It cannot be denied, however, that the whole aspect of the case is one markedly suggestive of those peculiar obsessional ideas and actions which at times possess the psychopath. These latter remarks may be applied with equal force to the case of the little girl in her repetition of the obsessional words which appear to come to her unbidden, yet she is compelled to use them throughout the act. In the case of Mr. A. there is a purer psychosis, and one perhaps exceedingly hard to explain, especially when we recall the experience of every healthy man who feels a sense of relief, satisfaction, wellbeing, and stimulation, physically, mentally and psychically following a normal and thorough evacuation of the bowels. An inversion of this sensation would account very readily for his depression and dejection which brought to him the most somber ideas, including fearful ones of self-destruction. But why when the conditions changed and he was relieved of his difficulty it later returned as an accompaniment of micturition, no explanation can be offered except that of an ingrained psychic obliquity.

NOTE.—Since the above article was written, the following case was related to me by Dr. H. B. Kurtz, of Cleveland:

Mrs. H., a healthy married woman, without any marked nervous or psychic stigmata has never been able to urinate or defecate while sitting upon the closet seat. The only way she can accomplish either act is to get upon the seat with her feet, and sit down, as it were, upon her legs, the nates not being brought in contact with the seat. She states that this condition has existed since childhood, and the only explanation that she can offer is that, when a child, the opening on the out-door closet seat was large and that she recalls a fear that she might fall into this opening and consequently always got upon the seat, placing her feet astride the opening. In using the night-vase, if she sits firmly down upon the vase she experiences to some extent the same inability, but it immediately disappears when she raises herself. This lady is a woman of education and refinement and there is nothing in her family history that is indicative of degeneracy or mental or psychic disease.

#### Even Governors Have Not Lost the Sense of Humor.

—Governor Pennypacker, referring to the statement of Chairman Bliss, of the House Appropriations Committee, that the appropriations now pending carry \$10,000,000 in excess of the estimated State revenues, said that it was necessary to reduce appropriations, and that the question was simply one of elementary arithmetic. "Everybody who has an appropriation bill in the Legislature," said the Governor, "comes to see the Executive about it. I have had scores of visitors of this kind. Women come to me about their hospitals, and men about their asylums, and I have questioned them closely to find if there are 'rake-offs.' I have failed to find a single case, and if the newspapers can give me any information on the subject I would receive it gladly."—[Press dispatch.]

## THE PREVENTION AND OUTDOOR TREATMENT OF PULMONARY TUBERCULOSIS.

BY

FRANK WARNER, M.D.,  
of Columbus, Ohio.

Member of the Ohio State Board of Health.

The history of tuberculosis is a story as long as the history of medicine itself. Great epidemics of contagious and infectious diseases have come and gone. Tuberculosis came to historic light with the dawn of medicine. It has remained a reflection upon medicine—the greatest scourge of the human race. One-seventh of those dying from all causes die of tuberculosis. When we come to consider what a large number of children who die in infancy of diseases peculiar to childhood and the long array of diseases which sweep away adults, as well as the army that is carried away by the infirmities due to old age, it is apparent what frightful ravages tuberculosis makes in the ranks of mankind.

The question of its cause and prevention is not a new one. For 2,000 years the interrogation of its contagiousness has had many answers in the affirmative. The war of discussion at times became intense, some localities accepting the theory of contagiousness more promptly and thoroughly than others, but all communities possessing its adherents. In Italy, 400 years ago, the tuberculous were driven to segregation.

All of these debates were at most a matter of opinion rather than of scientific fact, for it was not until 1865 that Villeman began his experiments which proved that the sputum taken from a tuberculous patient was capable of inoculation of infecting guineapigs and rabbits with tuberculosis. And not until 1884 did Koch demonstrate the principle in this sputum that is capable of transmitting the infection to be the tubercle bacillus.

Since this discovery the civilized world has taken new hope. The immediate cause discovered it was but reasonable to suppose that a sufficient remedy would be found to cure the disease, or failing in this, a means of prevention would be found in the near future. Disappointment has been largely the fate. However, a hopeful sign that the future will unlock the box containing the coveted secrets of its prevention and its cure is that all our great nations are working, through their physicians as leaders and the laity as co-workers, to establish societies for the prevention of tuberculosis and hospitals and sanatoriums for its cure, and that the scientific laboratories of the world, with their trained bacteriologists, pathologists, and chemists are seeking the underlying causes, prevention, and cure of this disease. Physicians treating these patients in hospitals or in the home are today giving greater attention to the details associated with its prevention than ever before. Such vigorous effort by such scientific men makes us hopeful that the dawn of a new light is more than a mere dream.

The relation of tuberculosis to civilized communities is an intimate one. The higher the state of civilization the greater the number of cases of the disease. There is something in the mode of living that contributes to its production. You do not find tuberculosis among the Indians in their native, open air mode of life, but it quickly develops when they are brought into civilization. We would think that persons living in the country and in small towns would be peculiarly free from tuberculosis. Air, sunlight, and exercise are all there in abundance. Yet many persons living in these places take no pains to have properly ventilated living and sleeping-rooms. Many do not seem to grasp the first principle involved in securing proper ventilation. If a small sleeping-room is aired slightly, or even thoroughly, within or during the day, it is regarded as sufficient and is shut up tightly at night. I do not mean that one should always have a window open in all kinds of weather, but they should at least make preparation to

have sufficient cubic feet of air space to draw on for the night by opening their doors or transoms into hallways which have been thoroughly aired.

Again it is certain that many farmers living in a land of plenty do not always take the time or trouble or patience required in the selection of proper food. But this question I shall discuss more fully when I come to consider the facts relating to improper diet as a predisposing cause of tuberculosis. In crowded portions of cities, as tenement districts, tuberculosis prevails to an extent beyond the mere percentage of inhabitants, but this is only what we might naturally expect when we consider how unsanitary many of these surroundings are.

*Infectious Nature of Tuberculosis.*—While Villeman fairly demonstrated in 1865 what had previously been suspected, that tuberculosis could be induced in certain animals by the injection of sputum from a patient suffering from the disease, it was left to Robert Koch to discover and prove that the tubercle bacillus was the immediate or exciting cause of the disease; that the sputum of a person suffering from pulmonary tuberculosis usually contains the germs. An important query promptly arose as to whether these germs were the result of the disease or its cause. It did not take long, however, to prove to the world that the tubercle bacillus was the cause, and not the result of tuberculosis.

If these bacilli are the cause of the disease, and the sputum of the patients contains them in large number, the query again arose and stands prominently before us today as to whether tuberculosis is a communicable disease. After Koch's discovery that these bacilli by inoculation were capable of infecting guineapigs with the disease, it was but natural that the medical profession in large numbers began to accept tuberculosis as being a communicable disease from one patient to the other; that it is contagious; that it is with considerable risk that a patient suffering with the disease mingles with others. Many physicians imbibed very extreme notions along these lines. One does not need to read many of our medical journals to see that there is a tendency among a class of physicians with opposing views, with notions as extreme against its communicability as the others are for it. But like so many extreme views, it is quite likely that tuberculosis occupies a middle ground in its infective capabilities, and that it is neither so communicable as some physicians would lead us to believe, and a great deal more so than many others believe today; that the truth lies between these extreme views. Is tuberculosis a contagious or infectious disease? What is contagion, and what is infection? Gould's dictionary says contagion is the process by which a specific disease is communicated between persons, either by direct contact or by means of an intermediate agent, also the specific germ or virus which a communicable disease develops. And that infection is the communication of disease germs or virus by any means, direct or indirect.

These definitions are perhaps as good as any given in our dictionaries, and still I think we conceive a better understanding of contagious diseases and those of an infectious nature by running over in our mind some diseases which we clearly regard as communicable by contagion and those which simply develop by infection. Yet strictly speaking, I suppose every disease which is communicable by contagion is a specific infectious disease, but not the converse. Measles and smallpox are highly contagious diseases. They are at the same time infectious; the patient is infected with the germ or virus of these diseases. Malaria and septicemia are infectious diseases, but not contagious. One who is not immune may take smallpox or measles by sitting in a room with a patient suffering with one of these diseases. He will not take malaria nor septicemia in like manner.

Now, will tuberculosis infect by mere exposure to the patient, as smallpox and measles do—that is, is it, like them, a contagious disease; or does it follow rather the mode of infection as displayed in malarial poison-

ing and septicemia—that is, is it simply an infectious disease?

The laws governing the mode of infection of malaria and septicemia are too well understood for me to repeat them here. I do not believe any one thinks that it would be possible to contract tuberculosis from a patient if that patient were to step into one's office or house, so long as he did not cough nor expectorate. And even then the sputum would first have to dry before the germs would be liberated to become diffused in the air. In other words, in the absence of the sputum, you might stand in the presence of the patient indefinitely without contracting the disease. Then it is not contagious, but as you can become infected with the disease through the sputum in the manner stated it is communicable. As animals are easily infected with tuberculosis by injecting the bacilli into them it seems but reasonable to conclude that they may likewise infect a person and that person another. Without the direct proof of experimental observation which we have in infecting animals, facts seem to prove clearly the truth of the infectiousness of tuberculosis. So we are next confronted with the proposition: To what degree is this infection communicable?

With proper antiseptic precautions against the bacilli there would no longer be fear of the disease. This, however, is an ideal condition to think of and try to attain, rather than to hope to attain absolutely. There are so many persons afflicted with tuberculosis who never heard of the bacilli producing the disease. How can they be expected to care for their sputum when they know nothing of the danger associated with its indiscriminate deposit? Nor is this practice confined to the ignorant classes by any means. I am sure it is only thoughtlessness when an educated person, suffering from pulmonary tuberculosis, permits the sputum from a cuspidor to be emptied into a water-closet without first destroying the germs with some antiseptic agent. For without the use of these antiseptic agents the sputum with its living germs enters the streams, and from the streams either finds its way into the pipes of a public water supply to the stomachs of those using it, or at least, animals depending upon that water supply, and upon which we are dependent for our food supply, drink it, and perhaps become infected to in turn infect those who eat the meat. Whatever may be the final outcome of the discussion of the similarity between bovine and animal tuberculosis, the fact remains that there are very few who believe otherwise than that there is a sufficient similarity to make us guard carefully the health of the animals we eat.

So far as the communicability of the disease is concerned by association with tuberculous people, the danger only lies in the careless disposal of the sputum. And then only after the sputum dries and is breathed into the lungs, barring some exceptional cases of the sputum of the infected individual getting into the stomach of one who is not infected; as through the use of the same dishes which have not been sufficiently cleansed and sterilized.

There is nothing, to my mind, that stamps tuberculosis more clearly as an infectious disease, pure and simple, and not as a contagious one, than the fact that in well-regulated hospitals and sanatoriums where the germ is constantly and rationally destroyed the physicians, nurses and attendants do not acquire the disease more frequently than those in other salubrious walks of life. But we have only to look to some of the old cloisters where tuberculosis had once secured a foothold to see the frightful decimation which has been made in their numbers. Notably was this true in some of the cloisters of France, where the deathrate, according to Cornet, reached 62.88% of those dying from all causes. This was based upon a population of 4,028 people for a period of 25 years. On the other hand, at the Brompton Hospital, in London, where all the patients treated are

tuberculous, no greater number of cases of tuberculosis have arisen among the physicians and attendants than in well-regulated sanitary communities. This latter circumstance would only seem to indicate that the disease is not a strictly contagious one; that the sputum was so cared for in an antiseptic way as to prevent infecting others. In the former cases, the cloisters of France, the large deathrate speaks volumes in favor of the communicability of the infection under conditions that are favorable for the transmission of the germs. I have spoken of this high percentage of deathrate in the past tense. I hope the use of the present tense might permit a different statement. But it would seem to emphasize the fact that people may associate with the tuberculous with impunity if only the sputum is cared for properly and the general hygienic surroundings are of a high type. If the reverse obtains, we can only look for a continuance of the high mortality rate from the disease.

In everyday life there must be an immense number who breathe into their lungs tubercle bacilli. Yet a very small percent become infected with the disease. I presume there is no one reason so accountable for this as the resisting power of the individual. In just the ratio that the vital forces are lowered the individual is more likely to acquire pulmonary tuberculosis, or any form of tuberculosis for that matter. In discussing this question I have in mind simply one form of the disease, that assailing the lungs. If diminished resistance is one of the causes which permit a person to become infected with the disease, we should consider well some of the things that contribute to lessening this power of resistance.

Among the things which contribute to lower one's capacity to resist tuberculosis are the following:

1. *Neglected Colds.*—One may say perhaps that the power of resistance is diminished when a cold implants itself upon the patient. This is unquestionably true when a person takes one cold after another; though the resisting power may not have been below the normal when a cold was first acquired, it may have been wholly the result of carelessness or unavoidable circumstances. If a person has become greatly overheated and bathed in perspiration, following which he remains in a draught, it does not follow that his resisting power has been diminished. There has simply been a strain put upon the resisting power that he cannot bear. The time comes when by reason of one cold after another the resisting power is not only diminished to prevent the taking of colds but the individual is in a condition that will more readily permit the infection of tuberculosis. The consequent congestion in the lungs, following these repeated colds, doubtless prepares a more suitable soil for the propagation and growth of the tubercle bacilli. Therefore the patient should not only be cured of this cold, but a vigorous attempt should be promptly made to place the patient's system in such a condition, either by the use of medicine, or by a change of conditions and environment, perhaps both, as will place the resisting power at a high level. Certainly, by this means, many cases of tuberculosis will be avoided.

Closely allied with the taking of cold is the matter of insufficient clothing. It is not always among the poor, who are not able to buy it, but quite as frequently among the well-to-do or rich who can well afford the clothing, but conceive the idea of wearing less than they should. It is true some people go to the other extreme and load themselves with excessive clothing, which keeps them most of the time bathed in perspiration. They are made tender and susceptible to colds, and these repeated colds soon lower the power of resistance to tuberculosis. A happy medium in the matter of clothing must be found; enough worn to keep warm and prevent sudden chilling of the surface, but not so much as to produce a continual perspiration.

2. *Vitiated Air.*—There is probably no one cause that so frequently impairs the health and consequently the

power to resist tuberculosis as the lack of ample pure air to breathe. It seems strange, indeed, that when air is at the same time so valuable and yet so cheap that it should be regarded so lightly. This may be the result of one's own fault or the fault of others over whom he exercises no control. If it be one's own fault, it may be the result of ignorance or of carelessness. One may not know that the richness of air in oxygen is quickly exhausted where the air is in a confined space, of course depending upon the size of that space; but the cubic feet of air space in any of our modern living-rooms are not of such proportions that its frequent replenishing can be dispensed with. Instead of ignorance being the basis of breathing air over and over again without replenishing, carelessness or thoughtlessness may be wholly accountable for it.

All educated people know, in a general way, the chemistry of the air and the physiology of the lungs; that the lungs require oxygen to perform their task of oxidizing the blood; that this task is best accomplished when the air contains its normal amount of oxygen, and not only when it contains its normal amount, but also when it is largely free from the waste products of combustion contained in air that has been once breathed. If any one stops to reflect he recognizes at once that the highest standard of resistance cannot be maintained unless the air is maintained in a pure, normal condition. If the air is not kept in a normal condition how can one expect the health to be maintained and the lungs to offer a normal power of resistance? To be sure, the length of time during which a person is deprived of pure air is an important element. If the time has been short it will be insufficient to lower the resisting power. But when it is constant, or at frequent and prolonged intervals, the normal resistance will be quickly impaired.

It is easy to say that sleeping-rooms should be large, light and airy, but these are not things that people can always control. But, take the rooms as they are, people could manage them much better than a large percentage do. In the first place, the rooms should be well aired in the daytime. Next, if it is small, there should be some provision made for replenishing the air during the night, either by communication with a well-aired hall through a transom or door, or by window to the open air. But in securing the air in this way one must arrange to avoid sleeping in a draught. An open fireplace also makes a good means of ventilation. In summer time the ventilation of the rooms will take care of itself; for then windows and doors are left open. But in the fall, winter and spring, it will be necessary to give some thought and attention to these little details.

Again, the air of a room or house is frequently vitiated to an extreme degree by reason of an insufficient vent for the escape of the products of combustion of natural gas. Take many of these asbestos fronts in our grates; you will find nothing more than a mere crevice above for the fumes of the gas to make their escape. Most of them are entirely insufficient to carry off the products of combustion, as a result of which they escape with the heated air at the top of the grate. It was a great relief to have stepped into one of the hospitals of this city a few days ago and find that provision had been made here for using the gas with these asbestos backs. Two inches intervene between the top of the asbestos and the jamb, which gives a vent two inches wide and the length of the flue opening. In these grates you get simply the radiated heat; in those with the mere crevice the radiated heat and the hot air that overflows above plus the gas fumes accompanying it.

Now the products of combustion vitiate the air and this in turn brings about an excessive and persistent anemia. Even with careful treatment, and after removal of the cause, the anemia is slow in subsiding. The resisting power of the individual has been diminished and continues below par during the time of the convalescence. If there were smoke associated with the

combustion of natural gas, people would at once demand that a sufficient exit be provided for the escape of the gases consumed. But as there is not, this dangerous deception of filling the room with hot air filled with consumed gas continues to an extent that needs correction. Even still worse are some of the natural gas stoves, where in their use you will find, in many houses, the damper in the pipe turned either completely or to such an extent as practically to prevent the escape of the consumed gas. Even occasionally you will see gas stoves without a pipe at all; simply allowing the fumes to escape into the room. How can persons reasonably expect, living in that manner, to maintain a normal resistance?

3. *Employment in Confined Spaces with Insufficient Light and Air.*—This has been a proposition well understood for many years, and it is noted with pleasure that our own architects are continually striving to construct public buildings and workshops along sanitary lines. This has been in part the result of agitation by health boards and health officers, and in part also the result of the labors of the Superintendents of Workshops and Factories. Then, too, capitalists have come to see the necessity of employing educated and skilful engineers and architects to design many of their factories. Many of these show the improvement along sanitary lines over those which have been constructed from a drawing which represented neither knowledge of the best manner of construction, that the owners might receive the best and largest amount of work from their men, nor an insight into the sanitary needs of these men to preserve their health and consequently their power of resistance to pulmonary troubles.

There is still need of greater knowledge along these lines. Especially is this true of some of our public institutions where overcrowding is often a necessity. In many places men are found working, if not in confined spaces, in darkness or semidarkness. All physicians know that the highest standard of health can no more be maintained in these places than a flower can be made to flourish in the absence of ample light.

4. *Insufficient Sleep.*—Constant and continuous loss of sleep is a factor in impairing and undermining the health. Sleep in sufficient amounts and regularly secured is important in keeping up one's power of resistance.

5. *Excessive and Continuous Use of Alcoholics.*—There is no one fact better understood in medicine than that the excessive and continuous use of whisky or beer greatly weakens one's power of resistance to disease in general, and to pulmonary troubles in particular. Such a patient developing pneumonia not only stands less chance of recovering from the immediate attack, but the lungs are less inclined to clear up, and are made an easy prey to the tubercle bacillus. The power of resistance has been brought to a low ebb.

6. *Congenital Feeble Resistance, Known as Hereditary Tendency.*—When Koch made known his discovery of the tubercle bacillus there was immediately a large body of physicians who arose to proclaim that "heredity had fallen to the ground," but now, I think, most physicians are inclined to believe that heredity occupies a middle ground between the two extremes of its never being hereditary, as the new class of thinkers seem to believe, and its always being hereditary as such a large number had come to believe. Heredity would seem to occupy the position that many persons are born with feeble resisting power, and consequently they are less able to withstand the onslaught of the exciting causes with the same degree of success that one of a vigorous type would. It is unnecessary to quote statistics, but there is no doubt they would prove that the death of many persons who have died in a family one after another would be found to be the result of infection received by constant association with invalid relatives. So those with a hereditary tendency may well take new heart. Their resisting power may be increased. Their health cannot be

neglected with the same degree of impunity that others neglect theirs. They cannot withstand, equally free from danger, the immediate exciting causes of tuberculosis. There has got to be unusual care exercised in the selection of occupation, mode of life, and environments of such an individual, if many of the dangers of falling a victim would be avoided.

7. *Diet.*—A sufficient amount of carefully prepared food is essential to the maintenance of the health in a state that will offer the greatest degree of resistance to the implantation and growth of the infective germs of tuberculosis. There is a large class, in greater relative numbers in our cities, who cannot always obtain a sufficient quantity of nourishing food to maintain a high degree of strength. But there is another class who pay too little attention to the selection of proper food and the cooking of the same. As a result of this the nutrition suffers and the strength declines. There is quite as apt to be overeating, when you may look for indigestion, which, if continued, will only result in lessening the resisting power of the individual. Food of a nourishing character should be taken at regular intervals in sufficient quantity, and be properly cooked.

8. *Enfeebled Health Following Pneumonia and Various Fevers.*—Pneumonia, typhoid fever, malarial fever, measles, and indeed any of the fevers, lower the resistance and make more likely the development of tuberculosis if a decided opportunity has been offered for the germs to gain entrance to the lungs. The soil has been prepared and the tubercle bacilli find ready lodgment. This should serve to admonish us that after these diseases the system should be brought up at once to as high a standard of resistance as is possible. More especially is this true of those who possess already a feeble power of resistance. These should not be allowed to return so soon to a confining occupation after a pneumonia or typhoid fever as others may do. Their health and their resisting power should first be fully restored.

9. *Various Causes Diminishing Resistance.*—Anything that tends to lower the vitality diminishes the resistance which an individual may ordinarily offer to tuberculosis. Environment has everything to do with health. To best preserve the health sanitary laws in general must be obeyed. Many are so situated that they cannot follow these laws, for we must remember that while one may frequently but not always be able to follow the laws of personal hygiene he cannot control always matters of a general character. His environments may be unsanitary and he be unable to control them. Every day that one lives amid such surroundings contributes to the development of a feebly resisting pulmonary soil that yields more readily to the first decisive exposure to some of the immediate exciting causes of pulmonary tuberculosis. When the resisting power of the individual is greatly depressed and consequently the soil more suitably prepared for the development of the disease the tubercle bacilli find lodgment in the system and develop tuberculosis. These bacilli usually enter the system through (1) the lungs; (2) the stomach.

If the entrance be through the lungs the infection is the direct result of breathing the germs from the sputum of some other patient. If the entrance be through the stomach then these germs have emanated (a) from another individual suffering from the disease; (b) from infected meat or milk from tuberculous animals.

If the entrance of these germs has been through the lungs, and that is undoubtedly the usual method of infection, it results in most cases from the careless and indiscriminate spitting in various places. Upon the sidewalks, where it dries and is caught up by the ladies' dresses and dragged into their respective homes; into the streets, where a gust of wind carries the dried sputum mingled with dust into the mouths of pedestrians; into cuspidors about the home or public places, the sputum drying upon the edges of these vessels and from there getting into the air of the room to be breathed

by those about. How frequently in public buildings we see tuberculous patients spitting upon the floor. Herein is the consumptive's crime; it is this which has made so many people ready to ostracize the consumptive.

I have no doubt that if the Pullman Company once understands the importance of having the sputum of tuberculous travelers, and of all travelers, more carefully looked after by frequent cleansing and disinfecting the cuspidors, that they would gladly obey rules of health boards along these lines. They would doubtless, too, be willing to sterilize the blankets by steam after each long trip, if health boards ordered it and popular opinion seemed to demand it.

There is no danger from association with a tuberculous patient if sanitary precautions are taken, but we all know that there are many more who do not take any precaution whatever than there are who do. Still, the number who are seeking to know what to do to protect their fellow men, and who are exercising these sanitary and hygienic measures is constantly on the increase. It is by this assistance becoming still more general that the hope arises of checking the wild career of this disease.

There is a class of people, however, to whom we cannot look for much assistance. This class lives in ignorance, squalor, and poverty. If special hospitals for the treatment of tuberculosis were constructed and these people should avail themselves of their care, there would not only be a very less number of foci of infection to contend with, but at the same time they would be taught many of the sanitary measures to be followed in preventing, not alone the infection of others, but the reinfection of themselves; so that those who recover and return to their homes would better understand how to live along sanitary lines.

These special hospitals or sanatoriums would not only be of value to this class of patients and to the community in which they live, indirectly by lessening the foci of infection, but at the same time to all classes and conditions.

That tuberculous meat was one of the modes of infection of the human race was accepted as a settled proposition until Robert Koch questioned the proposition before the Tuberculosis Congress at London last year. He does not believe that tuberculosis in cattle and the human being is the same. Dr. Koch is practically alone in this position. While he still maintains the same ideas relating to this question it is interesting to note what he had to say at the meeting just recently closed of the same congress at Berlin. In a report of the proceedings of the meeting published in the *Revue d'Hygiene* he said that "he did not doubt that we ought to continue to take precautions to prevent the possible transmission of tuberculosis of animals to man by the milk of cows affected with mammary tuberculosis, but it is necessary from all the evidence to direct our attention in the future for the greatest part of our efforts to the fight against the transmission, infinitely more frequent, of tuberculosis from man to man, and to preserve the greatest sum of our resources and our energy for combating this source of transmission."

At the same meeting Nocard gave the result of experiments which showed very conclusively that animals may become infected either by the bacilli procured from cattle or man. He reported a series of very interesting experiments made by himself illustrating this fact. He fed monkeys, as being more nearly related to man than any of the other animals, on cooked rice infected with cultures of tubercle bacilli obtained in some cases from cattle and in other cases from man.

He fed different monkeys some of the rice infected from the bovine species; the others he fed the rice infected with the bacilli obtained from man suffering with pulmonary tuberculosis. The results are interesting and instructive. He found that all the monkeys fed in this way developed intestinal tuberculosis. The only

difference was that those which were fed bovine tuberculosis cultures, developed more quickly and a more severe grade of the disease than those fed with the human tuberculous cultures. He has no doubt that if man, instead of the monkey, had been the subject of these experiments he, too, would have succumbed to the disease.

One of the strongest arguments offered by Koch against the likelihood of tuberculous beef and milk being the cause of tuberculosis in man is the fact that primary intestinal tuberculosis is rare. Nocard admits this, but points out the fact that there is nevertheless a real danger present. More especially he believes this to be true in the case of convalescents from various diseases, whose resisting power is below normal. Their chief ailment is frequently milk, and in this way he believes many patients become infected. Besides, we must not assume that simply because intestinal tuberculosis as a primary disease is infrequent that the patient who has developed tuberculosis in other parts of the body has not acquired it through the food. We must remember that mesenteritis and peritoneal tuberculosis often exist without other complications. It is more rational to assume that the infection reached these places through the stomach than through infected lungs.

There have now been collected many cases of butchers who have developed local tuberculosis from wounds received accidentally in dressing tuberculous cattle. Some of these cases have gone on to general tuberculosis. Salmon, in the *Journal of the American Medical Association* of December 20, 1902, reports some of these cases. Still, the consensus of opinion now is that by far the greater number of cases of pulmonary tuberculosis develop as a result of the careless disposition of the sputum of infected individuals.

The prevention of the disease is then going to be brought about by the correction, in a large measure, of the predisposing and existing causes of the disease. How best to accomplish this is a large problem, but one which I believe will be solved in the not far distant future. There is greater need of the laity understanding more fully the causes leading up to the disease; of physicians taking occasion more frequently of acquainting their patients with the causes producing the disease and the means of preventing it.

The Ohio Society for the Prevention of Tuberculosis has been established, and this association of people, not all physicians, will doubtless do considerable in not only diffusing information among the public along preventive lines, but through their strength as an organized body be the means of doing much in the way of establishing sanatoriums for its treatment. It seems to me that physicians over the State would do well to help enlarge this organization by coming into it, as it seems reasonable to believe that greater good along preventive lines will be accomplished in this way than fighting the disease single handed. "In union there is strength" applies here as forcibly as in other situations.

It seems but reasonable to suppose that, as the various conditions associated with the predisposing and exciting causes become more fully understood, the dream of its prevention will become largely realized. Koch, at the recent Berlin Congress, insisted: that we should make our greatest efforts along lines that have for their aim the abolishing of the direct and exciting cause; that this main cause he believes to be due to the inhalation of dust containing the bacilli from human tuberculosis; that less effort be expended to search out predisposing causes and more to combating the exciting cause. This last proposition he doubtless offers as the final solution of the prevention of the disease.

*Possible Prevention of the Disease Through a Form of Vaccination.*—At the close of the recent Berlin Congress, already referred to, a number of the delegates, acting on the invitation of Behring, visited his laboratory at Marbourg, where he, with his two assistants, Doctors

Ruppel and Röhmer, have done much during the past year to demonstrate the sameness of bovine and human tuberculosis. Behring demonstrated to these delegates what had already been affirmed by the experiments of Nocard of Berlin, and reported to the congress that there was a great difference in the virulence of different tubercle bacilli. Behring had inoculated mice with the virulent form of the bacilli, and these little animals promptly succumbed to the disease. With the mild cultures the animals either did not become infected, or only after many weeks. He also found that by regulated intravenous injection of human tuberculosis virus into calves he would render them immune to injection of bovine tuberculosis virus that was absolutely fatal to calves which had not thus been immunized. He terms this immunizing antituberculous Jennerization. He has demonstrated that human tuberculous virus in passing through some animals infected by it, as sheep and goats, acquires additional virulence, which is then capable of infecting cattle with uniformity. While he has succeeded in vaccinating cattle against the disease of course it is too soon to know how long this Jennerization as he terms it will hold good. And if it continues over a long period to render the bovine species immune the problem would still remain to be reversed: to vaccinate man successfully against tuberculosis.

Whatever is the final solution of his problems, he has certainly done some of the most important work in tuberculosis since Koch's discovery of the bacillus.

*The Outdoor Treatment of Tuberculosis.*—This is not an altogether new form of treatment of the disease, but it is one that has come into considerable favor of late. Especially is this true in sanatoriums where it is adopted as one of the chief forms of treatment. The outdoor treatment is carried on: (1) At home; (2) in tents, usually roughing it; (3) in sanatoriums.

1. *At Home.*—At first thought it might seem that the open air treatment might be carried on anywhere with any one. This is doubtless true if one lives in a place with suitable environments; if he have the means to secure skilled attention and constant direction. He needs to be informed when and in what manner to live out; whether this outdoor life shall be associated with exercise and its amount. Some days the patient is better off without exercise; other days with it. There is nothing to be gained by a patient's exercising with a greatly elevated temperature and feeble and accelerated pulse. At that time exercise exhausts and does harm. The food needs to be a subject of constant inquiry and direction. Carefully selected medicines will form a part of the treatment. Some physicians, in their enthusiasm, have sought to discard medicine and depend upon the open air treatment alone. But we must not lose sight of the fact that the open air treatment is not a specific agent for the cure of tuberculosis. It is a valuable therapeutic agent that should not be lightly regarded, but it is not a cure-all. Much valuable aid will still be found in medicines adapted to the case.

It is not always possible to secure the requisite cooperation of the patient with the physician at home. Some people are mortally afraid of air. It is difficult to induce them to seek it in the way it should be sought. It is one of the effects of a tuberculous deposit in the lungs to set up a bronchitis. So, that as soon as a bronchitis is aggravated, perhaps by the tuberculous deposit, the patient immediately insists that he has taken cold. It is then his belief that the exposure to the outside air is the basis of the bronchitis. From that time on cooperation is difficult to secure. These patients will do better in sanatoriums, where they will receive the encouragement to carry out faithfully the treatment through the example set by the other patients.

Can tuberculous patients be treated as well at home with open air treatment as by a change of climate? In

some seasons of the year they can, at others not. In the summer, fall, and late spring, we have weather, a large part of the time, that is suitable for the outdoor treatment. In the winter there are periods when there must be some interruption in the treatment. Much may be accomplished in our own climate by the open air treatment. However, a climate that has a maximum amount of sunshine and a minimum amount of rain and an equable temperature permits a patient to be out of doors more days in the year than a climate where winters are more or less severe, and at other seasons rain and cold raw winds driving the patient to cover. Still, in a climate like our own, we may successfully treat many of our patients at home, and in their homes by the open air treatment.

2. *Roughing it in Tents.*—Quite a considerable number try this method of treatment in some regions of Colorado, Arizona, and California. But for one to try this method he should not be in a greatly enfeebled condition. He should not be suffering from a considerable elevation of temperature. Roughing it means a large amount of exercise. When one is suffering from a high elevation of temperature he is no more able to endure the fatigues due to the amount of exercise associated with this form of life than one suffering from typhoid fever. This same rule applies to those who go or are sent by their physicians to those regions possessing a reputation for the cure of tuberculosis to live in cabins and rough it. Only in the very early stage, and then when the patient possesses considerable strength and there is comparative absence of fever, can he be assigned to this mode of life with a reasonable degree of hope of benefit or cure.

3. *Treatment in Sanatoriums.*—In England and Germany large numbers of sanatoriums have been constructed. These have been built and are operated for the purpose of instituting treatment for tuberculosis by the open air method. A large number of other countries have followed in their wake. The United States now has quite a few, as a government, however, it operates but two; one, the Army hospital and sanatorium for the treatment of pulmonary tuberculosis, at Fort Bayard, New Mexico, and the other, the United States Marine-Hospital Service sanatorium, at Fort Stanton, N. M. Both of these sanatoriums show good results. Some of the States have established sanatoriums, and in all cases good results have come by reason of their construction and operation. They are all operated upon much the same lines, but one only has to read the report of the Army and Navy sanatorium to see what is accomplished. The most rigorous system of hygiene prevails throughout the sanatoriums. The sputum is all collected in cups and burned. A patient is not permitted to expectorate promiscuously and thus infect others and reinfect himself. The patients are kept in the open air, but have shelter arrangements as necessity requires. Medicines are given as required; exercise is regulated; food carefully supervised. The Fort Stanton (Marine) sanatorium reports in the *American Medical Association Journal*, December, 1902, 24% of recoveries. The Fort Bayard (Army) sanatorium in the same journal, November, 1902, shows good results but a lower percentage of recoveries. Still some of the patients admitted may have been in such an advanced stage as to account for this discrepancy. This sanatorium is doing equally good work with its sister sanatorium of the Marine-Hospital Service. Some sanatoriums show a still higher percentage of recoveries.

But we must not expect too much of sanatoriums in general, or of the open air treatment. Judiciously used it is a valuable aid in treatment. No doubt some in their enthusiasm will go so far as to do harm. But the principle involved seems to be clearly right, that by spending much of his time in the open air the patient increases his appetite, his weight, his resistance to the disease; while the fresh air and sunlight diminish the

virulence of the tuberculous virus. But the sanatoriums have another function than the cure of the disease. Their establishment is a wonderful sanitary measure for its prevention. They will draw for their patrons, in large measure, those who are living in unsanitary surroundings; those who do not understand the means to avoid infecting others and re-infecting themselves.

Ohio should place herself abreast of the times, and establish sanatoriums for the treatment, and indirectly the prevention of pulmonary tuberculosis.

## POSTPARTUM SUBINVOLUTION.<sup>1</sup>

BY

JAMES E. KING, M.D.,  
of Buffalo, N. Y.

Lecturer in Embryology and Instructor in Obstetrics, University of Buffalo; Assistant Attending Gynecologist, Buffalo General Hospital; Attending Obstetrician, St. Mary's Maternity Hospital; Member N. Y. State Medical Association; Fellow British Gynecological Society, London, etc.

In performing its part in the function of reproduction the uterus passes through a great cycle. A cycle which begins with the first changes in the mucous membrane preparatory to the reception of the fertilized ovum, and ends with the final shrinkage and return to normal after the birth of this child and placenta. The changes which occur during the cycle have afforded interesting study, and a brief reference to those bearing upon our subject may not be out of place. The most conspicuous changes are those occurring in the size of the uterus. A small organ weighing  $1\frac{1}{2}$  ounces becomes in nine months a muscular sac weighing 2 pounds, which in about six weeks shrinks again to its original size. Up to the fifth month the enlargement is due not so much to the pressure of the fetus as to the hypertrophy of the uterine walls. These increase by a very considerable growth of the individual muscular fibers, which become 10 times longer and 5 times broader. Whether or not there is a formation of new muscle fibers is a matter still to be decided. The interstitial connective tissue increases also, but here a true hyperplasia with numerical increase in the cells takes place. The uterine appendages and ligaments undergo changes. The round ligament elongates and the small amount of muscle fiber seen in the unimpregnated state becomes augmented to an appreciable extent. The ovarian and uterine arteries enlarge, and by the formation of new vessels penetrate every part of the rapidly-growing organ and provide the means of nourishment to the child, until by its first cry it makes its claim to an independent existence. From the fifth month to the end of pregnancy the developing fetus with its appendages is largely responsible for the increasing size of the uterus, the walls of which become thinned and stretched.

The first pain of labor inaugurates the retrograde process or involution. By contraction and retraction the uterus diminishes its volume and empties itself of child and placenta. The contractions and retractions continue, and the blood supply in consequence is decreased by obliteration of the vessels. The exact manner in which the muscle fibers return to normal is still a subject of discussion. The older theory attributes the shrinkage to fatty degeneration and absorption. The investigations of Helme, however, lead him to state that fatty degeneration does not occur and that the contraction is accompanied by a peptonization of parts of the muscle fiber, and this liquid portion of the cell is taken up by the circulation. With these changes in the uterus a corresponding process goes on in the ligaments, though more slowly in proportion. Without entering into the

discussion of the theory of involution, it can be said without question that two factors are necessary for its successful accomplishment. Those two factors are a continued and firm contraction of the muscle and a much diminished blood supply. When one or both of these factors are absent and the uterus fails to return to its normal size in 8 to 10 weeks subinvolution may be said to be present.

Sir James Simpson first called attention to this condition nearly 50 years ago, and spoke of some of its relations to pelvic pathology. As a pathologic entity subinvolution is rarely seen, and it is more from its association with other pelvic conditions that it calls for careful consideration. Subinvolution may hardly claim the dignity of a position in pathology, for it is simply a condition. It occupies rather a unique place in its relation to disease of the pelvic organs, as it may be in one case the immediate cause, and in another the direct result of the same pelvic condition.

The changes that are found in the uterus are those of enlargement. The size of the organ varies from a uterus that may be felt above the symphysis to one which may only be discovered by a bimanual examination, or by the use of the sound. The condition is due simply to a failure of the individual muscle fibers to retract and become smaller. Inflammation is only present as a secondary process. If the condition remains untreated, the interstitial connective tissue will proliferate as an inevitable result of chronic congestion. This tissue later becomes contracted, and the uterus becomes, in consequence, somewhat smaller, but still larger than normal. The vessels by this contraction are also obliterated to a great extent. In the earlier stages the mucous membrane is thickened, congested, and bleeds easily upon the introduction of the sound. The uterine appendages remain large and congested. The round ligaments fail to return to their normal size, but are elongated and weakened, thus easily permitting a large, heavy uterus to become retroverted. The associated pelvic conditions are perhaps a lacerated cervix, a corporeal or cervical endometritis, and frequently a retroversion. With acute or chronic pelvic inflammatory conditions, or in the presence of a fibroid, subinvolution will almost surely follow labor.

The etiology of subinvolution means, generally, a consideration of the influences which prevent contractions of the uterus, or which maintain an abnormal congestion during the period of involution. These two factors are usually interdependent, but occasionally one or the other alone is responsible. Constitutional disease may sometimes be accountable for subinvolution, but usually a disease which will cause it must be serious enough to overshadow the importance of an enlargement of the uterus. Too early rising from childbed may be mentioned as a causal factor by maintaining pelvic congestion, but this probably exerts its influence as a cause most often in the presence of other pelvic conditions. Of all causes, local ones are the most frequent. Laceration of the cervix is doubtless a common cause, though on this point there exists some difference of opinion. So great an authority as Herman tells us that injury to the cervix, in the vast majority of cases, is productive of no trouble other than local inflammation of the cervix. But the frequency with which a subinvolved uterus is found with an injured cervix, certainly must convince us that the association is not always an accidental one. Emmet, on the other hand, held lacerations to be almost the only cause for subinvolution, for he says in his book on diseases of women "for many years past I have met few or no cases of subinvolution that were not due to laceration of the cervix."

The relation that subinvolution bears to retrodisplacement as a cause or an effect is worthy of careful attention. Its influence as a cause is easily appreciated. The round ligaments in sharing the failure of the uterus to undergo involution, remain elongated, and a bulky uterus, with

<sup>1</sup> Read before meeting of Erie County (N. Y.) Medical Association, September 8, 1902.

a tendency to fall backward, soon results in further displacement, until finally it occupies a position of retroversion. Or as an effect, a retroverted uterus becomes pregnant. During the puerperium, as soon as its size will permit, the uterus resumes its old position that continues a congestion which must almost surely result in subinvolution. Other obvious local causes would be the presence of retained clots or bits of placenta which, naturally, prevent perfect uterine contraction. Unfortunately, subinvolution as a rule does not make itself manifest until, as a cause of other pelvic conditions, it forces the patient to seek aid. Possible symptoms are a feeling of weight in the pelvis, a continuance of the lochia beyond the usual period, and later, perhaps, an assortment of reflex signs. Marked symptoms accompanying subinvolution are those of the exciting or resulting pelvic conditions.

The diagnosis presents no special difficulties. An examination will reveal its existence. If the bimanual method is unsatisfactory, the careful use of the sound is harmless and will give conclusive results. The uterus is not painful, and this point distinguishes it from chronic metritis with enlargement, the only condition with which it is liable to be confused. The history will also usually discover inflammation to be the cause of the latter. The question as to when involution should be completed may arise in connection with the diagnosis. As a general rule involution should be completed at the end of eight weeks, and if then the uterus has not returned to normal a diagnosis of subinvolution may be made safely. One should not be satisfied with the diagnosis of the condition alone, but with a view to treatment the underlying causes should be sought for as well.

From the connection subinvolution has to pelvic pathology, prophylaxis and treatment will necessarily mean attention to the prevention and treatment of those conditions which act as causative factors. It is for this reason that the systematic examination of patients during the puerperium cannot be urged too strongly. I believe that the blind reliance in the puerperium as a physiologic state is responsible for many adherent retroverted uteruses. A labor which has proceeded and terminated in accordance with every physiologic law governing it, does not necessarily give us assurance that the period of involution will likewise be normal. Many careful physicians attend their patients in labor ever ready to correct any departure from normal, and yet these same physicians permit their patients to resume household duties without any attempt to learn whether or not the pelvic organs have in any way suffered, and only in the presence of symptoms that seem to demand it is such an examination made. There should be at least two examinations following every labor. The first at the end of two weeks, the second at the end of two or three months. By the first the existence of injury to the cervix or displacement of the uterus may be determined. The progress in involution may be also noted, and if it be satisfactory, in the absence of laceration or displacement, it may be safely assumed that, with reasonable care on the part of the patient, involution will proceed. By reasonable care is meant the gradual resumption of household duties and avoidance of all that may tend to produce pelvic congestion. The custom prevailing among many women of the better class of putting on the corset so soon as they are on their feet must, in many cases, have an evil influence on the position and condition of the uterus. Actuated by the desire to restore her figure to normal proportions the patient often compresses the waist, exerting sufficient pressure to disturb the position of the pelvic organs and maintain an undesirable congestion.

If on the first examination a torn cervix is found, remembering the influence it has upon the production of congestion, the physician should, during the remaining period of involution, take steps to deplete by the hot

douche and even in some cases by the tampon. On a subsequent examination at the end of 10 or 12 weeks, if we find that involution has not proceeded in a satisfactory manner, the question as to the advisability of repairing the cervix is an important one. Allusion to the difference of opinion as to the part a laceration of the cervix plays in subinvolution has already been made. That its repair does seem to have an influence in lessening the size of the uterus seems to be well founded clinically. But an opposite opinion which claims that it is only the enforced rest in bed that benefits cannot be entirely ignored. Granting even that this be the case and that it is the rest that is responsible for the improvement, with repair of the cervix the patient has the additional satisfaction of knowing that the injury is repaired and the surgeon may enjoy the consciousness that a possible avenue of infection has been closed and a favorable site for cancer removed.

Much may be done during the puerperium, both preventive and curative in backward displacement. If on the first examination tendency to retroversion is found, measures to support the uterus should be promptly taken. The Hodge-Smith pessary should be carefully fitted and the patient required, if possible, to remain in bed beyond the usual time. By thus supporting the uterus the round ligaments have the opportunity to become properly involuted. As involution proceeds a smaller pessary should be fitted and worn until involution is complete. In those cases in which a retroversion is known to exist before the occurrence of pregnancy the backward displacement in many cases may not only be corrected for the time, but even cured by care during pregnancy and the months following confinement. During the early weeks of pregnancy a pessary should be worn until the uterus rises in the pelvis and its falling backward is thus prevented. Four or five days after labor a large pessary should be inserted until involution has proceeded far enough, when a smaller one may be fitted and finally, when involution is completed, if necessary, the pessary may again be changed and this worn for four or five months. Not infrequently on removal it will be found that the uterus will remain in its proper position. Not every case is so successful, but it is worth the trial, as at least opportunity is given for involution to take place.

The treatment of other etiologic factors may consist in curettage when a hypertrophied endometrium is at fault; the removal of clots or membrane if these are found to be the cause; the management of acute or chronic pelvic inflammations should be conducted along general lines. The treatment for uncomplicated subinvolution is simple and in most cases satisfactory. Rest in bed, attention to the general condition, combined with the hot douche and glycerin tampon will ordinarily give the desired result. The application of the faradic current to the subinvolved uterus has been used with success. Theoretically ergot should be of benefit but clinically it is disappointing in effect.

Improvement in the care of women during confinement has resulted in doing away with a vast amount of suffering. Hundreds of women yearly are saved much discomfort by prompt repair of the perineum, for in these days no intelligent physician leaves his case before an examination satisfies him as to its condition at the close of labor. The timely use of forceps has made fistulas of the parturient canal a rare result of childbirth. Still even now the large majority of women seeking relief from the gynecologist date their condition to errors or accidents during labor or the puerperium. If then by more careful attention to the puerperium we may further lessen the number of unfortunates, should not our every effort be to carry out in practice, and educate our patients to the fact, that it is not the labor alone but inattention to conditions during the puerperium whereby recruits are added to the great army of suffering woman-kind.

## COURSE OF DISEASES DURING PREGNANCY.

BY

E. CASTELLI, B.A., B.Sc., M.D., L.M., ROTUNDA, DUBLIN,  
of Washington, D. C.

The physician who has under his observation the diseases complicating pregnancy should be not only an accomplished accoucheur but an intelligent pathologist as well, in order to understand thoroughly the alterations that pregnancy brings in the course of the disease, and those that the disease will assume during pregnancy. We must bear in mind that the functions of the pregnant organism undergo special changes at this time—and that, as an after result, the diseases either existing before or those complicating pregnancy assume a particular character. This fact must be taken into serious consideration by the physician, whether he is a specialist or a general practitioner, for, as statistics clearly show, such a lack in our clinical education is very often the source of mistakes which are sometimes fatal.

## DISEASES OF THE CIRCULATORY APPARATUS.

Corresponding to the enormous development of the vascular system in the gravid uterus, there is an increase in the total quantity of blood in the circulation, accompanied by an alteration in its constituents (water, hemoglobin, globules, albumin, etc.). The amount of water in the blood of the nonpregnant woman is about 799 per 1,000. In the pregnant woman it reaches during the last months from 815 to 818 per 1,000. The proportion of the red and white corpuscles is diminished; the number of the red varying from 2,500,000 to 4,000,000 per cm., and that of the white from 4,000 to 10,000 per cm.

Max Miskeman and Quinquad say that the hemoglobin and respiratory power of the blood is diminished during pregnancy, while Richard Shroeder asserts that it is increased. The fibrin is augmented in the last three months of pregnancy, and renders the blood more coagulable, thus contributing to moderate hemorrhages after delivery. The hydremic condition is consequent to the demand made upon the maternal system by the growing fetus. As a necessary result of the addition to the total blood supply there is increased work thrown upon the heart. We have, during the period of pregnancy, the same condition described by Professor Murri as *plethora hydremica*, and observed by him among persons drinking great quantities of water, and this is especially noticeable in the laboring country class (contadini) of the Italian campagna. This condition gives rise to slight dilation and hypertrophy of the left ventricle of the heart, very often accompanied by a systolic murmur (souffle) heard in the cardiac area, equal in character to the souffle of chlorosis. The hypertrophy and systolic murmur gradually disappear after delivery. Dreizel, Paul and Charpentier deny the hypertrophy.

The arteries show an augmentation of the arterial pressure. There is stasis in the venous circulation, especially marked in the lower part of the body. It is for this reason that there is so frequently hemorrhoids, edema and varicosity of the lower limbs, of the vulvo-vaginal portion, and sometimes of the abdomen. The physiologic changes in the circulatory apparatus increase the liability of the healthy pregnant woman to heart disease. This would lead to the question, Can pregnancy alone be the cause of a permanent heart disease?

In consulting the literature there is found considerable confusion and difference of opinion. The obstetrician, especially one practising in hospitals, generally has no chance of observing the patients after delivery, and the general practitioner in detecting a disease of the heart does not consider previous pregnancies as a predisposing cause.

Professor Pinard, of the Clinique Bandeloque in Paris, believes that pregnancy is only a secondary cause of heart disease, that the hyperactivity of the heart

functions during pregnancy helps in disturbing the equilibrium of the circulation in a person who already conceals a determined diathesis. Thus, according to Professor Pinard, all the so-called gravidocardiac disturbances so carefully described by Peter are due to a previous diathesis.

My personal observations, made during 18 months on patients in the Rotunda Hospital, in Dublin, the Clinique Bandeloque, in Paris, and the Clinica Obstetrica of Bologna, have given me the opportunity of noticing that heart lesions, detected in women who have had three or more pregnancies, and whose history did not show any special diathesis, were, in the proportion of four to five, affected by valvular insufficiency. I am inclined to believe that this kind of insufficiency is the so-called relative insufficiency and is due principally to the hypertrophic condition of the different segments of the heart during pregnancy, which is always accompanied by a diminished nutrient power of the blood. This relative insufficiency would also seem to explain the systolic murmur noticed sometimes in the cardiac area. If we admit a tendency to primary heart lesions, due to pregnancy, we should adopt prophylactic treatment during pregnancy to guard against the possibility of these troubles.

*Treatment.*—Owing to the fact that the heart troubles, if admitted, are due to the overworked condition of the heart in consequence of the hydremic plethora, the rational treatment would be to counteract this condition by prohibiting any unusual muscular work on the part of the patient. We should prescribe a great deal of rest, especially if the patient is weak and anemic. To avoid the unpleasant complications of stasis that could arise from the rest cure we must supply the lack of exercise with massage. To counterbalance the diminished respiratory power of the blood corpuscles and the consequent hemolysis, a cytogenic treatment could be adopted during the last months of pregnancy.

The endocarditis, either acute or chronic, observed during pregnancy, is generally caused by streptococcus, and in the majority of cases is due to a preexisting metritis.

*Influence of Pregnancy on Coexisting Cardiac Diseases.*—If the heart lesions coexist with pregnancy the various effects produced by pregnancy depend entirely upon the seat and character of the cardiac affection, but, as a general rule, pregnancy renders the course of cardiac diseases more serious, and very often the results are most disastrous. This is due to the fact that an amount of cardiac hypertrophy, which is entirely compensatory for preexisting valvular lesions, is not able to overcome the increased arterial and venous pressure prevailing during pregnancy, nor to adapt itself to the sudden variations in the vascular tension during labor. The mitral lesions, and especially stenosis, suffer from the *contrecoup*, while aortic lesions are only affected in a slight degree.

What the physician must know is that the asystolia in pregnancy assumes a special character due to the predominance of pulmonary troubles. Peter says that "La femme enceinte atteinte d'une cardiopathie meurt par le poumon." The asystolic troubles assume the character of regularly intermittent crises and are accompanied by pulmonary congestion, intense dyspnea, and very often by pulmonary apoplexy. The patient reaches rapidly the terminal period of asystolia, while in the nonpregnant woman that point is reached by degrees. Another special character of these cardiac troubles during pregnancy is the contrast between the gravity of the pulmonary affections and the benignity of the other phenomena (edema of the lower limbs, congestion of the liver, and congestion of the kidneys).

Besides those cases in which the mechanical troubles are more evident, we have others in which the predominant symptoms are those due to a want of compensation of the cardiac innervation. In this last case there exists tachycardia with considerable arterial hypotension.

*Influence of Cardiac Diseases on Pregnancy.*—Professor Porack, of the Maternité Hospital in Paris, has demonstrated, with his careful and valuable statistics, that an average of 41% of pregnant women affected with cardiac troubles do not reach the full term, abortion or miscarriage terminating the pregnancy. Brown-Séquard thinks that the excess of carbonic acid in the blood of the woman with cardiac disease is the cause of premature contractions of the uterus, and as a natural consequence of premature delivery. If the patient with cardiac trouble does reach full term one of the most common and very dangerous complications is the metrorrhagia during or after labor; the hemorrhage endangers the life of the patient, and when death is not the immediate result, a severe chronic anemic state with all its consequences follows delivery.

*Prophylactic Treatment.*—Very often the unmarried woman comes to the physician for special advice. She wishes to be married but has heart trouble, and therefore desires to know if it will be safe for her to marry. Some authorities think that such a woman should be absolutely prevented from marrying, while others would allow the marriage according to the degree of heart lesions, but all, speaking theoretically, forget that the young woman comes only for a positive consent. If the physician refuses to give this consent she will try to find a more lenient one, and possibly she will do so, but if she does not, she will marry without this consent. Such examples are before our eyes every day and everywhere. In theory I should feel more inclined to allow marriage to a woman with aortic lesions than to one with mitral lesions, but in practice we must not give rude denials, but should talk sensibly to the patient, showing her the dangers of marriage, and prescribe for her a program of life suitable to the lesion with which she is affected and if necessary caution her against child-bearing.

*Medical Treatment.*—This is the usual treatment of cardiopathies, bearing in mind that the woman has a special tendency to congestions. Bleeding would be very useful in such cases.

*Obstetric Treatment.*—If the woman is in danger during pregnancy, induce abortion or premature labor. If she dies in the last weeks of pregnancy, and the fetus is alive, cesarean section should be performed. During labor the strength of the heart should be kept up by cardiac stimulants. If the cardiac troubles become dangerous to the life of the patient, labor should be accelerated by dilation of the internal os and accouchement forcé performed. After labor tonic treatment should be instituted, and the mother prohibited from nursing the child.

*Varicose Veins.*—Dilation of the veins of the legs, rectum, and vulva occur with greater frequency in multiparas than in primiparas, and is referable, in part, to the pressure exerted by the gravid uterus on the iliac vessels, to the increased tension of the pelvic vessels, and to the modification of the nervous system (nervous lesions of the veins). The tendency of the gravid uterus to lie on the right side of the body explains why varicose veins tend to affect the right side instead of the left, as usually happens. Varicose veins of the lower limbs can be deep or superficial. The saphena are always first affected, then the lateral branches upon the inner surface of the leg and thigh, especially above the knee. They generally appear after the second or third pregnancy, unless the patient is predisposed to them. The tissues that surround the varicose veins become more or less thickened, and the limbs are much increased in size. The natural tendency of varicose veins is to disappear after delivery. It should be borne in mind that if the varicose veins disappear before delivery intra-uterine death of the fetus may be suspected.

*Complications.*—The varicose veins of the inferior limbs in the pregnant woman generally disappear without giving any inconvenience, but sometimes, especially

in the laboring classes, they prevent work on account of the complications, the most frequent being (a) edema, especially of the dorsal part of the foot, and of the inferior third of the leg; (b) eczema, which if left untreated, generally gives rise to (c) varicose ulceration; (d) phlebitis, periphlebitis, and phlegmonous periphlebitis, (e) rupture of the varicose veins, and hemorrhages.

*Treatment.*—As the varicosity of the veins of the lower limbs disappears after delivery it is not only useless but dangerous to resort to any radical treatment during pregnancy; the hygienic treatment is the only one to be used at this period. The woman affected by varicose veins must avoid long standing and walking and abolish garters. If any of the foregoing complications are threatened complete rest must be advised.

*Organs of Generation.*—Varicose veins of the broad and round ligament seldom occur and are of no consequence. Varicose veins of the cervix are not uncommon, and are easily detected by an examination with the speculum. When a physician is attending a pregnant woman he must assure himself if there are or are not varicose veins of the cervix, as their rupture is easy, especially during labor and after delivery. When prepared for such an occurrence he can easily avoid severe and dangerous hemorrhages by pressure, before, or by ligature, after delivery. The vulva and vagina are very frequently the seat of varicose veins. Those of the vulva are generally situated between the labia majora and the labia minora, or only on the labia majora. They are nearly always unilateral, and sometimes extend to the clitoris and mons veneris, and also to the vagina. At times they assume immense proportions, so that they appear to be large tumors of the labia. These varicose veins can be broken easily during pregnancy and during labor; one of the common causes of rupture during pregnancy being the frequent scratching of these parts by the patient, on account of the tormenting sensation of pruritus that is produced in the vulva. Varicose veins of the vagina are detected by separating the labia minora. They appear like blue flexuous cords piercing the walls of the vagina. They are apt to rupture during labor and during pregnancy. One of the causes of rupture during pregnancy is coitus. Tarnier speaks of a butcher's wife who died of hemorrhage in a few minutes after coitus. Varicose veins of the anus and rectum are of frequent occurrence during pregnancy and after delivery. During pregnancy they are due to the common cause of varicose veins in the pregnant state, and also to constipation, while those that we sometimes detect soon after delivery are due to a traumatic cause, *i. e.*, to the pressure of the head of the fetus on the rectum during delivery. Treatment: Avoid by the use of enemas the straining of constipation, and try to diminish the size of the veins by slight massage in a warm bath.

## GASTROPTOSIS AND GASTRECTASIS.

BY

E. S. FOGG, M.D.,

of Bridgeton, N. J.

The subject of gastric surgery is coming more prominently before the profession every day. While a few pathologic conditions of the stomach have been treated successfully by surgical means for a considerable time there are two conditions with which surgeons have dealt but very recently, *viz.*, gastroptosis and gastrectasis. These offer a highly satisfactory field for the employment of the surgeon's art. It is natural to consider these two conditions together. The symptoms are practically the same, the medical treatment is identical, and the two conditions often coexist. Before considering the surgical treatment of these conditions it is well to refer briefly to the medical.

The administration of proper medicines, regulation of the diet, and the careful control of daily habits may afford relief in many cases and make life fairly comfortable; others may be greatly benefited, but some patients, even with the most careful observance of dietetic and hygienic rules and the most intelligent administration of drugs, fail to receive benefit, continue to suffer most distressing symptoms, and gradually lose weight and grow weaker. Then there are patients, relieved somewhat while taking medicine and receiving the usual care, who immediately lapse to the old condition upon cessation of treatment. They receive no permanent benefit.

Lavage is of the greatest value in the treatment of acute gastric disease in children, and in certain forms and in special individual cases of gastric disease in the adult it is of benefit, but it has not the *curative* value nor is it of such value as a means of relief in simple dilation, in gastroptosis or in chronic indigestion as was once believed. The mechanic treatment of gastroptosis seems quite irrational and in many cases impracticable, but it is probably useful in some cases and worthy of trial in all. All the means mentioned should be tried before a resort is had to surgery. Some patients, however, are not helped by any of these measures, no matter how thoroughly employed, and it is in this class that at present operation seems to me advisable.

The two operations which seem most rational and safe are Dr. H. D. Beyea's operation for gastroptosis, and gastroplication for gastrectasis.

According to *American Medicine*, October 11, 1902, gastroplication has been done about 17 times, the results being almost universally in its favor. This we should infer, as it does away with the dilation and is a safe procedure. I have done the operation three times on dogs for the purpose of learning the character of the union between the approximated borders of the infolded portion of the stomach. The animals were killed by means of chloroform three weeks after operation. In every case the result was all that could be desired, the line of union neat and most substantial. This was, of course, to be expected from the known results of other operations on the stomach and other parts of the alimentary canal. But I operated on these animals to satisfy myself by actual examination as to the results of this particular operation. On opening the abdomen of these animals postmortem, the peritoneal surface over the anterior wall of the stomach, the part in which the plication had been made, was seen to be perfectly smooth, and at first I thought the stitches had given way and the work was a failure. It could not be easily determined by ocular inspection just where the row of stitches had been placed. The line of union, however, could easily be made out by the sense of touch. A linear mass of what felt like cicatricial tissue could be detected, and corresponding to this in situation, on the inner surface of the stomach, was an elevation or fold of mucous membrane which was loosely attached and movable over the submucous tissue, as in other parts of the stomach, and, of course, unaffected by the healing process. It may be added that the glandular area was not diminished. Practically, this may not be of any advantage. Neither is it in the least probable that the normal movements of the stomach are interfered with by the long, narrow scar, as each muscle fiber receives its stimulus through its motor neuron. It might be objected that cases of marked atony would not be improved, but this is unlikely, as reducing the dilation would allow the muscles to regain their normal tone; and even if they did not, it is practically certain that a small atonic stomach would produce less distressing symptoms than a large one. So from every point gastroplication promises to be a complete success.

In regard to Dr. Beyea's operation, experience is likely to prove all that is claimed for it. At the present time (November 12, 1902) there have been seven patients operated on by this method. One of them happened to

be a patient of mine, and I desire to give a history of the case, with a few comments:

The patient was Mrs. D., aged 53, a housewife. Her family history is good so far as could be learned, except as regards two sisters, who have stomach trouble, one very severely. The patient had scarlet fever at 17 years, and diphtheria at 32. She has had four children, all born prematurely. Two died a few hours after birth, one at six months, the other at three years. The patient suffered from dyspepsia for years, with frequent pain ("cramps") and vomiting. The last stomach pain she had was in January, 1901. Since then she has had no pain, but has suffered greatly from indigestion. At times she was able to take but a very small quantity of water, and would go for several days with practically nothing to eat, the least food causing the most distressing symptoms. When a young lady she weighed 116 pounds; in September, 1901, she weighed 89 pounds, and on April 8, 1902, her weight was 77 pounds. She was quite deaf. She had no desire to urinate while standing, but from  $\frac{1}{2}$  to 2 hours after lying down she had to get up to pass urine. She urinated 2 or 3 times each night, but never during the day unless she lay down.

Physical examination showed the lesser curvature of the stomach to be at the umbilicus and the greater curvature near the symphysis pubis. Test of the gastric contents showed the presence of hydrochloric acid. Both kidneys movable. An attempt was made to determine the capacity of the stomach by introducing the stomach tube and filling the organ with water. The patient was told to raise her hand when the stomach became so full as to cause distress. When this sign was given the water was siphoned off. Two such tests were made at different times and both indicated that there was no dilation. Thirty-six fluid ounces were poured into and drawn from the stomach each time, due allowance being made for possible errors. This method was used because it was found more difficult to decide whether there was dilation with the presence of gastroptosis. There being no dilation the pylorus was assumed to be normal.

During the first week of May last Dr. H. D. Beyea saw the patient with me, concurred in the diagnosis, and recommended his operation, which was heartily agreed to. Dr. Beyea operated at the Bridgeton Hospital on May 8, using the method for elevation of the stomach which he devised, which, as is well known, consists in the shortening of the gastrohepatic and gastrophrenic ligaments. The patient, though extremely weak, recovered promptly from the operation. She was kept in bed six weeks, left the hospital on July 11, and has had no symptom of indigestion since. She is now in good health, is able to take all kinds of food, and has gained 10 pounds. This is not such a great gain, but the patient was never stout, and she is still gaining.

A few days after the operation it was noticed that the patient's hearing had greatly improved—seemed entirely normal—and this improvement has continued to the present time. Further, she does not have to get up at night to urinate, but urinates during the day as other people. I accounted for the nocturnal urination before the operation by the theory that as the stomach was low and the mucous membrane in an abnormal condition fluid was not absorbed from it. The pylorus was also higher than a great part of the stomach, consequently fluid remained in that organ until the patient placed herself in the horizontal position, when it passed more readily into the intestine, from which it was absorbed. It is unnecessary to assume, however, a diseased condition of the mucous membrane to account for the non-absorption of water by the stomach. Vierordt states that "water in only small quantities is absorbed by the stomach; the freer it is from dissolved constituents the more completely is it transported, portion by portion, into the duodenum." This statement is confirmed by the work of von Mering and Moritz, mentioned by Vierordt. It would be interesting to know if the symptom of nocturnal urination in extreme cases of gastroptosis and gastrectasis is at all constant.

A thought which suggests itself to me in considering this subject concerns the work of physicians and surgeons in this class of cases. While the work of the latter is enlarged there is no detracting from that of the former. It would seem now that physicians instead of having lists of these patients who go about from one doctor to another, receiving no benefit here and very little there, reflecting discredit upon the science of medicine wherever they go, can, with the cooperation of their patients, supplement their own work by that of surgeons and share with them the credit of restoring to health patients who have heretofore gone without relief.

A DIAGNOSIS BY POSTMORTEM LAPAROTOMY.<sup>1</sup>

BY

C. A. DREW, M.D.,  
of Bridgewater, Mass.

Medical Director Massachusetts State Asylum for Insane Criminals.

Because of the misleading character of certain symptoms and the difficulty of making a positive diagnosis, the following case may be of sufficient interest to place on record:

Mrs. D., aged 44, previously in good health, was taken sick November 18, 1901. The leading symptoms were severe pain in the left hip on motion, first felt on the seventeenth, increasing in severity till she went to bed on the eighteenth. As the attack seemed much like previous attacks which had yielded promptly to antirheumatic treatment she was given potassium acetate, 1 gram (gr. 15), every three hours, largely diluted in aqua gaultheria, this being the remedy which had uniformly given most speedy relief in previous like attacks. On the nineteenth she was better and sat up most of the day, but walked about with difficulty. On the twentieth she was again worse and the evening temperature was found to be 101.5°. From this time the symptoms seemed to justify the diagnosis of a subacute type of rheumatic fever. Within a few days there was moderate swelling with marked tenderness over the left sacroiliac synchondrosis. The left knee was painful on motion within a week and the left ankle, less painful than the knee, a little later. There was only slight swelling of the knee and ankle, which were kept wrapped in absorbent cotton for three weeks or less. Like symptoms continued for about six weeks when the temperature reached normal in the morning for several consecutive days. Then the right side became painful; especially the hip, with most swelling at the right sacroiliac synchondrosis. There was very little swelling elsewhere, although the muscles over the ilium part of the thigh and calf of the leg were painful on motion and tender on firm massage.

Again about the twelfth week it seemed as if convalescence was beginning, but again recrudescence of symptoms set in, gradually fading but not entirely absent at the end of four months. Many of the drugs recommended for rheumatism were tried, but of them all the stomach would tolerate only the vegetable salts of potassium for more than one day. Salicylic acid, rubbed into lard, was used freely in connection with massage of tender muscles and joints with some apparent benefit. Early in February the patient took whoopingcough from her young daughter, and during the next six weeks suffered from a severe form of that distressing affliction. The heart had not apparently been seriously affected, but in her emaciated condition it often seemed as if those distressing paroxysms of coughing might be too great a strain for the weakened cardiac muscles. By the latter part of March the cough had abated considerably, and there was not much pain on movement of the lower extremities. By April she could use her limbs fairly well and was nearly free from pain. During April she gained in freedom of motion so she could get out of bed and walk across the room with some support. All this time there was a daily rise of temperature to about 102° in the evening. Even the morning temperature was only rarely normal. Urine had been normal throughout. No tubercle bacilli could be found in the sputum which seemed to be merely watery mucus. In March I first discovered an abnormal dullness and resistance on palpation in right flank reaching below the normal liver dullness about the extent of a man's hand. This was only slightly sensitive on pressure and did not seem to change in size or shape as the weeks passed. The patient had attacks like acute indigestion several times following our attempts to give her more nutritious diet.

Being placed again on milk, beef jelly, rice, and other light diet, she would seemingly make slight gains, but temperature remained steadily elevated and pretty constantly between 101.5° and 102° F. in the evening, while there was manifestly a steadily increasing emaciation. She was uniformly cheerful and optimistic as to final recovery; this, with constant pyrexia and growing emaciation, strongly suggested tuberculosis, of which we could get no positive evidence. About April 26, 1902, Dr. F. C. Shattuck, of Boston, saw the patient in consultation. His very searching examination was practically negative, except for the mass in the right flank, which seemed most like an enlarged and displaced kidney or a neoplasm connected with the kidney. The absence of positive knowledge whether the mass had existed before her illness added to the obscurity of the case and a positive diagnosis was not made. Examinations of blood, sputum, and urine at this time were negative. The question of possible relief by surgical interference was fully considered and advised against. Two weeks later Dr. Reginald Filtz, of Boston, saw the patient, and again, after a careful examination and thorough consideration of all the symptoms, no positive diagnosis could be made. An enlarged and displaced kidney seemed to explain best the dullness and resistance in the right flank, and no pathologic condition of the

lungs could be made out. During May, June, and July our patient grew more and more emaciated, although taking a fair quantity of nourishment and sleeping fairly well. She sat up from one to two hours on many days, and did considerable sewing. She was inclined to make her own diagnosis, and thought at one time she had cancer of the stomach, and at another time asked if she did not have consumption of the bowels—about the only pain she had was referred to stomach and bowel. There was nothing about the stools to aid in the diagnosis. During the early part of August it was evident that she would live but a short time, and by the middle of that month the patient had ceased to expect recovery.

Examination of sputum and urine at this time was again negative. She died August 23, having been conscious and clear mentally until about six hours before death. She had twice requested that an autopsy be made after her decease that her physician might know what to do for other like cases, as she expressed it, patient having understood that no positive diagnosis had been made. An exploratory laparotomy was made six hours after death by my colleague, Dr. Elliott, and Dr. G. C. Brown, of Medfield, the family having requested that only the abdominal organs be molested; if a tuberculous condition existed there, it being believed that any involvement of thoracic organs must be secondary, as all the symptoms had been referred to the abdominal viscera. Dr. Elliott's memorandum was as follows: "Liver prolapsed, right lobe reaching down into lumbar region, flattened, elongated and almost of an ox-tongue shape. Liver tissue appeared to be normal, ligaments relaxed and lengthened. A few adhesions were found around left lobe and gallbladder, latter normal. Stomach and intestines were slightly distended with gas and former lower in place than normal, ligaments lengthened. No intestinal lesions found, but only a superficial examination made. The mesentery was everywhere studded with tubercles varying in size from a small pea to bean, many of them having undergone fibrous changes. Glands in lesser omentum and transverse mesocolon were greatly enlarged, many of them caseated, a few were fibrous. In the lesser omentum there was a nodulated mass about the size of a man's open hand. At first the nodules appeared to be closely adherent, but they could be easily separated and most of them had undergone caseation. The spleen was about one-half larger than normal, but showed no gross lesions. Kidneys were normal in size and position and with palpation no pathologic changes could be made out. No fluid was present in abdominal cavity."

By exclusion the pathologic findings had been anticipated, but it was a surprise, and an instructive lesson to know that both kidneys were apparently in normal position, and of normal size, and that what had been taken for an enlarged and displaced kidney or neoplasm by each physician called, including two of the best diagnosticians, was an abnormally shaped right lobe of liver prolapsed, presumably by severe straining during a severe attack of whoopingcough following a long illness with rheumatic (?) fever. It may be well to add that the patient's mother died of a wasting lung disease, presumably pulmonary tuberculosis at about the same age, and a sister of our patient, the eldest of the children, of the same disease at about 18. One sister, five years older, and one brother, three years younger, are in fair health, although the sister has had moderate hemorrhages, apparently from a bronchus, on three different occasions; all subsequent to the menopause—to which, in the absence of any pulmonary symptoms discoverable, a relationship has been credited. Our patient had always been robust, not having been in bed for more than a day or two from illness, except when her one child was born, for 20 or more years. She had had several rheumatic-like attacks, perhaps an average of three such attacks a year, each coming on suddenly, affecting most the muscles about one or the other hip, and uniformly yielding promptly to potassium acetate, freely diluted. During the summer prior to her illness she had several "colds," something so unusual with her as to cause comment, but otherwise she seemed in robust health. Her home was in the country, and the environments all that could be wished for. Her living-rooms and sleeping-room were all large, airy and sunny.

She had not visited or been visited by tuberculous people, did not ride on the train frequently, and not for some years in a sleeping-car. While she was suffering from what seemed subacute rheumatic fever for three months or more, her nutriment was almost wholly uncooked milk, furnished from a large dairy which had not been tested with tuberculin for several years. During our patient's illness, one cow killed from the herd

<sup>1</sup> Read before the Plymouth District Medical Society, October 15, 1902.

which supplied the milk was found to be far advanced in pulmonary tuberculosis, and an ox on the same farm, but not kept in the same barn, was also found to be tuberculous. Whether there was a causal relationship between the nutriment depended on almost solely for a number of months, while patient was in an unfavorable condition to resist pathogenic bacteria, and this case of "tabes mesenterica" might be a question for interesting speculation.

### GLIMPSSES OF THE PRACTICE OF MEDICINE AND DISEASES IN THE WEST INDIES.

BY

NICHOLAS SENN, M.D.,  
of Chicago.

Recent political events of far reaching significance have awakened our interest in and brought us in closer touch with the beautiful tropical West Indies. Before the war with Spain our nation knew little of the mountain peaks of the lost Atalanta, but since the fortunes of war have placed us in possession of one of these, and destiny gave us an opportunity to liberate another one from foreign rule, our eyes are turned in the direction of these landmarks which divide the great Atlantic Ocean from the blue waters of the Caribbean Sea. The West Indies offer so many inducements for the midwinter tourists and chronic invalids from the North that a brief description of my recent three weeks' tour may interest the many readers of *American Medicine*. It is a strange but pleasing experience to leave icebound Chicago and in less than a week find yourself in a new country, among strange people and surrounded by the luxuriance of a tropical climate. It is on an occasion like this that we are reminded of our school-boy days when we were made to study geography and stock our youthful imaginative minds with the location of distant countries, their people, their climate, products of the soil, manufactories, and workshops. It is a source of great gratification to look at the dizzy height of the gigantic palms, to pick from the shrubby nutmeg tree its aromatic fruit of the color of gold, and from the pepper vine the grape-like clusters of pungent green-yellow berries, and to attack the bark of the cinnamon tree with a pocket-knife to satisfy yourself that you have found the real article remembered so well by many as one of the ingredients of the favorite delicate dishes of childhood days. Spend a short midwinter vacation in the West Indies, as I did, and you will experience the same delight, and will return to your arduous duties, as I did, with pleasant dreams of what the special senses enjoyed and in a better humor to bear the burdens of the daily routine toil. Besides admiring nature's exquisite beauties which only a tropical soil can build and a tropical sun can paint the medical visitor to the West Indies is most interested in the shady side of life in the tropics—tropical diseases. With our present methods of rapid navigation a physician living east of the Rocky Mountains can visit the most interesting and important islands of the West Indies and obtain a fair knowledge of their people, natural resources and prevailing diseases and return in four weeks well satisfied with what he has seen and learned. The trip during which the following observations were made extended from January 15 to February 5, 1903, with New York and the island of Martinique as opposite points. The passengers on the "Kaiserin Maria Theresa," of the North German Lloyd, left New York wrapped in furs and the heaviest overcoats, and many demands were made of the stewards for additional blankets to fight the cold in the chilly staterooms when the shivering passengers retired for the night. This source of discomfort did not last long as the great ship under full steam made a bee line for the equator, evidently anxious to relieve her human freight of the cumbersome winter clothing. On the third day out a general overhauling of the contents of the steamer trunks in search for lighter clothing became the main

occupation of the passengers. Silk and linen took the place of wool and fur, and white and yellow became strong rivals of the sombre black, brown and gray of the wearing apparel, a change from which caps, hats and shoes were not exempt. In a very few days the dome of gray threatening clouds disappeared as by magic, and the lifting of this heavy impenetrable curtain by invisible hands exposed to the unobstructed vision the azure blue boundless sky of the tropics, decorated during the day by the warm sun of the South which approached nearer every day with ever increasing fervor, and by night by the pale crescent-shaped moon and countless luminous stars. Before we were aware of the distance we had traveled land was sighted, and on the morning of January 19 we reached our first destination, the harbor of Charlotte Amalie.

*St. Thomas*.—This is one of the three islands in the West Indies belonging to Denmark. It is an important coaling station for merchant vessels from the most remote parts of the world. More than half of its small population live in Charlotte Amalie, the seat of the colonial government. A small military force is located here. The principal revenue is derived from the export of bayrum, which is noted for its superior quality and cheapness. The soil is unproductive and the negro population miserably poor. The government officials, the military, and a few business men make up the small body of white inhabitants. Two Danish doctors attend to the needs of the sick. The government is obliged to do what it can for the sick poor.

*Kommune Hospitalet*.—This hospital can accommodate 115 patients when it is taxed to its utmost capacity. It is arranged in the form of an open square, and consists of one-story barracks divided into small wards for six to eight patients; all of these wards open on the square. On the left at the entrance of the square is the building for men, on the right for women, and in the rear is a one story frame building for the insane. The hospital is furnished in a most primitive way, and the filth appeals both to the eye and nose. We found here the usual variety of diseases which ordinarily prevail here, syphilis, rheumatism, ulcer of leg, bronchitis, endocarditis, and myocarditis, and a number of cases of elephantiasis. Only one of the insane was locked in his room, the remaining patients were either in their open rooms or wandering about in the yard. I was interested to ascertain who was responsible for the filthy condition of the institution. After a somewhat prolonged search we found the female nurse who had charge of the patients who belonged to her sex. She was a colored woman of doubtful age, clad in a dirty calico dress, her dusky face made more so under the shadow of a large straw hat with drooping broad rim that evidently had done service for many a season. To the inquiry where she had received her training, she made no direct reply. The only argument she made as to her proficiency as a nurse was that she was the mother of seven children and thought that that kind of practical training ought to suffice to prepare her for her vocation in life. With this kind of training she entered the institution 17 years ago and has held her place ever since. She was particularly anxious to impress upon us the wonderful results of her extensive obstetric work. The convalescent women give her assistance in the performance of the more arduous and menial part of her work. The nursing on the opposite side of the square made no better showing. A negro, who looked like an ordinary day laborer, served in the same capacity here. A vest that once was white and a clumsy pair of cowhide shoes distinguished him from his subordinates, so far as external appearances were concerned. The doctor who is in charge of this hospital is said to be a very busy man, but he never fails to take his siesta between high noon and 3 p.m., a time he claims for himself, and during which when called upon he sends his compliments by a dark-skinned *bonne* of the island, that is if she can muster enough courage to disturb her master's nap by conveying a message to him during that time of the day. The poverty of the island may offer a partial excuse for the way in which this hospital is conducted, but it is high time that the general government, so long as it persists in holding it as a colony, should look into this part of the management of its black subjects.

*St. Kitts*, a small speck in the mighty ocean, is one of the numberless colonies of England, as well as one of its oldest. It.

is reached from St. Thomas in a few hours by steamer. It does not take long for the visitor to learn that he is on British soil. English is the language of this island. The native policemen are splendid specimens of the colored race, well uniformed and disciplined, clean, courteous, and faithful in the execution of their duties. The clean streets and splendid country roads are a good evidence of a modern progressive government. St. Kitts has a population of about 30,000, of which the negroes furnish the bulk. Basse Terre is the only city of any size. It is the seat of the local government and important charitable institutions. Like nearly all of the West Indies, the interior of the island is mountainous. Our country is represented here by Consul Dr. Haven, a graduate of Rush Medical College, who practised his profession for many years with great success in Chicago, and who accepted his present position to recuperate his health by a change of climate. To him we are indebted for many courtesies.

*Lazaretto or Leper Asylum.*—Leprosy is found in all of the West Indies, but is quite prevalent in St. Kitts. The Lazaretto is located on a high elevation by the seashore and near the

Acute exfoliative dermatitis (St. John's).

base of Brimstone Hill, with the remains of an old fortification upon it, which was abandoned 36 years ago. The Lazaretto is connected with the city by a magnificent macadamized road which follows the seashore and passes through a number of quaint negro villages, the landmarks of former large sugar plantations. The asylum buildings are well adapted for the purpose for which they were intended. An open space between them has been transformed into a charming flower garden, intersected by beautiful gravel walks. A tract of several acres of land belongs to the institution, but the soil is so poor that nothing has been done in the way of cultivating it. The colony was founded 10 years ago, and has been managed ever since by Dr. John Foreman, who takes a deep interest in its welfare. Absolute segregation does not exist in any of the islands. In St. Kitts and the rest of the West Indian British colonies ample provision is made for the indigent lepers. The law requires that lepers should not pursue any vocation which would be likely to spread the disease, such as the hand-

ling of foodstuff and clothing. If a leper is found begging or engaged in a business or trade calculated to disseminate the disease he is arrested, convicted and sent to the asylum for treatment and isolation. At present there are 72 lepers in the Lazaretto, the youngest a little boy of 6. The macular and tuberculous variety are about equally represented, as well as the sexes. All of the patients are negroes, with the exception of two Portuguese women. The treatment is palliative and symptomatic.

*Cunningham Hospital.*—This is the government hospital of the city of St. Kitts and commemorates the name of a former Governor of the island. It has a capacity for about 100 patients. The buildings are two-story barracks, the lower of solid masonry, the upper of wood. The wards are well lighted and plainly but comfortably furnished. Dr. W. J. Branch is the medical officer in charge. He is assisted by two graduate colored pharmacists. I found here two cases of amputation of the leg for elephantiasis, the operation having been made necessary by extensive ulceration. The patients were doing well, but the wounds failed to heal by primary intention. The colored female nurses under the direction of a trained English nurse take care of the sick, and the general cleanliness which prevailed here spoke well for their efficiency and industry.

*St. Johns.*—We landed at Antigua, St. Johns, January 21, and lost no time in looking up the medical aspects of the island city. A visit to the ancient cathedral reminded us that the public is sometimes appreciative of the services of physicians after they have completed their unselfish career and have gone to their reward. On a marble tablet on the wall on the right side of the main entrance I found the following inscription:

To  
The Memory of  
Robert Peddie,  
Surgeon,  
Native of Kelso in Roxburghshire, N. B.,  
Who died in this island  
On the XVI of November, A.D. MDCCXXLI,  
At the age of XLI years.  
This Tablet  
Is consecrated by the sympathies of  
A few of his friends.  
In life they esteemed him  
As well for  
His faithful discharge of his duties  
As a member of the Legislature  
As for  
Exemplary conduct in all the Relations  
Of Professional and Domestic Intercourse.  
And now that he is departed,  
They desire to record their feelings  
Of sorrow and respect  
That these may not pass away with  
Their own fleeting existence.

The wording of the above tribute reflects the feelings of esteem and veneration for the life work of an exemplary member of the medical profession.

St. Johns has been impoverished since the depression of the sugar-cane industry. The streets of Antigua, the capital, are thronged with beggars who are noted for their aggressiveness when visitors make their appearance. Outstretched black hands and the plaintive "give me a penny" constantly menace the peace of mind of the stranger on the streets. If the hungry crowd becomes too large it is sometimes necessary to look for a policeman for relief or enter or seek peace and rest in some public establishment. Malaria is quite common in St. Johns. On the other hand, typhoid is quite rare.

Vaccination is enforced by the Board of Health, consequently the mass of the people is protected against smallpox. The entire population is saturated with syphilis. The disease has existed for such a long time, and is so common, that it has lost much of its virulence. Some idea may be formed of the prevalence of this scourge of the colored race from the fact that 150 pounds of potassium iodid are consumed in the hospital annually. Tuberculosis here, like elsewhere in the West Indies, has a firm hold on the black race. The insane asylum

is located on an island in the harbor, formerly a strong fortification. The leper colony is located on a high ridge overlooking the harbor, and numbers at the present time 40 inmates, all colored.

*Holderton Hospital.*—This is the only hospital on the island, and can accommodate 200 patients. It bears the name of a deceased rector of the ancient cathedral. It is in charge of Dr. Frederick L. Norris, a young and most capable physician. The wards are airy, neat and fairly well furnished. The buildings occupy the eminence of a hill behind the city, and the ample grounds are well laid out and ornamented with tropical trees, shrubs and flowering plants. From here a beautiful view of the city and harbor, as well as distant mountains, can be obtained.

*Elephantiasis in St. Johns.*—The visitor need not go to the hospital to see this disease, it is constantly seen in all its stages in the streets. The bare legs displayed by men, women and children make it possible to study this disease in the streets any time of the day. Through the courtesy of Dr. Norris I had an opportunity to examine 72 cases of elephantiasis, 20 in the hospital and 52 in the poorhouse. Among this number were two cases of scrotal elephantiasis. In one of them a negro, aged about 30, the disease involved first the right leg, and two years ago it extended to the scrotum, which at the present time has reached the size of the head of an adult and is complicated by enormous enlargement of the penis. In the second case, an old negro, the disease was limited to the scrotum and had reached about the same dimensions. In the poorhouse, 50% of the inmates were disabled by this disease. Dr. Norris is averse to operative interference in such cases, as the disease as a rule has impaired the general health of the patients to an extent as to interfere seriously with the satisfactory healing of wounds and subsequent restoration of the general health of the patient. The vulva is very seldom affected by this disease, otherwise women are as susceptible to it as men. The nursing here, like in all the British possessions of the West Indies, is in charge of a graduate English nurse, who at the same time serves as matron. Colored girls of desirable age enter the hospital and without any special instruction or training begin their work. They become very useful hospital servants but lack the high qualifications of our nurses. They receive from four to eight dollars a month for their services, according to the degree of efficiency and experience in their work. The poorhouse and prison are near the hospital, the former on the same grounds.

*An Innocent Prisoner.*—Under the guidance of the prison captain and Dr. Norris we visited the prison. The prisons in all English colonies are models of their kind, and the Antigua prison proved no exception. The discipline is perfect, and the prisoners are made to pay the penalty of their offense against the law by hard manual labor that requires no skill, principally crushing stone. In one part of the prison rough coffins are made for the burial of the poor. The execution chamber in the prison building has been idle for more than two years, but the machinery for hanging is kept in good repair. Corporal punishment is only resorted to in the most obstinate and refractory cases, and consists usually in the use of the lash or four hours in the treadmill. The women contingent is larger here than in most prisons. Washing is their principal employment. In the female department we found a coal-black baby boy only a few days old curled up on a floor-mat on the stone floor. This little convict was certainly incarcerated without any cause for which he could be held legally responsible. His mother was serving her sentence for a petty offense, and before her time expired one more inmate was added to the prison roll. This instance illustrates well that the innocent have often to suffer the crimes of the guilty. May this infant prisoner never know where he was born!

*Hospitals of the West Indies as Postgraduate Institutions for the Study of Tropical Diseases.*—It is a great pity that the medical officers of the hospitals of the West Indies have neither the time nor the appliances for the scientific investigation of the many as yet obscure tropical diseases they are called upon to treat. The material is simply enormous, and could be readily made available by our young graduates in medicine and by prospective health officers. These are the places to which the attention of our foremost medical schools should be directed.

Some of the scholarships should be devoted to the study of tropical diseases in these colonies. I am sure every hospital would throw open its doors widely to students, provided the investigations would be made without increasing the financial outlay. I became so deeply impressed with the great opportunities that I determined to use all my influence to have Rush Medical College take an initiative step in this direction, with the hope that other institutions would follow the example, so that in a few years a competent bacteriologist might be found in all of the hospitals. There is no better place for the study of elephantiasis than St. John's; St. Vincent, for ankylostoma duodenalis, and St. Kitts for leprosy, and all of these islands for acute and chronic intestinal diseases.

*Martinique.*—This island, under French rule, was the principal objective point of my short midwinter vacation. It is the most picturesque of all the West Indies, and the most widely known since the last eruption of Mount Pelée, which completely destroyed St. Pierre and nearly one-third of the entire population of the island. This island was discovered by Columbus, June 15, 1502. He landed at Corbet, near the present ruins of the ill-fated city, St. Pierre.

*Fort de France* is the capital of Martinique and has at present a population of nearly 40,000. Very few of the original race, the Caribs, remain. Like all primitive peoples they have disappeared by the ravages of the diseases brought to their beautiful island by the invaders. They struggled long and fiercely for their rightful possession but finally had to yield to the inevitable. The negroes have increased to an alarming extent, and since the sugar industry has been waning the government is seriously taxed in taking care of the poor. The city is well drained and lighted and has excellent streets. The whites are few and by no means in a cheerful mood owing to financial reverses which have occurred in the past and which are in store for them in the future. Most of the houses show indications of decay and very few buildings are in process of erection. The hotels are primitive and the table still more so. Meat is poor and scarce. Fish is plentiful and in great variety, but cannot compare in quality with those of our northern waters. The negroes subsist largely on bread fruit, guavas, mangoes, cocoanuts, bananas, plantains and other cheap tropical fruits. A small military force occupies the garrison. The policemen are negroes under command of French officers. The prevailing language is French, which by the lower class of people has been changed into a patois unintelligible to the Parisian. The military hospital is an elegant red brick structure, well equipped, a credit to the military branch of the government.

*Hôpital Civil.*—This is the general hospital, open to the sick from the entire island. It is situated outside of the city limits on a mountain side several hundred feet above the level of the sea. It was built five years ago at great expense and has room for 250 patients. The ample grounds are artistically laid out and beautified in a way only possible in a tropical country. Pure water is supplied from mountain springs in abundance and all of the buildings are lighted by electricity. Seven two-story pavilions face the valley in a straight line, all of these connected by excellent sidewalks. The lower stories are made of solid stone walls, the upper of wood painted white. The red roofs of tiling furnish a pleasing contrast with the exquisite verdure of the mountain side behind and snowy whiteness of the walls beneath. The nursing is in charge of nine Sisters of Charity, which in itself would account satisfactorily for the scrupulous cleanliness inside and outside of the buildings. The operating-room is a separate frame building octagonal in shape. The instrument supply is a very limited one, which means that no unnecessary operations are performed. I found here again many cases of elephantiasis; the affected leg of one of the patients must have weighed at least 75 pounds. The enormous weight of the limb required much effort on the part of the patient when he attempted to walk. Dr. Bouvier is the medical director. He is assisted by a resident interne.

*The Ruins of St. Pierre.*—The former city of St. Pierre, now in ruins, is by the coast line 20 miles distant from Fort de France. Before its destruction by the volcanic eruption of Mount Pelée it was a thriving city of about 36,000 inhabitants. Mount Pelée is 4,500 feet high, and separated from the ruins by a low

mountain ridge and a small river. The destruction of the city was as sudden as it was complete. The terrible catastrophe occurred at 5.30 a. m., May 8, 1902. The eruption was in reality an explosion of the most terrible kind. Before the explosion the water from the little lake which occupied the basin of the extinct crater disappeared. It is claimed that the entrance of such a large volume of water into the subterranean furnace was the principal cause of the explosion; at any rate it is certain that the hydrogen gas which escaped when the explosion occurred filled the entire valley occupied by the city, ignited and destroyed everything living and ignitable within reach. The explosion tore open the mountain below the crater on the side of the city and the gas escaped with such tremendous force that the largest trees were uprooted and the most substantial buildings torn down. The positions of the prostrate trees and the torn down walls are everywhere the same—away from the mountain. The death of the people and the destruction of the city came with an awful suddenness. In less than five minutes the furious mountain had accomplished its deadly work. Not a house remains, and of the nearly 40,000 people only one was saved. What was formerly the rival of Fort de France is wiped out of existence. The recent ruins present today an awe-inspiring picture. Many of the houses are leveled to the ground. The stately churches are mere piles of brick and stone. The giants of the forests, charred and mangled, obstruct the vacant streets. All signs of animal life have disappeared. The ruins are really a great cemetery in which more than 30,000 bodies remain. More than 6,000 bodies have been found, and were either buried or cremated; the others are buried underneath the debris of the ruins and a layer of lava mud of varying thicknesses. It is said that no man is so wicked as to be entirely devoid of virtue. The same may be said of Mount Pelée. What she did in a rage of anger she did quickly. Probably not a single one of the victims suffered the pangs of death for more than five minutes. The deadly gases, the burning atmosphere and the force of the explosion killed almost instantly every living thing within reach. Then the volcano undertook the task of the undertaker by throwing out a rain of soft mud until most of the corpses were out of sight. The former city is now a deserted ruin. Not a soul lives there. At the time of our visit a number of negro women were picking up tiles along the beach. A few negroes were busy here and there with picks and spades in search for buried treasures and relics of the disaster. Bones and whole skeletons are being uncovered daily by the drenching rains washing away the thin layer of mud under which at first they were buried. Not a roof remains, and many of the narrow streets are completely obstructed by the debris of the ruins and the volcanic mud. St. Pierre will live in history, but will never be rebuilt on its present site. On the day of our visit the summit of Mount Pelée was wrapped in mourning, but through the dense veil of clouds ascending columns of steam could be seen, a warning that the volcano so far has refused to rest. The next day an explosion blew off the top of the mountain. The force of the explosion and the fire which destroyed the city extended far beyond the limits of the city. In the direction of the explosion not a single living tree could be seen. It was in the neighborhood of the destroyed city, near the limits of the sea of fire, that many people were injured and suffered from more or less extensive burns. Of these, 250 were sent to the Civil Hospital at Fort de France. I had an opportunity to examine a few of these patients that remained at the time of my visit, recovering slowly from the effects of burns.

*A Miraculous Escape.*—Only one of the inhabitants of St. Pierre escaped. He was a prisoner, and was not discovered in his prison cell until four days after the disaster. All the remaining prisoners were killed. The prisoner who found his freedom in such a miraculous way is a negro aged about 35. He has suddenly risen in distinction. He is now a successful beggar in Fort de France. I met him in a little cigar store and was successfully appealed to for a small contribution, in consideration of which he willingly exhibited large scars over the left shoulder and saine side of chest, following the healing of an extensive burn. Later he came on board the ship for exhibition and realized \$20, probably more money than he ever handled before.

*St. Vincent.*—This little island possession of England has come into notoriety by the volcanic eruption of its highest volcanic mountain (3,000 feet), La Soufrière, which became active at the same time with the distant Mount Pelée. Two thousand lives were lost and a whole village destroyed. Ashes were blown as far as Barbados, over 100 miles away. Kingstown is the capital city. It has 9,000 inhabitants, with few exceptions negroes. The botanical garden is one of the finest in the world. It was established in 1764, the first in the West Indies. The visitor will find here the greatest variety of palm trees, indigenous and from foreign tropical countries, cacao, cinnamon and nutmeg trees, and the pepper vine.

*Colonial Hospital.*—This is the principal hospital of the island and has room for 80 patients. The grounds upon which the hospital is built present a truly tropical appearance. The towering gigantic palms, flowering shrubs and ferns, make a most attractive foreground. Like all of the West Indian hospitals it is built on the barrack plan. The pavilions are two stories high, the lower of stone, the upper of wood. The upper story projects about eight feet beyond the lower. The furniture is of the plainest kind but answers all of the existing requirements. The wards are kept clean and in excellent order. An English trained nurse is the matron and supervises the work of the colored nurses. Dr. C. W. Brauch is the attending physician. He is a graduate of Edinburgh and is an earnest, enthusiastic and progressive man. He and another physician take care of all the sick in the city and surrounding country.

*Ankylostoma Duodenalis in St. Vincent.*—Uncinariasis (Ankylostomiasis) is very common in all the West Indies, but particularly so in St. Vincent. Dr. Brauch believes that at least one-third of the entire population is affected by this disease. The principal symptom is a gradually increasing anemia. Ultimately fatty degeneration of the liver invariably takes place. During the early stages of the parasitic invasion the disease is often overlooked. Careful examination of the stools must be relied upon in making a positive diagnosis. In one year Dr. Brauch treated 120 patients. His treatment consists in the administration of large doses of thymol. To an adult he never administers less than 8 grams (120 grains) of the drug divided in four equal parts, which are administered in capsules one hour apart, beginning early in the morning. In the evening following castor-oil is given in sufficiently large doses to produce free catharsis. The reputation of thymol in the treatment of this disease has been well established, not only here but in many other hospitals in the tropics. Sometimes the treatment has to be repeated. Toxic symptoms are not often observed, but should they appear speedy elimination of the thymol by early and free catharsis will soon relieve the unpleasant symptoms.

KINGSTOWN, ST. VINCENT, January 24, 1903.

[To be continued.]

*The Fashions in Invalids' Dinners.*—San Francisco, it appears, has a festively buoyant disposition and a vigorous Western hardness of physical sensibility which can bear up under all conditions. An appendicitis dinner, in which the board was decorated with a miniature equipped operating table, surgical instruments, hot water bags, and wax dolls, representing patient and surgeon, was given by a resident of that city, who had successfully passed through the operation, to 20 companions similarly fortunate. The usual floral embellishments served to soften an impression that might have been destructive of those feelings necessary to secure the enjoyment of a banquet, and there was no shadow of sudden indisposition, as might have been expected. The feast went on, hot water bags, surgical instruments, and all. This suggests an entirely novel form of social entertainment, which has never been exploited. Persons run down by trolley cars, who may have had the mumps, or the grippe, or escaped from the hands of a dentist, may find by that tie of misery that binds those in similar unfortunate circumstances a motive for festal reunion. There might be vaccination parties, rheumatism afternoons, neuralgia teas, influenza smokers, freckle seances, and progressive union euchres. A chiropodist reception, to be followed by a dinner dance, or a dyspepsia "small and early," with skim milk and pepsin tablets, served promptly on arrival. Conversation need never languish at these attractive functions, for people who are dumb on every other human topic can always talk about their physical infirmities with an astounding opulence of language.—[*St. Louis Globe-Democrat.*]

- 3.—See *American Medicine*, Vol. III, No. 24, p. 991.
- 4.—See *American Medicine*, Vol. III, No. 11, p. 418.
- 5.—See *American Medicine*, Vol. III, No. 25, p. 1059.

6.—**Otitic Brain Abscess.**—G. F. Keiper reports two cases, following Bashan's plan of describing the aphasia in one, with a brief review of the varieties of the latter, and its relation to ear disease. To prevent mastoiditis every case of otitis media should be carefully treated. In doubtful cases exploratory operation is justifiable. [H.M.]

7.—**Anesthetics in Nose, Throat, and Ear Operations.**—T. J. Gallaher recommends ether in prolonged operations, as mastoid, middle ear operations, etc., and nitrous oxide in those not requiring over a minute of anesthesia. He uses it frequently in tonsillotomy, incising the ear drum, and perforating the antrum. The most convenient and apparently as safe as any of the other anesthetics is bromid of ethyl. It should not be used in prolonged administration. From 1 to 4 drams is required, according to age, the whole quantity being thrown on an inhaler or towel and placed over mouth and nose, air being admitted only in threatening asphyxiation. This should not be confused with bromid of ethylene, which is highly poisonous. Gallaher operates with the pharynx on a lower level than the larynx, to prevent blood or severed growths entering the latter. When the upright position is necessary he prefers bromid of ethyl as the anesthetic, second choice being nitrous oxid. [H.M.]

8.—**The Giant Magnet in Ophthalmic Surgery.**—L. Connor reports two cases of foreign body in the vitreous, in each of which enucleation would have been imperative without the aid of the magnet. Experimental and clinical work show that at contact and up to 2 mm. the power of the small magnet equals or surpasses the giant, but from this to 10 mm. the power of the giant increases in almost geometric ratio. This demonstrates the need of the giant for splinters in the vitreous. The farther from the splinter the magnet can be used the more uniform, less jerky its action. Either the eye should be brought close to the magnet point and the current increased slowly or the eye should be brought up slowly from a considerable distance. The limitations of the giant magnet are exhibited when there is firm fixation in the posterior wall of the eye or in the ciliary body, or in a fibrinous exudate or when the splinter has healed over in the lapse of months. [H.M.]

9.—**Ergot.**—A. T. Livingston recommends ergot in the hyperemia of the brain found in insanity, especially in the melancholic class. He reports a case illustrating its use in vomiting and nervous excitement due to cerebral engorgement. Ergot acts on dilated vessels wherever they may be, producing general equilibrium of the circulation. It has ten thousand applications. It is not only the most effective agent in insomnia, but causes the most natural sleep. It is indicated in headaches, which are congestive in the majority of instances. Even an anemic headache might be benefited, as it might be due to hyperemic conditions elsewhere. He has found it beneficial in iritis, retinitis and optic atrophy, and suggests its use in glaucoma. He has had marked results in chronic deafness. He reports instances of relief from pain,

acute morphin poisoning, and appendicitis. He has used it with success in chronic morphinism and alcoholism; also in spasmodic conditions, such as asthma, puerperal eclampsia, hysteroepilepsy, and chorea. He has had brilliant results in bulbar paralysis, general paresis, etc. He has also repeatedly demonstrated its value in meningitis, pneumonia, peritonitis, erysipelas and other acute inflammations, and recommends it in typhoid, angina pectoris and other heart affections. He advises a course of ergot preliminary to operation. It prevents the objectionable sequels of anesthesia, such as vomiting, delirium, etc., and modifies shock and pain. He uses it altogether hypodermically, recommending Squibb's solid extract dissolved in a solution of formalin 1 to 3,000 and slowly injected. [H.M.]

2. Lipoma Arborescens. CHARLES F. PAINTER and WILLIAM G. ERVING.
3. Suppuration of the Frontal, Ethmoid and Sphenoid Sinuses: With Brief Report of the Treatment of 237 Cases. EDGAR M. HOLMES.

2.—**Lipoma Arborescens.**—C. F. Painter and W. G. Erving report seven cases. The presence of these fatty growths in the joints—most frequently the knee—has been usually attributed to tuberculosis and arthritis deformans. The authors believe these diseases are responsible for fewer cases than has been supposed. In none of the reported cases was a tuberculous process found. This is important from the standpoint of surgical treatment, for without the presence of tuberculosis the fatty bodies are only a mechanical impediment in the joint, and no erosion or resection is indicated. The clinical picture presented is that of a more or less swollen joint, without signs of acute inflammation and most commonly without excess of fluid. The patient complains of imperfect function, usually without pain. The joint sometimes "locks" in a partially flexed position, and can be straightened only after considerable effort. The lipomas vary greatly in size, reaching often that of a good-sized hen's egg. They are attached to the synovial membrane by a pedicle, usually slender, which on cross section is found to consist almost wholly of bloodvessels lying in a mass of small round cells. In consistency they vary from a soft, fatty to a tough, fibrous condition, both varieties often found in the same specimen, while the color varies from a yellowish-gray to a dark purplish-red. [A.B.C.]

2. Sigmoidproctectomy for Cancer of the Rectum. GEORGE W. ROBERTS.
3. A Case of Adenoids with Malaria. WALTER F. CHAPPELL.

1.—See *American Medicine*, Vol. III, No. 24, p. 997.

2.—**Sigmoidproctectomy for Cancer of the Rectum.**—G. W. Roberts insists that operations heretofore for cancer of the rectum or sigmoid have been bungling and imperfect. He advocates laparotomy, packing away the intestines, securing the sigmoid far above the growth and cutting the same between firmly clamping wires. To establish an artificial anus carry the proximal end of the divided gut through the abdominal wall internal to the left anterior superior spine, after the Sbanajew-Franke method of gastrostomy. Now grasp the distal end and dissect the same free deep into the true pelvis, carefully removing all the sacral and other contiguous glands. If a woman complete the operation by splitting the posterior vaginal wall and completing the dissection of the rectum and anus, together with related glands, and removing the same in toto. In the male the rectum is approached from behind, removing the coccyx if necessary, and the entire rectum and anus removed, special stress being laid on the thorough and complete removal of the sacral glands. Three cases are reported operated upon after this method, one patient dying. He considers the prevailing method of operating for rectal cancer analogous to the old-time imperfect operations for cancer of the breast. [A.B.C.]

**3.—Adenoids and Malaria.**—W. F. Chappell reports removing adenoid vegetations from the nosopharynx of a child of five months. General improvement was noted for ten days when fever and general constitutional disturbances were noted. The temperature oscillated between 100° F. and 105° F. for several days before a pyogenic infection was excluded. Malaria was suspected and a blood examination amply confirmed the suspicion, the plasmodia being found in abundance. Quinin bisulfate was administered and gradually increased to 1.3 gms. (20 grains) daily before the temperature finally showed that the malarial parasites were under control. The total amount of the drug given in 27 days was 16 gms. (241 grains). A careful history taken showed the first mosquito bite to have been 10 days before the first symptoms of malaria, thus fixing fairly accurately the incubation period of the parasite. Of 30 mosquitos obtained from the same locality three were of the malarial bearing variety. [A.B.C.]

1. Some of the Complications of Abdominal Surgery. ROBERT T. MORRIS.
2. The Diagnosis and Treatment of Hereditary Syphilis. E. HARRISON GRIFFIN.
3. Some Observations on Tuberculosis. J. O. COBB.
4. Report of a Case of Inguinal Hernia with Incomplete Sac. J. SHELTON HORSLEY.
5. Transportation and the Ophthalmic Referee. JUSTIN L. BARNES.

**1.—Complications of Abdominal Surgery.**—Robert T. Morris in discussing these complications says that the gastritis resulting from ether anesthesia may be modified by keeping a considerable amount of fluid in the stomach and that this result is best obtained by giving the patient small quantities of hot water at frequent intervals after an abdominal operation. If the vomiting is severe relief may be obtained by washing out the stomach freely with warm water. In the kidneys a preexisting nephritis is often excited to a point of exacerbation and primary nephritis may be caused by prolonged ether anesthesia. The prognosis of the after effects is not very different from the prognosis of a similar nephritis caused by cold. Some cases of nephritis caused by excretion of toxins from an acute infective process in the abdominal cavity will cease instantly in many cases after ether anesthesia, provided the focus of infection has been rendered inactive by the operation. Morris believes that iodoform is particularly dangerous when used in the peritoneal cavity because of the absorptive powers of the peritoneum. He says iodoform poisoning is commonly mistaken for septicemia. In iodoform poisoning the wound looks well while the patient does not and free iodine is found in the urine. In hemorrhage occurring after abdominal operations the prognosis is not so grave if the blood remains within the peritoneal cavity as when it escapes externally because it is still in circulation in a way owing to the action of the lymphatics. [C.A.O.]

**2.—Hereditary Syphilis.**—E. H. Griffin reports several cases of hereditary syphilis in which a wrong diagnosis had been made and in which recovery followed antisyphilitic treatment. In five of these cases the diagnosis of tuberculosis had been made. Griffin says the reason these cases are not diagnosed properly is that Hutchinson's teeth are looked for in every case, and if they are not found, hereditary syphilis is excluded. These teeth are only present in 10% or 15% of the cases; also that these diseases are very seldom touched on in a medical college; and the buccal cavity is not given the prominence it deserves in medical teaching. [C.A.O.]

**4.—Hernia with Incomplete Sac.**—Such a case is reported by J. S. Horsley in a man of 38 who had had a left inguinal hernia for more than 12 years that was incompletely controlled by a truss. Upon reaching the cord it was noticed that what appeared to be the sac was on the outer side exceedingly thick and was found to be a portion of the wall of the descending colon. A portion of this intestine without any omentum constituted the hernia. On the inner side it was almost normal to inspection and palpation. The explanation given is that the patient being stout, the parietal peritoneum was more loosely attached than it would be on a thinner individual. The lower part of the descending colon evidently burrowed under the

peritoneum at that portion of the gut where it is devoid of serous covering. Having thus formed a pocket, it continued to work its way down to the internal inguinal ring, dragging the peritoneum along with it, forming a sort of funnel. [C.A.O.]

**5.—Railway Ophthalmic Referees.**—In order to learn the methods of testing the sight, color-sense, and hearing of operating employes J. L. Barnes has been in active correspondence with 50 leading railway companies of the United States and Canada, submitting to them a form of questions. Of the 50 companies addressed, full replies were received from 32; and of these 21 stated that they retain a medical expert (ophthalmologist) for ensuring accurate examination of sight, color-sense, and hearing, while the remaining one-third confess that they do not make use of such advice, but either resort to examinations by officials of their own lay bodies or are "contemplating the idea of examinations." Most of the companies which do not retain a consulting medical expert referee are among the older and eastern companies. The author heartily indorses the recommendation adopted by the American Ophthalmologic Society on Standards and Methods of Examining the Acuteness of Vision, Color-sense and Hearing for Railway and Marine Service: "That a trained ophthalmic surgeon be selected by each company who shall instruct and examine the man selected by the company to make these tests, shall recommend the standards and methods to be used, shall see that the equipment furnished to such examiner is sufficient, that it is kept in proper order and renewed when necessary, and who shall be the authority to whom doubtful cases shall be referred for final adjustment." He demonstrates the importance of this recommendation by commenting upon the usual methods now in force, especially among those transporting lines which rely upon lay examinations and judgment. [C.A.O.]

#### Medical News.

March 21, 1903. [Vol. 82, No. 12.]

1. Some Types of Retinitis and Chorioretinitis. ALEXANDER DUANE.
2. The Indications for Operative Interference in Intracranial Tension. FREDERIC S. DENNIS.
3. A Preliminary Report on the Venous Hum in Relation to the State of the Blood. C. N. B. CAMAC.

5. Pneumonia: An Infectious Disease. J. O. COBB.
6. Observations on American Climates and Localities in the Treatment of Pulmonary Tuberculosis. JAMES K. CROOK.

**1.—Types of Retinitis and Choroiditis.**—A. Duane reports several cases of focal exudative chorioretinitis. These are distinguished by their acute onset, rapid course, and on the whole favorable prognosis. They occur especially in young people, and often without assignable cause. They are marked by the presence of a single circumscribed exudate, situated usually not far from the optic disc, forming a whitish mass, which may be either prominent and pointed or low and flattened, and which is often associated with considerable edema and milkiness of the surrounding retina, but not often with much engorgement of the papillary vessels or much swelling of the nerve. Impairment of vision depends on the site. Scotoma frequently remains. The salicylates, calomel, and rest in bed seem the best treatment. [H.M.]

**2.—Operative Interference in Intracranial Tension.**—Frederic S. Dennis, after an exhaustive and somewhat technical discussion, concludes substantially as follows: Cases of intracranial tension can be divided into two classes as regards operative interference. The first includes those in which intracranial tension is sufficient to produce profound coma. The second includes those in which the intracranial tension is not sufficient to produce profound coma. Operation will save cases included in the first class that uniformly died under the expectant plan of treatment. Operation will save cases embraced in the second class when the symptoms are gradually increased in severity. In those cases included in the second class in which coma is not present, the problem is difficult of solution. The author has been guided as to the operation by the condition of the patient from hour to hour and from day to day. If the arterial pressure rises to a point and remains stationary, and the vasomotor system does not fail, even with a well pronounced vagi disturbance, no operative procedure was practised, and

recovery has taken place. In addition to the symptom of increase of arterial pressure the blood count must be studied, the eye grounds examined, the urine tested, the reflexes studied, the disturbances of the cranial nerves noted, and all other phenomena investigated. If the pressure is not daily increasing and the leukocytosis not rising, the red blood cells not increasing, and the urine not becoming glycosuric, the hebétude not emerging into coma, and the cephalalgia not increasing, delay in operative interference is indicated. Otherwise operation is indicated. [A.B.C.]

**3.—Venous Hum in Relation to the State of the Blood.**—C. N. B. Camac has observed the occurrence of a cervical bruit in persons with normal blood. Anemia may exist without this bruit—33% to 50%; it occurs in some anemias and not in others, and is more frequent in chlorosis than other forms. The most probable cause of the hum is variation in the caliber of the bloodvessels, the tone of the vessels entering into the causation. The practical point to clinicians is that cervical bruit and pallor may not indicate anemia, that the blood should be examined to determine this point. If the vascular tone is faulty cardiovascular stimulants and not iron are indicated. [H.M.]

**5.—Pneumonia: An Infectious Disease.**—J. O. Cobb considers the greater prevalence of pneumonia and influenza in cold weather to be due to the greater dosage of contagium, due to the overcrowding and overheating in theaters, cars, and other stuffy places, where the heat is great enough to desiccate the germs planted there by coughing and spitting. In sparsely settled places there is little pneumonia. The deathrate is appalling, and yet nothing is done to check the spitting habit, which seems to be the only cause of its spread. [H.M.]

**6.**—See *American Medicine*, Vol. V, No. 7, p. 248.

**Philadelphia Medical Journal.**

March 21, 1903. [Vol. XI, No. 12.]

1. Cryoscopy. D. S. GRIM.
2. Trunccek's Serum, and Its Value in Disturbed Cerebral Functions Caused by Circulatory Changes, With Report of 12 Cases. ALFRED GORDON.
3. The Operative Treatment of Goiter. INGERSOLL OLMSTED.
4. Psychopathic Epidemics. JOHN B. HUBER.
5. A Case of Diabetes Mellitus in a Young Child. JAMES HENDRIE LLOYD.

**1.—Cryoscopy.**—From the study of a large number of normal urines and over 400 determinations of pathologic urines, D. S. Grim concludes as follows: Cryoscopy cannot replace, but only supplement, the older qualitative tests and microscopic examination of urines; it is probably the most delicate test we possess in detecting and estimating the effect of therapeutic measures directed toward cardiac and renal lesions; it permits of reasonable accuracy in diagnosing renal insufficiency and the type of renal lesion present, though the examinations should be prolonged over a number of days, these conclusions coinciding with Lindemann's; uremia cannot be diagnosed from the examination of the urine alone; cryoscopy of the urine from each kidney, obtained by ureteral catheterization, and especially when supplemented by the phloridzin and methylene-blue tests, becomes very delicate and reliable in determining a unilateral kidney lesion and the degree of insufficiency of the affected kidney. [F.C.H.]

**2.—Trunccek's Serum.**—A. Gordon gives the results he obtained from the employment of Trunccek's serum in 12 cases and its value in disturbed cerebral functions caused by circulatory changes. Of the 12 cases reported 3 gave negative results and among the 9 successful ones some gave only slight and some considerable improvement. The combination of the inorganic salts known under the name of Trunccek's serum may be a valuable remedy in some cases of disturbed cerebral function caused by circulatory changes; this remedy may give favorable results not only by hypodermic and intravenous administration, but also internally; when the iodids, nitrites, and other means used in such cases are without avail Trunccek's serum should be given a trial, sometimes a combination of both may be necessary; at least a week must elapse before the desirable results can be expected. [F.C.H.]

**3.**—See *American Medicine*, Vol. IV, No. 15, p. 567.

**5.—Diabetes Mellitus in a Young Child.**—J. H. Lloyd considers that diabetes mellitus in young children is sufficiently rare to justify the report of an individual case. The special features to be noted in such cases are the obscurity of the symptoms and the possible action of such a cause as trauma, shock or heredity. The one symptom to attract the attention of the mother or nurse is usually the excessive thirst, a thirst which is urgent and often shown in very characteristic ways. The case detailed is that of a white male 26 months old. The specific gravity of the urine was 1,040 and reacted strongly to Fehling's test. The child failed rapidly and died in coma about three weeks after the mother first noticed he was ill. It had been subjected to a surgical operation and had been under ether for nearly an hour about 10 days previous to the onset of the symptoms. Thirty-six cases are quoted from literature of undoubted cases of diabetes mellitus in children under 3 and 6 cases of alimentary glycosuria in children under 3, formerly classified under diabetes mellitus. The essential cause is just as obscure as in cases of adults. [F.C.H.]

**CLINICAL MEDICINE**

DAVID RIESMAN

A. O. J. KELLY

**REVIEW OF LITERATURE**

**Lumbar Puncture and its Value in Cases of Meningitis.**—Warrington<sup>1</sup> considers at length the technic of lumbar puncture, the characteristics of cerebrospinal fluid, and the following points as determining its abnormal states: (1) Cryoscopy; (2) altered permeability of the meninges; (3) abnormal organic constituents; (4) microorganisms; (5) cytology. Abstracts of three illustrative cases are appended. In Case I, a child of 8 months, the fluid was cloudy and contained flakes of lymph and a considerable number of multinuclear cells, but was sterile. At repeated punctures the fluid became clearer, and multinuclear cells were replaced by lymphocytes. Temporary improvement followed each puncture and recovery ensued. Puncture in Case II, a child of 16 months, gave a turbid fluid with masses of pus. Multinuclear cells predominated and *Diplococcus intracellularis* was present. Autopsy 10 days later revealed purulent meningitis. In Case III, a child of 8 months, the fluid was turbid, contained multinuclear cells and *Staphylococcus albus*. Autopsy revealed purulent meningitis. [A.G.E.]

**Acute Circumscribed Edema.**—Mendel<sup>2</sup> reports a case which occurred in a girl of 18. The disease had been present in her family for four generations, and had affected 12 of her relatives, of whom six died. Since early childhood she had suffered from many attacks, the area affected being in different parts of her body, including the eyes and mucous membranes. The edema develops in the course of a few hours, remains an hour or a week and then disappears rapidly with no after effects. It may be brought on by trauma, or it may occur without any known cause. This condition is not influenced by excitement, food, menses, or the seasons. Aspirin was administered, and the swelling which involved her forearm from the finger tips to the elbow, disappeared, the girl remaining well until the drug was stopped, when her trouble returned. Mendel considers this disease a form of gastrointestinal infection and not a neurosis. [W.E.R.]

**Primary Tuberculosis of the Spleen Followed by Vegetative Endocarditis.**—Ferrand and Rathery<sup>3</sup> report this case, which they believe to be the first recorded case of tuberculous endocarditis without pulmonary lesions of the same nature. The tubercle bacillus was found in the endocardial growth and also in the blood clots from the heart. The spleen was the only organ involved, the lungs being absolutely sound. The case is regarded as one of tuberculous septicemia. [A.G.E.]

**Enuresis Nocturna and Adenoids.**—O. W. Cautorovitch<sup>4</sup> reports a case of enuresis nocturna in a boy 12 years old. Since the age of 6 the boy regularly wetted his bed in spite of all treatment. His parents were well; he was normally developed, and the genital organs presented nothing to account for the

<sup>1</sup> Pediatrics, February, 1903.

<sup>2</sup> Berliner klinische Wochenschrift, December 1, 1902.

<sup>3</sup> La Médecine Moderne, February 18, 1903.

<sup>4</sup> Practisches Vratch, October 5, 1902.

incontinence. The sole possible cause was found in the presence of extensive adenoid growths in the nasopharynx. Accordingly these were removed and since the operation the boy does not wet his bed. [L.J.]

**Purpura Hæmorrhagica.**—Two cases, one terminating in recovery, are reported by R. L. Wadhams and W. B. Foss.<sup>1</sup> The first was a man of 24, in whom the prominent symptom was epistaxis, accompanied by a hemorrhagic eruption. Death occurred on the eighteenth day. The second was a girl of 5, who also had severe epistaxis with cutaneous and mucous extravasations of blood. Two attacks occurred, one in September and one in March, with recovery following each. As treatment ergot was given in large doses. [A.G.E.]

**Gastric Digestion in Icteric Conditions.**—S. S. Zimnitski<sup>2</sup> has made a thorough clinical and experimental study of the influence exercised by retention of bile in the system upon the secretions of the stomach. The gastric contents were analyzed in cases of catarrhal jaundice, Weil's disease, Hanot's hypertrophic cirrhosis, and obstructive icterus due to a pancreatic tumor. In all these instances the temperature remained normal, thus simplifying conclusions. The state of gastric secretion in catarrhal icterus was studied with especial thoroughness, as jaundice in this affection develops gradually, reaches a maximum of intensity and then gradually subsides, thus affording an excellent opportunity for observing the phenomena of systemic intoxication in their rise and fall. Whenever jaundice was not complicated with distinct gastric catarrh a condition of high hyperacidity was noted in the stomach contents after a test-breakfast. The hyperacidity was demonstrably due to hypersecretion and experiments on dogs confirmed these clinical observations. In harmony with Parlor's elegant and important researches the author attempts to explain these alterations by postulating a diseased or asthenic state of the secretory cells, due to poisoning with biliary products. Incidentally some interesting facts were noted: The wellknown preference shown by icteric patients, human and animal, for carbohydrates and their aversion to meats and fats could be accounted for by the influence of the latter upon digestion; it was found, namely, that albuminous food retarded the passage of gastric contents into the intestine and produced certain irritative phenomena, like vomiting, diarrhea, etc., while carbohydrates did not alter the secretions and the motor activity. The diet usually prescribed in icterus (milk and carbohydrates) was very well tolerated, thus showing a complete harmony of empirical and experimental data. These results, obtained from a study of acute jaundice, apply with equal force to chronic icteric conditions as seen in hypertrophic hepatic cirrhosis, etc. A gradual transition from gastric hypersecretion to hyposecretion has been noted in protracted jaundice and is due to the same cellular asthenia in its varying grades and stages. When gastric acidity is thus seen to fall the peptic power of the stomach remains unabated, justifying the conclusion that the pepsin-producing activity has a greater stability than the secretion of hydrochloric acid. [L.J.]

**Reaction to Mercury Observed in Syphilis.**—Herxheimer and Krause<sup>3</sup> have observed a peculiar reaction in syphilitic patients which they consider of considerable value from a diagnostic and prognostic standpoint. It occurs only after the first absorption of the mercury; 15 to 24 hours after the first inunction with mercurial ointment (5j) or injection of salicylate of mercury or calomel, the existing eruption changes. The ordinary syphilitic exanthem increases in intensity, the number of lesions increase, and their character changes to an urticarial hive. Many of the papules run together; fever manifests itself in some cases, and occasionally symptoms of general intoxication are observed. There are no subjective symptoms. This violent character disappears within 48 hours, and it is claimed by the authors that the more intense the change the better the prognosis. This reaction is not noticed when mercury is given internally, or after the initial treatments. The reaction was studied by them histologically. They advise the use of this reactive test in doubtful cases of macular eruptions. [E.L.]

## GENERAL SURGERY

MARTIN B. TINKER  
A. B. CRAIG  
C. A. ORR

### REVIEW OF LITERATURE

**An Atypical Case of Cancer of the Stomach.**—Lerch<sup>1</sup> reports a case of gastric cancer masked by hepatic cirrhosis. The patient was a man of 49, a heavy drinker, who also used tobacco in excessive amounts. For four years he had had severe stomach trouble, aggravation of which caused his appearance at the hospital. Vomiting became more frequent and after three weeks rectal feeding had to be substituted. The patient's appetite remained good, his tongue was clean, and no disgust for meat was present. The face presented the venous hue that marks the alcoholic skin, the body was white. A tumor as large as a child's fist, replacing the whole left lobe of the liver, could be detected moving upward and downward with respiration. The abdominal veins were distended. The stomach contents showed traces of hydrochloric, and absence of lactic acid. The diagnosis of gastritis due to liver cirrhosis with entirely cirrhotic tumefied left lobe and contracted kidney was made. The patient died four weeks after admission, and autopsy confirmed the diagnosis in every particular, but revealed also a carcinoma of recent growth almost filling the pyloric orifice. After a detailed review of the symptoms, Lerch states that the case has to be classed with those of latent cancer of the stomach. The tumor was one of rapid growth, originating presumably not more than five weeks before the patient's death. [A.G.E.]

**Surgical Treatment of Exophthalmic Goiter: Cocainization of the Superficial Cervical Nerve.**—Huntington<sup>2</sup> reports four cases in which he has operated for exophthalmic goiter by excision of the thyroid gland, with recovery or improvement in all cases. To obtain anesthesia in these cases he used direct injection of cocain solution into the superficial cervical nerve. He devotes some space to a description of the anatomy of this nerve, and advises exposure by incision along the posterior border of the sternomastoid muscle at about the level of the thyroid cartilage. The area of anesthesia obtained by injection of this nerve is triangular, with its apex at the point of injection of the cocain solution, and its base at the median line. The base of the triangle should extend from the suprasternal notch to the lower border of the jaw. Experience has shown, however, that the boundaries of anesthesia are variable because of the overlapping areas supplied by adjacent cutaneous nerves. He finds this method of anesthesia of great value in these cases. [M.B.T.]

**Mercurial Treatment of the Grave Complications of Syphilis.**—Leredde<sup>3</sup> advocates the administration of mercury by injection as the only means we have of insuring to the patient a definite quantity since the therapeutic effect depends on the amount. In visceral lesions quick results are of the gravest importance. In spinal and cerebral lesions it may be a question of hours, and these, like certain cutaneous manifestations, resist inadequate doses. Stomatitis depends on the state of the mucous membrane. Persons with teeth and gums in good condition tolerate a very large dose, therefore hygiene of the mouth is indispensable. Tabes, general paralysis, and other parasyphilitic affections are amenable to mercury if given soon enough and in sufficient doses. [H.M.]

**Appendicitis.**—Gilbert Darling,<sup>4</sup> in summing up the considerations which determine the necessity for operation says we should be guided always by the severity of the symptoms present, and ignore the absence of symptoms usually present. If the patient has a rigid abdomen, with a pulse of 120, much stress should be laid on these two facts and the absence of other symptoms ignored, though if the pulse be moderately quick and the temperature not high, yet there is persistent vomiting, the indications point strongly to operative interference. He denominates it as "safe abscess" the condition in which pus has formed in the neighborhood of the appendix and has become circumscribed by adhesions, the abscess wall becoming

<sup>3</sup> Deutsche medicinische Wochenschrift, December 11, 1902.

adherent to the abdominal wall. In such case incision and drainage are indicated. The adhesions should not be broken up in an attempt to find the appendix, though if this organ can be found in the abscess cavity without violence, it should, of course be removed. Should the abscess not be adherent to the anterior abdominal wall, it should be packed about with gauze, opened and evacuated. Again, adhesion should not be broken up in attempt to find the appendix. Recurrence, even in such cases when the appendix is not removed, is uncommon. If no abscess has formed, and we find a diseased condition in the abdominal cavity—seropurulent fluid or thick pus lying among the intestines and omentum—it must not be inferred that there is a general peritonitis. In a considerable number of cases the pus, though not bounded by such adhesions as would warrant the term "abscess" is yet not distributed all over the abdomen. In this condition, as in the case of widespread peritonitis, a second incision in the middle line of the abdomen for irrigation may be necessary. [A.B.C.]

**Gaseous Subphrenic Abscess Due to Perforated Gastric Ulcer.**—Macaigne and Souligoux<sup>1</sup> report two cases. The one, in a woman of 46, was on the right side between the liver and diaphragm. No operation was performed and the woman died. The communication with the stomach was patulous and the passage of pus through it gave rise to an intractable diarrhea. The second case was in a man of 50, and operation was followed by recovery. The opening from the stomach was not found but the abscess contained a number of raisin seeds. [A.G.E.]

**Volvulus of Cecum.**—Fripp<sup>2</sup> reports the case. The patient was a spinster of 52, of an exceedingly nervous temperament. She had suffered from constipation since childhood. For a month previous to the attack she had suffered from marked indigestion and constipation. She complained at the beginning of the attack of discomfort in the lower part of the abdomen, more particularly in the right iliac fossa. There was some nausea, some tenderness in the right iliac region, temperature subnormal, pulse 68, tongue furred. This condition persisted for several days, and operation was deemed advisable. This revealed a volvulus of the cecum, involving the appendix and also part of the ileum. The patient made a good recovery. [A.B.C.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Etiology of Uterine Rupture.**—H. Futh<sup>3</sup> gives the history of a primipara, aged 24, brought into the hospital after three days of labor, in spite of which the head had not yet entered the pelvis, the passage thereto being obstructed by a dermoid cyst of the left ovary. The child was delivered by cesarean section in the middle of the anterior uterine wall; the edges of the incision were accurately approximated and sutured. The tumor was removed and the omentum drawn over the uterine wound and fastened at the lower angle. The patient recovered and at her second labor was again brought to the hospital and another laparotomy performed on account of uterine rupture. Supravaginal amputation was performed and the peritoneum drained through the vagina with recovery of the patient. Examination of the uterus showed that the rupture was in the line of the previous cesarean section. Futh does not accept the theory of some that there had been a tubouterine pregnancy with this place as the placental site. He believes that the healing of the muscular wall after the cesarean section was incomplete, and that in the changes undergone by the puerperal uterus there was a disarrangement of the cicatricial tissue and consequent weakening, resulting in rupture, although there seemed to be no abnormal resistance to delivery. [w.k.]

**Secondary Abdominal Pregnancy.**—K. Kamann<sup>4</sup> states that in the necropsy on a rabbit a complete fetal sac was found

in the abdominal cavity containing a full-term fetus which had recently died. The sac was attached to a very vascular portion of the great omentum, which had been drawn out in the form of a pedicle. The placenta was situated on the wall of the sac opposite its point of attachment to the omentum, which was the only means of connection between the fetal sac and the mother. The internal genital organs lay at some distance from the sac, and appeared to be free from any marked changes. At first he considered it a case of primary abdominal pregnancy, but examination of the uterus showed a recent cicatrix in the uterine wall which proved conclusively that the fetus had developed primarily in the uterus and had escaped into the abdomen through a tear in the uterine wall, and its secondary attachment took place during the course of a gradual protracted rupture of the uterus, so that the fetal sac, becoming adherent to the omentum, received its blood supply from it before being completely expelled from the uterus. [w.k.]

**Pelvic Tumors Complicating Parturition.**—H. Schwarz<sup>1</sup> details two cases. The first was that of a woman of 34, pregnant for the second time. Vaginal examination during the first stage of labor showed that the upper part and posterior two-thirds of the lesser pelvis was filled by a smooth tumor partially divided into two portions. While preparations were being made to puncture the tumor through the posterior vaginal wall and follow this by cesarean section if necessary, the fetal heart sounds ceased and craniotomy was performed. The patient died two weeks later. Autopsy showed a large, vascular, myxomatous fibroid that originated between the layers of the left broad ligament. The second case was somewhat similar, the tumor being discovered three months before term. A few days before full term the tumor was punctured, colloid material being obtained. Cesarean section was then performed, and the tumor, a large colloid of the left ovary, removed. Mother and child are both living and healthy. [A.G.E.]

**Obturator Hernia of Left Tube and Ovary.**—To the four cases of obturator hernia of the ovary previously known, Franz Schopf<sup>2</sup> adds the fifth. These furnish many differences. In one case the uterus was included; in two cases the ovary and tube alone, and in the others the ovary and the intestines. In the case described by Schopf the left tube and ovary had passed through the left obturator canal, and the intestines were injured by pressure. Operation was performed to relieve the condition but the patient died the next day. After section the diagnosis was "acute paralysis of intestines from internal incarceration in obturator hernia." The writer states that in 20 years in a Vienna hospital there were 393 cases of strangulated hernia, three of which were obturator hernia. He gives many other statistics showing the rarity of this condition, and states that most of these cases were not diagnosed but were learned at the autopsy or when laparotomy was performed for intestinal obstruction. He shows also the frequent fatal results of operation but thinks that with improved technic and earlier diagnosis and operation better results will be obtained. [w.k.]

**Attachment of the Ovum to Atypical Places.**—F. Hitschmann and O. Lindenthal<sup>3</sup> review the theories of many authors and the observations made upon animals in order to ascertain the normal place of implantation, and the modifying circumstances which cause abnormal attachment of the impregnated ovum. A known development of the impregnated ovum, requiring a definite time, must take place before it reaches the stage of attachment. Under normal conditions the ovum will find itself within the upper segment of the uterus when this stage of development is reached. But if impregnation occurs at an earlier period in the journey of the ovum, or the impregnated ovum meets with unusual hindrances to its passage, the time of attachment will be reached before the normal place of implantation, and then the ovum will attach itself to the lower uterine segment as in placenta prævia, or at a still earlier period in its journey to some portion of the tube as in ectopic gestation. The normal place of impregnation is not yet certainly determined, neither are the circumstances that control the movements of the impregnated ovum fully known, hence the causes of tubal gestation are still obscure. [w.k.]

## TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR. L. F. APPELMAN

## REVIEW OF LITERATURE

**Methylene-blue in Tuberculosis.**—Herbert<sup>1</sup> reports the results of the employment of medicinal methylene-blue in 15 cases of tuberculosis. He found that it impeded the expectoration and sometimes caused a choking sensation. It reduced in purulent-mucoid sputum, the proportion of mucoid substance making the quantity of sputum smaller and the number of bacilli increased. He did not note, however, any change in the lesion of the lungs, nor any influence upon the temperature. It is useful only for the purpose, therefore, of relieving cough and reducing expectoration when the latter is too profuse. [H.C.W.]

**The Use of the X-ray in Dermatology.**—Schiff<sup>2</sup> employs the Röntgen rays as the treatment of choice in favus, sycosis and all parasitic diseases of the hairy portions of the body. Care must be taken that the applications are not continued too long; it is better to give them frequently for short periods, usually not over 10 minutes, using a current of 2 amperes. The tube should be held 15 or 20 centimeters from the diseased area. The healthy skin should be protected by lead foil. [L.F.A.]

**The Influence of Some Modern Drugs on Metabolism in Gout.**—Bain,<sup>3</sup> summarizing the results of certain investigations, states (1) there was an increase in albumin in the urine with the development of a subacute attack of gout; (2) a preponderance of serum globulin over serum albumin was observed; (3) there was present in the blood the peculiar leukocytes described by Chalmers Watson (myelocyte-like cells); (4) lithium benzoate and urotropin were ineffective as regards uric acid excretion; (5) piperidin tartrate, piperazin, lysidin, and sidonal in the order named, showed an increasingly augmenting effect on the uric acid excretion; (6) the excretion of uric acid was diminished during the administration of colchisal and the conjugated sulfates increased; and (7) the solvent action of tetra-ethyl-ammonium hydrate on sodium biurate probably depends upon its alkalinity. [A.O.J.K.]

**Methylatropinbromid.**—Methylatropinbromid is a new preparation of atropin concerning which Vaubel<sup>4</sup> reports that it acts very much more promptly and less permanently than atropin. Maximal mydriasis occurs within five minutes after the instillation of two drops of a 1% solution into the conjunctival sac, and disappears within six hours. It has very much less effect upon the pulse-rate than atropin and very large quantities are needed to cause the cerebral intoxication characteristic of this group of drugs. Although Vaubel asserts that it acts less actively upon the glandular secretions than atropin, he recommends the drug for the suppression of the night sweats of tuberculosis, believing it to be especially advantageous because it is free from the unpleasant secondary effects of atropin, especially great dryness of the mouth. [H.C.W.]

**Lactic Acid in the Treatment of Dysentery.**—According to the experience of J. D. Hunter,<sup>5</sup> of Arequipa, Peru, lactic acid, which has been employed in cases of infantile diarrhea, gives equally good results in cases of acute or subacute dysentery, where stools are green and viscid. In such cases the lactic acid is prescribed in doses of 15 drops repeated every two hours, preferably in solutions with syrup or gum. [C.S.D.]

**Hydrogen Dioxid Water as an Epilatory.**—Gallois<sup>6</sup> has found the application of hydrogen dioxid one of the simplest and most inoffensive means of removing superfluous hairs. He recommends that the part be touched with a pledget of cotton moistened with the hydrogen dioxid; it should be left in place for several minutes. This application should be repeated daily until the desired result is obtained. Under this treatment the hairs grow paler and finally become absolutely colorless. If the applications are continued they atrophy and entirely disappear. [L.F.A.]

**Treatment of Tetanus by Baccelli's Method.**—Claude and Chauffard,<sup>1</sup> at a meeting of the Société Médicale des Hôpitaux for October 24, 1902, reported on cases of tetanus treated by intravenous injections of phenol. Their experience differs so greatly as to throw considerable doubt on the efficiency of this method of treatment. [C.S.D.]

**Potassium Permanganate in Opium Poisoning.**—Finkelstein<sup>2</sup> declares potassium permanganate to be a specific and unequalled antidote in acute poisoning with morphin and other opiates. Since its introduction in 1893 by Moor, of New York, this remedy has been repeatedly employed with life-saving success. In Russia Velamovitch has published a series of experiments which have demonstrated the direct chemical action of the permanganate on morphin and the opiates in the stomach and in the blood as well as in the test-tube. The doses are hypodermically 16 minims of a 4% solution every half to one hour until marked improvement follows; internally about 4 grains of the salt are requisite to neutralize 3 grains of morphia or 5 drams opium tincture. In the author's case, that of a young girl who had swallowed about 16 grains of morphin hydrochlorate and who 1½ hours later presented all symptoms of profound poisoning, two injections of a 4% solution of the permanganate (15 minims each) administered with an interval of one-half hour sufficed to restore the patient. [L.J.]

**The Internal Uses of Potassium Permanganate.**—A. Khoury<sup>3</sup> reports four patients with painful dysmenorrhea who were cured, and three patients with anemia greatly improved by the administration of potassium permanganate. It was given in doses of from 5 centigrams to 0.26 gram (½ to 4 grains) usually in pills, which have the advantage of not staining the mucous membrane of the mouth. In all cases this drug was well borne by the stomach. It caused no constipation or diarrhea; in only one case was the urine tinted a light pink. Menstruation does not counterindicate its use. [L.F.A.]

## PATHOLOGY.

J. EDWIN SWEET

## EDITORIAL COMMENT

**Antitoxic Serums.**—It is well known that one of the difficulties encountered in the production of an active immune serum against typhoid and related diseases has been the impossibility of obtaining a toxin of sufficient strength to incite a high degree of immunity. The search for a method of obtaining a powerful toxin has resulted in two interesting papers, one by Conradi,<sup>4</sup> "On Soluble Toxins of the Typhoid and Dysentery Bacilli Obtained by Aseptic Autolysis," and one by Neisser and Shiga,<sup>5</sup> "On Free Receptors of Typhoid and Dysentery Bacilli, and on Dysentery Toxin." Conradi believes that the inhibition of growth and final death of bacteria seen in older cultures is not due to an exhaustion of the culture medium, but to the accumulation of certain detrimental metabolic products of the bacteria themselves, which have been set free by a process of self-digestion—autolysis. He further believes that the toxins—products of the cell metabolism—can also be obtained by autolysis, but that this process must be of short duration in young cultures, else the further products of the cell life will destroy the toxin already formed. He therefore suspends in salt solution the mass of bacteria obtained from a young agar culture, places the suspension in the thermostat for 24 to 48 hours, centrifugalizes, filters through a porcelain filter, and finally evaporates in a vacuum to from one-tenth to one-fiftieth of the original suspension. Autolysis for a longer time gives poor results; the addition of antiseptics before the autolysis also depreciates the yield of toxin. With this method Conradi claims to have manufactured a toxin from dysentery cultures which will kill a rabbit in a

<sup>1</sup> Jour. of Tuberculosis, 1903, Vol. v, p. 32.<sup>2</sup> Journal des Praticiens, Vol. xvi, No. 46, 1902, p. 733.<sup>3</sup> British Medical Journal, 1903, viii, 243.<sup>4</sup> Therapeutische Monatshefte, xvii, January, 1903, p. 37.<sup>5</sup> La Semaine Médicale, November 19, 1902.<sup>6</sup> Le Mois Thérapeutique, Vol. III, No. 9, 1902, p. 105.<sup>1</sup> La Semaine Médicale, November 5, 1902.<sup>2</sup> Russki Vrach, January 4, 1903.<sup>3</sup> Journal des Praticiens, Vol. xvii, No. 5, 1903, p. 68.<sup>4</sup> Deutsche med. Wochenschrift, No. 2, 1903, p. 26.<sup>5</sup> Deutsche med. Wochenschrift, No. 4, 1903, p. 61.

dose of 0.1 cc., with characteristic lesions of dysentery as seen in man. A typhoid toxin was obtained which was fatal for guineapigs in doses of 0.2 cc. Neisser and Shiga, on the other hand, first killed their cultures by an exposure to 60° C., then placed the suspension of killed bacteria in the thermostat for two days, then filtered. The authors claim to have produced a toxin nearly as active as that of Conradi—this without concentration in the vacuum—and they describe very satisfactory immunization experiments. They explain the formation of toxin according to the principles of Ehrlich's theory—the receptors, *i. e.*, that atomic complex of the toxin which, acting upon the body cells, causes the production of the antibodies, are "split off" from the bodies of the dead bacteria at the temperature of the thermostat.

**Experimental Fat Necrosis.**—The fact that the escape of the normal pancreatic secretion into the peritoneal cavity is followed by a more or less widely disseminated fat necrosis had never been satisfactorily analyzed until Flexner<sup>1</sup> demonstrated that lipase, or steapsin, the fat-splitting ferment of the pancreas, is found in the necrotic foci, while it could not be demonstrated by his method in normal fat. The conclusion seemed warranted that lipase is at least one of the causative factors in fat necrosis. But later experiments of Kastle and Loevenhart<sup>2</sup> have shown that lipase can be demonstrated in all the tissues of the body in which there is any utilization or storage of fat. The question was therefore opened whether lipase has really anything to do with the causation of the necrotic process. Wells<sup>3</sup> contributes an able and very interesting paper designed to throw light upon this question. He finds that the ordinary commercial "pancreatins" are equally as active in producing necrosis as fresh extracts of the gland and has the advantage of containing fewer pathogenic bacteria than the extracts of the fresh gland prepared in the usual manner. By saturating bits of cotton with pancreatin and fastening them to different parts of the omentum and removing them at different intervals he was able to study the sequence of changes which enter into the complete picture of fat necrosis. The most important conclusions of the paper are those in regard to the nature of the causative factor. The necrotic action of the pancreatic products can be inhibited by heating to 55° C. and is completely destroyed by heating to a temperature above 71° C. The action is therefore due to a ferment. But the question of which ferment is left unsettled. Wells did not succeed in producing a necrosis with extracts of hog's liver or with cat's serum, both of which possess lipolytic power. Mixtures of lipolytic extracts with pancreatic trypsin were inactive; trypsin alone had likewise no effect. It is impossible to isolate the lipase of the pancreas, which may differ from the lipase of the other organs. Wells believes that the necrosis is primary and may be caused by some unknown ingredient of the pancreatic secretion, while the fat-splitting, due to the lipase, is secondary and is not the cause of the necrosis. Of secondary interest are the conclusions in regard to the dissemination of the process and the order of the changes produced. The route by which the dissemination is accomplished seems to be the lymphatic system. The necrosis progresses for but a few hours at any one point, the extension being apparently limited by leukocytes and by the connective tissue septa. Necrotic areas are absorbed by leukocytes and healing is by proliferation of connective tissue from the margin. The foci of necrosis become visible to the naked eye in from three to five hours and may disappear in eleven days, or may persist longer, depending upon their size. Fat necrosis by itself is not dangerous to the affected animal.

## REVIEW OF LITERATURE

**Old and New in Regard to the Pathology of Noma.**—V. Ranke<sup>1</sup> has collected 28 cases of ulcerative stomatitis from the literature, and adds one new case, in which the mycelium of a fungus has been demonstrated, and which is believed to be the etiologic factor. Perthes<sup>2</sup> places the fungus with the streptothrix group. It is an obligatory anerobe. No one has yet succeeded in inoculating animals with this organism, so that the pathogenicity of the organism cannot be considered as proved. [J.E.S.]

**True Hypertrophy of the Brain, with the Description of the Thymus and Adrenals.**—Anton<sup>3</sup> describes the brain, thymus, and adrenals from an epileptic of 23 years. Excepting the great size of the brain—2,055 grams (68½ ounces) in weight—there was nothing especially noteworthy in the condition found. The thymus was of unusual size for the age of the patient, a condition noted by many pathologists as occurring in cases of hypertrophy of the brain. The adrenals were noticeably atrophied and contained an abnormally large cavity. The case is of especial interest in connection with the work of Zander, who found that in a large majority of anencephalics, hemi-cephalics, and cyclops the adrenals were imperfectly developed. [J.E.S.]

**Local Tissue Changes After Injections of Hydrargyrum Salicylicum.**—Pezzoli<sup>4</sup> describes the changes caused in the muscle tissue by the injection of hydrargyrum salicylicum. The patient was a man who was murdered sixteen days after the last injection. The effects of these injections may be grouped under two heads: The mechanical effect, consisting in forcing apart the muscle fibers and in filling the lymph tracts with the injected mass; the result is a destruction of some fibers and the formation of small cysts filled with the mass. The second effect is a chemical one, the necrosis of more muscle fibers and the production of an inflammation with fibrinous exudate, infiltration, and granulation tissue. The microscopic picture is therefore that of waxy degeneration of the muscle fibres in the immediate neighborhood of the injection, inflammation, and small cysts surrounded by the giant cells, which characterize the absorption of a foreign body in the tissues. No such cavities as those described by Allgeyer, Jullien, and Audry were found—cavities with the characteristics of abscesses—and Pezzoli concludes that the paraffin suspension of hydrargyrum salicylicum has less irritative properties than calomel and is preferable to calomel for the intramuscular injections. [J.E.S.]

**Salolithiasis.**—Hanszel<sup>5</sup> describes three cases of calculi of the salivary glands or their ducts. Hanszel inclines to the view that the etiologic factor is to be found in some inflammatory process, followed by a prevention of the salivary flow and subsequent thickening of the secretion. The article concludes with an exhaustive discussion of the differential diagnosis. [J.E.S.]

**Osteoplastic Carcinoma.**—Comisso<sup>6</sup> gives in full the case history and microscopic description of a tumor, starting probably from the mucosa of the left nostril, eventually attacking the bones of the entire base of the skull. An operation was done, but the patient died from meningitis. The tumor, a carcinoma, was marked by the production of new bone tissue, such as is found in metastases of osseous carcinomata. [J.E.S.]

**Bacteriologic Diagnosis in Medicine.**—In connection with diphtheria, Woodhead<sup>7</sup> points out the difficulty of obtaining positive cultures in cases in which the lesion is laryngeal or tracheal, and also in very young children, owing to the difficulty in procuring a satisfactory "swab." In case of a first negative report, repeated attempts should be made. Thus in 6.7% of Woodhead's cases (12,172) the first examination was negative, but subsequent examinations demonstrated the presence of the microorganisms. "Mixed infections" with staphylococci give a greater mortality than those with the streptococcus, while in mixed infection of any kind the death rate is higher than in infections with the diphtheria bacillus alone. In the majority of cases the bacilli persist for from two to nine weeks,

<sup>3</sup> The Journal of Medical Research, Vol. 1x, No. 1, 1903.

a fact which emphasizes the importance of not discharging patients until bacteriologic examination reveals the continued absence of the bacilli.

**Leukocytosis in Pneumonia and Diphtheria.**—Paul Heim<sup>1</sup> states that pneumonia begins with a leukocytosis. Diminution of the leukocytosis indicates the appearance of the crisis. The eosinophiles disappear in the course of the pneumonia and reappear at the time of the crisis. These cells are of value in the differential diagnosis between croupous and bronchopneumonia. In diphtheria occurs a marked leukocytosis. The administration of the curative serum is accompanied by a diminution of the number of white cells. The eosinophiles diminish in number during the early course of the disease, but after the loosening of the membrane appear in great numbers.

**Leukocytosis in Scarlet Fever and Epidemic Parotitis.** Sacquippi<sup>2</sup> reports results of examinations in 14 cases. In the first week occurs a marked hyperleukocytosis, especially of the polymorphonuclear leukocytes, to a slight extent of mononuclear cells. The eosinophiles increase considerably after the first few days. In the second week the leukocytosis is moderate, the increase being especially of the mononuclear cells. During and after the third week the normal condition is approached, except that the number of eosinophiles still remains high. The persistence of increased number of the polymorphonuclear cells indicates a complication. Transitional forms in considerable number indicate a doubtful prognosis. The increase of eosinophiles, the writer thinks, may be of value in doubtful cases. In epidemic parotitis occurs a moderate hyperleukocytosis, the increase being chiefly one of mononuclear cells. Only when complicated by an orchitis is the increase of the polymorphonuclear cells prominent.

**The Pathology of Nerve Degeneration.**—To determine the nature of the chemistry of nerve degeneration, Mott<sup>3</sup> estimates the amount of phosphorus in the two halves of spinal cords in which unilateral degeneration had resulted from recent cerebral lesion. Less phosphorus was found in the degenerated side, which, according to the writer's interpretation, indicates that the Marchi reaction develops upon the splitting of the complex phosphoreted fat lecithin into simple bodies such as glycerophosphoric acid and stearic or oleic acid. The former escapes into the blood and the nonphosphoreted fatty substance left behind is blackened by the osmic acid. An increase of cholin in the blood and cerebrospinal fluid in many forms of acute degeneration of the nervous system, and in some chronic forms (beriberi, alcoholic neuritis, disseminated sclerosis, general paralysis). A definite relation was found between the presence of cholin in the blood and the degeneration in the nervous system as controlled by histologic method. Cholin hydrochlorid introduced in animals produces a fall in the blood-pressure. Cholin may, therefore, though a feeble poison when present in the blood in abundance, accelerate cardiac failure.

**Influence of Soil, Fabrics, and Flies in the Dissemination of the Typhoid Bacillus.**—Firth and Horrocks<sup>3</sup> reach the following conclusions: The bacillus shows no increase in numbers or tendency to grow in any direction when placed in soil. It may be washed through eighteen inches of closely packed soil in which no cracks or fissures exist. It assumes a vegetative existence and survives in ordinary and sewage polluted soil for varying periods, in some instances seventy days. The presence or absence of organic nutritive material in the soil appears to be of little importance. The organism can be recovered more readily from dry than from continually moistened sand, probably owing to the fact that in the latter it is washed into the deeper layers. In peat it cannot be recovered after the thirteenth day. In moderately rain dampened soil it can be recovered up to the sixty-seventh day, in dampened sewage up to the fifty-sixth. After heavy rainfall it at once disappears from the surface layers. It can readily be recovered from dried wind-blown sands, which indicates the possibility of the dissemination of dried infected enteric material by currents of wind. From infected fabrics (khaki serge and drill) the organism was

recovered after periods varying from 9 to 87 days. On surface soil it survives an exposure to 122 hours of direct sunshine extending over a period of 21 consecutive days, on clothing (serge) a period of 50 hours covering ten days. Ordinary house flies can convey infected material from excreta or other polluted material to objects on which they walk, rest, or feed. The infective material appears to be attached to their heads, wings, legs, and bodies. It has not been proved that the bacillus passes through the digestive tract of the fly.

**Eosinophilia and Verminous Parasitism in Man.**—Launois<sup>1</sup> communicates in his name and in that of Emile-Weil the observations made on a patient afflicted with *Tenia inermis*. The blood of this patient exhibited eosinophiles throughout the entire period of infection, but the symptoms disappeared after the expulsion of the parasite by means of suitable medication. This observation together with those made in other cases of helminthiasis leads to the opinion that eosinophilia is far from being a constant phenomena in verminous affections and that while its presence may be of real diagnostic value its absence should in no way set aside the possibility of the existence of parasitism. In this connection, the observations on the occurrence of eosinophilia in human filariosis made by Vaquez, Clerc, and Sicard, are of interest. The number of eosinophiles reach from 7.5% to 12% of the total number of leukocytes, and appears to be more accentuated at the moment of the appearance of the embryos in the blood and to diminish with their disappearance. [C.S.D.]

**Croupous Pneumonia and Sepsis, Due to the Pneumobacillus of Friedländer.**—Opposing the statements of Fraenkel and Prochaska, that pneumonia is always produced by the diplococcus, Philippi<sup>2</sup> reports a case in an elderly man from whose blood he cultivated Friedländer's pneumobacillus during life; the same organism was isolated after death from sections of the lung and bone marrow. Fraenkel's diplococcus was absent. [E.L.]

**Mycetoma with Black Granules.**—Mycetoma or madura foot may be divided into two varieties, one with pale, the other with black granules. Laveran<sup>3</sup> reports the case of a Soudanese of 22, afflicted with mycetoma of the black variety, affecting the left foot. The tumor was situated near the outer part of the plantar surface, and discharged pus mixed with typical granules from several openings. He refused amputation until one year later, but died three days after operation. A dissection of the foot showed two tumors. Pieces hardened in formalin; in one showed numerous black, mushroom-like granules; the other was not infected; stained sections showed it to be made up of dense layers of mycelial threads; no spores were seen. The mycetoma with black granules is therefore formed by a fungus, which attacks the tissues slowly; so soon as suppuration is established the mycelial threads infiltrating the tissues are dissolved and thrown off as black granules. According to Laveran the fungus is not an actinomyces, and it is a different variety of streptothrix than that causing the mycetoma with pale granules. He proposes the name of *Streptothrix mycetoma*. [E.L.]

**On a Case of Tumor of the Cauda Equina.**—Volhard<sup>4</sup> describes a case which is of peculiar interest as well for its rarity as for the accuracy of the diagnosis which would probably have led to the saving of the patient's life by operation had not uremia intervened and caused death before operative relief could be secured. Following the carefully elaborated scheme for the differential diagnosis of lesions of the lower spinal cord given by Müller in his "Untersuchungen über die Anatomie und Pathologie des untersten Rückenmarksabschnittes," a diagnosis was made of a benign neoplasm about the conus of the cauda equina. The autopsy confirmed the diagnosis and demonstrated a cystopyelonephritis of recent origin. There appears to be but one previously recorded case of correct diagnosis of similar lesion, namely, that by Laquer of Frankfurt, who in 1891 described a case of compression of the cauda equina by a benign tumor crowding the canalis sacralis. [C.S.D.]

**A New Method of Isolating the Tubercle Bacillus from Body Fluids.**—Under the term "inoscopy," A. Jousset<sup>1</sup> describes a method of isolating organisms from bodily fluids, based on the observation that if the liquid be coagulated most contained organisms are caught in the meshes of the clot. If the fluid to be examined is noncoagulable, such as urine, a clot is formed by the addition of a prepared blood serum. The blood of the horse is used, being diluted with an equal quantity of 10% salt solution, and then centrifuged. The supernatant serum is added to the liquid to be examined, and coagulation occurs. With a fluid that is spontaneously coagulable this procedure is not necessary. The clots are collected on a filter; washed with distilled water, and then digested at 38° C. with 10 cc. to 30 cc. of the following artificial gastric juice: Pepsin, 1 to 2 gm.; glycerin, 10 cc.; hydrochloric acid (22° Baumé), 10 cc.; sodium fluorid, 3 gm.; distilled water 1,000 cc. When digestion is completed, the liquid is centrifuged and the sediment is examined for microorganisms by the ordinary methods. This method is especially valuable for the demonstration of tubercle bacilli, but may be used to recover any suspected organism from the fluid. [B.K.]

**The Action of Acids and Acid Salts on Blood-corpuses and Other Cells.**—An elaborate article on the above subject is contributed by S. Peskind,<sup>2</sup> who details many experiments suggested by the observation, made while investigating laking agents, that small quantities of ferric chlorid or hydrochloric acid cause agglutination and precipitation of blood-corpuses. It was found that the acids producing this effect number at least 20. Corpuses thus acted upon lose their agglutination and precipitation if treated with saline solution. The reaction affects the leukocytes as well as the red cells. The uses of the reaction are: (1) To obtain large quantities of blood-corpuses; (2) to interrupt the action of all hemolytic agents that are not affected by the precipitants; (3) to determine at any given moment what percentage of corpuses has been laked by a hemolytic agent; (4) perhaps for determining the alkalinity of blood-serum. The reaction, which also occurs with spermatozoa, yeast cells, bacilli, and ciliated epithelium, is believed to be due to the combination of the acid with the nucleoproteid of the cell stroma. Further experiments have led Peskind to conclude that the existence of an envelope in mammalian blood-corpuses is highly probable if not absolutely certain. This envelope, to explain all the facts, must contain nucleoproteid, cholesterin, and lecithin. [A.G.E.]

**Thermotaxis of Leukocytes.**—M. E. Mendelssohn,<sup>3</sup> of Paris, finds that white blood-corpuses possess thermotactic properties, *i. e.*, within certain limits they are attracted by higher temperatures. This so-called positive thermotaxis may be observed at 68°–77° F.; it is more pronounced between 77°–95° F., and reaches a maximum at 96.8°–102.2° F.; the thermotactic optimum for leukocytes lies between 102.2°–103.1° F. No thermotactic movements could be detected above 104° F. The existence of negative thermotaxis, *i. e.*, motion toward lower temperatures, has not as yet been demonstrated conclusively for white corpuses. Positive thermotaxis must play a most significant part in various pathologic processes. We may surmise that leukocytes are attracted to the seat of inflammation by the combined forces of chemiotaxis and thermotaxis, in order to exert their phagocytic energies in defending the organism against invaders. New light is thrown by these experiments on the doctrine of fever. The author promises a larger work on the subject in the future. [L.J.]

**The Principal Accessory Factors in the Etiology of Cancer.**—R. de Bovis<sup>4</sup> supplements his recent review of cancer statistics by a further discussion of the available data bearing on the racial, geologic, orographic, meteorologic, social, professional and dietetic factors in the causation of malignant growths. He reviews the more important contributions of the last few years to the subject, and is led to conclude: 1. That southern races (Italians, negroes, Israelites) show less receptivity for cancer than northern races; of the latter, Germans and Scandinavians are perhaps the most receptive. 2. While

statistically there is no objection to Kolb's observations as to the greater prevalence of cancer in lands of tertiary formation, the geographic and geologic theories have failed to supply any key to the frequency of cancer. 3. Investigations as to the bearing of atmospheric temperatures, *i. e.*, cold climates, fail as yet to afford any positive indications. 4. There appears to be about equal receptivity for cancer among the rich and poor. 5. Taking age into consideration there is no evidence to show that any particular profession or calling gives greater liability to cancer. 6. Persons addicted to the abuse of alcohol are more liable to cancer than others. 7. Of all the etiologic factors, direct or collateral, heredity appears to be most important. 8. The age of maximum frequency of cancer appears to be, in round numbers, 70 years for men and 65 years for women. 9. Marriage does not create any predisposition to cancer, and contagion between husband and wife is more than doubtful. 10. While contagion of cancer is doubtful, inoculability is certain if not frequent. 11. Maternity predisposes to uterine cancer. 12. Celibacy predisposes to cancer of the breast. [C.S.D.]

**A Case of Calcified and Ossified Sebaceous Cyst.**—Joannovic<sup>1</sup> gives the histology of a case of sebaceous cyst of the back of the neck, the contents of which had calcified and in part ossified. It was removed from a 30-year-old woman; the mass is hard, its surface porous and sections are made with difficulty. Stained sections show it to be a cystic tumor, the capsule of which is made up of squamous epithelium. The desquamated cells are in a state of cornification and calcification, the calcareous particles lying in and between the cells. A large part of the original contents is replaced by young connective tissue containing giant cells growing in from the capsule. The giant cells seem to be absorbing the original cyst contents; but even this connective tissue is not stationary; at those points where the epithelium is removed it becomes changed first into a bony tissue without limesalts, later with limesalts. [E.L.]

**Effect of Spider Venom Upon the Urine.**—R. Kobert<sup>2</sup> finds from his own observations and those of Dèlio, Anguilar, and Frédéric Landolf on the examination of the urine in cases of patients suffering from the bite by poisonous spiders (*e. g.*, *Lathrodectus erebus*, *L. mactans*, *L. tredecimguttatus*) that these arachnids secrete a powerful hemolytic enzyme which causes the appearance of albumin, methemoglobin, oxyhemoglobin, urobilin and other hemolytic products in the urin of the patients. [C.S.D.]

**Cerebrospinal Meningitis.**—Guinon<sup>3</sup> reports a case of cerebrospinal meningitis which ended in recovery. The patient was a girl 11 years old, who was suddenly seized with violent headache, cyanosis of the face, opisthotonos, and feeble pulse. The diagnosis was confirmed by discovering a large number of lymphocytes in the cerebrospinal fluid. After the acute symptoms had subsided there remained for a few days a paralysis of the arms and legs. The treatment consisted of mercurial inunctions and the administration of potassium iodid in large doses. [J.H.W.R.]

**Cancer in Norway.**—Geirsvold<sup>4</sup> has studied the official statistics of Norway for 32 years (1865–97) to determine the occurrence and frequency of cancer. He includes under this heading sarcoma and carcinoma, and expresses the mortality in figures per 10,000 of the entire population. The mortality from cancer has steadily increased: In 1865 it amounted to 319 (1.9 per 10,000 of population, or 3.3% of all announced deaths); in 1897 there were 1,802 deaths (8.5 per 10,000, 7.5% of deaths). The total from carcinoma mortality during these years is 29,099, an average per year of 882. During these years the population increased only from 1,701,756 in 1865 to 2,110,400 in 1897. This shows a steady increase actually occurring, and while a number of factors have been urged to account for this, such as improvement in diagnosis, greater number of patients being treated by the physicians, larger number of postmortem examinations, etc., these factors are insufficient to alone account for the increase. The disease shows a predilection for certain portions of the country over others. More cancer cases are to be found and the percentage in increase has been greater in the

<sup>4</sup> Nord Med. Arkiv., Vol. xxxiv, Pt. 2, No. 11.

interior than along the seacoast. The large valleys report more cases than the mountains. In the cold zone the disease is said to be rare, but Norway possesses several marked cancer foci in its coldest districts; Hammerfest, its most northern city, presents the greatest mortality from the disease—13.47 per 10,000; the cities in general, however, are more affected than the country districts. As the cities having the hardest water suffer most, the author sees a possible connection between bad water, so common in Norway, and cancer. In certain localities some houses are known as cancer houses. Of the two sexes, the number of men affected is slightly greater than of women. The aged, those over 60, suffer mostly from the increase in the disease. Eighty per cent of the carcinoma fatalities affect the gastrointestinal tract, 13% the female genitalia. [E.L.]

**Virulence of the Cephalorachidian Fluid During the Course of Tuberculous Meningitis.**—Widal and Le Sourd,<sup>1</sup> in a communication to the Société de Biologie of Paris, July 26, 1902, report that inoculations of guineapigs with the cephalorachidian fluid collected during the life of 12 patients affected with tuberculous meningitis, caused in every instance, even when used in quantities of 1 cc., all the classic lesions of tuberculosis. The cephalorachidian liquid of phthisis not affected with tuberculous meningitis is nonvirulent. It is, therefore, suggested that before speaking of the cure of cases of tuberculous meningitis the actual existence of the disease should have been determined by the inoculation of rabbits with the cephalorachidian fluid. [C.S.D.]

**Primary Cancer of the Lung with Pearl Bodies.**—Lépine<sup>2</sup> reports to the Société des Sciences médicales de Lyon a very rare pathologic condition, namely, a primary cancer of the lung containing pearl bodies. The histologic form of the cancer was that of stratified pavement epithelium. This tumor is an apparent histologic paradox, but in reality it bears out the embryologic observations of Kolliker and others, that the lungs, like the esophagus, are of ectodermic origin. [B.K.]

**Bacillus Coli Communis.**—As a member of a committee appointed to report on the relation of the varieties of the colon bacillus to public health, V. A. Moore<sup>3</sup> reports investigations regarding the boundaries of the species of *B. coli communis* and the extent and cause of its varieties. He states that it has not been found in any substance where the possibility of tracing it to previous contamination with human or animal excrement was precluded. This at once brings up the question regarding the relation of numerous forms that have been isolated from extraneous materials and classed without challenge among the varieties of the colon group. Moore believes that too narrow limits are often fixed as the determination of the specific boundaries of the organism, and gives the points he thinks sufficient to determine the species under the headings of morphology, physiology, and pathogenesis. His studies suggest that, normally, there are not many well-established varieties in the digestive tract, and it seems rational to assume that many of the varieties described from abnormal habits of the species are in some way the results of environmental influence. Tables are appended to show the action of colon bacilli, isolated from various animals, on the sugars and milk. [A.G.E.]

**The Bacillus of Eberth in Pharyngeal Mucopus.**—Gallois<sup>4</sup> found the bacillus of Eberth in pharyngeal mucopus in two out of five cases of "rhinopharyngite typhoïdique." The method proposed by Chantemesse was used. This would seem to indicate that typhoid fever may be transmitted by inhalation, the infection localizing itself first in the throat and secondarily in the intestines. Objects contaminated by the mucus may be a source of promulgating the disease and should be disinfected. [J.H.W.B.]

**Basophilic Granules in the Red Blood-corpuscles.**—Schmidt<sup>5</sup> considers the basophilic granules in the red blood-corpuscles an expression of regeneration and not of destruction; he says that both these granules, as well as the so-called "polychromatophilic degeneration" of the red blood cells, are the products of a more or less complete caryolysis. To support this

view he reports a case of black water fever, in which the patient during the height of the disease had 1,600,000 red cells and 23% hemoglobin, megaloblasts, normoblasts, poikilocytes, polychromatic red cells, myelocytes, increased number of lymphocytes and polynuclear leukocytes, a few eosinophiles, but no erythrocytes with basophilic granules. As improvement became apparent megaloblasts and normoblasts disappeared, and basophilic corpuscles appeared. They increased in proportion with the number of red cells and the hemoglobin. Concerning malaria, his experience has been that red corpuscles containing basophilic granules always increase during convalescence. [E.L.]

**Adrenal Tumors.**—Woolley<sup>1</sup> gives a review of the literature of tumors of the adrenal body, and describes in full the following benign adrenal tumors: Fibromas, lipomas, neuromas, gliomas, hemorrhagic cysts, and angiomas, and the following primary malignant tumors: carcinomas, sarcomas, endotheliomas, and peritheliomas. The primary malignant tumors he prefers to call mesotheliomas or mesolepidomas (Adami). He describes also certain secondary malignant tumors, tabulates the cases of primary carcinomatoid adrenal tumors thus far reported, and gives a good bibliography. [A.O.J.K.]

**Bacillus of Epidemic Dysentery.**—In a paper read before the Academy of Medicine concerning this germ, Chantemesse<sup>2</sup> claims some of the honors arising from its discovery and description, as in 1888 he, in conjunction with Widal, had reported to the Academy a microorganism which they had isolated from the stools of individuals dying of acute dysentery. It was present in pure culture in the mesenteric glands of such individuals, but was never found in the stools of individuals who had never had dysentery. He objects to Shiga having the bacillus named for him, as his own work antedated Shiga's at least ten years. At the time, however, their discovery was roundly criticised, everyone believing they had described an ordinary colon bacillus, but since then, many others, in particular Kruse, Celli, Shiga, and Flexner, have reported the same organism as the cause of the disease. He accurately describes the bacillus from a morphologic and cultural standpoint, and mentions briefly the different epidemics in which the organism has been isolated. He lays special stress on the difference between it, the colon, and typhoid bacillus. He recognizes but two types of dysentery, the amebic and the bacillary; the former is chiefly sporadic and chronic, ending fatally either through liver abscess or by exhaustion. Occasionally an acute fatal case is met with, it occurs chiefly in adults, and is characterized by stools which contain blood, pus, mucus, and amebae. The blood of such patients does not agglutinate the dysentery bacillus. Bacillary dysentery is epidemic (occasionally sporadic), infections may kill quickly or become chronic, producing ulcers of the large intestine. The blood of such patients agglutinates the bacillus of dysentery after several days. The bacilli multiply in internal cavities, in the walls of the intestines, in the mesenteric glands, in the spleen, and other organs. Bacilli swallowed either accidentally or on purpose have produced the disease, and the organism has been found in the evacuations. [E.L.]

**On the Evolution of Nagana and Its Variability in Different Species of Animals.**—Lavaran<sup>3</sup> communicated to the Académie de Médecine, Paris, June 10, the results of experiments made by Mesnil and himself on nagana or tsétsé fly disease. The disease is easily inoculable and the duration of the period of incubation and of the malady itself varies according to the species of animal inoculated, appearing as an acute infection in mice, rats, dogs and monkeys, as subacute in rabbits, guineapigs, horses, asses and swine, being in these animals invariably mortal, and occurring as a chronic infection, capable of terminating in recovery, in cattle, sheep and goats. The rapidly mortal effects are accounted for by the mechanic obstruction of the small vessels of the brain or medulla in the latter part of the disease, due to the enormous number of trypanosomes in the blood, as seen in rats and mice. The parasites

are rare in many animals which die of nagana, as in the rabbit, which necessitates the admission that the trypanosomes produce a toxin determining fever, paresis, derangement of nutrition and finally death. [C.S.D.]

**The Value of the Elastin Stain for Histologic Diagnosis.**—Fisher<sup>1</sup> recommends Weigert's elastic fiber stain associated with a nuclear counterstain for all cases in which a tumor particle or similar tissue is to be examined microscopically. He cites a case in which the ordinary stains led to a diagnosis of simple lymphoma; the fibrin stain, however, showed the point where the cells had broken through the bloodvessel wall, thus establishing the diagnosis of malignancy; another case which without Weigert's stain would have been diagnosed as a mass of vesical debris, with it was found to be a necrotic piece of tumor from the bladder. [E.L.]

**Hemolytic Action of Saponin.**—Saponin is a plant alkaloid, which when injected into the blood produces lysis of red blood cells, hemorrhagic enteritis, subserous extravasations, and death through collapse. The hemolytic properties were tested by Schanzbach,<sup>2</sup> whose results agreed in the main with those of Ransom: 2 mgr. are sufficient to dissolve the red blood-corpuses in 0.7 ccm. of dog's blood, but insufficient to produce any action on 2 ccm. of it. Animals can be immunized against it. Normal blood-serum delays action of saponin. This hemolytic property of saponin was made use of to determine whether the bactericidal property of the blood suffered by hemolysis. Rabbits inoculated with the bacteria of swine plague died 48 hours sooner in all cases when saponin had acted on their blood, thus proving the depreciation of bactericidal action; in case anthrax bacilli were injected, however, the control animals died as soon as the others; animals injected with saponin alone did not die. [E.L.]

**Investigation Upon Hemolysis in Heterogenic Serum.**—Baumgarten<sup>3</sup> reviews the literature upon hemolysis in heterogenic serum. He considers the agglutinins as identical with Ehrlich's amboceptors. Agglutination changes in the serum at a temperature of 55°, and while there is agglomeration yet there is no real agglutination. Baumgarten believes agglutinins the same as the hemolysins and bacteriolysins. Hemolysis occurs as a result of an osmotic disturbance and is not due to a solution of the red blood cells by the action of a ferment. [W.E.R.]

**New Reaction for Biliary Pigments.**—Baudouin<sup>4</sup> describes a new reaction for detecting biliary pigments in the urine. The reagent consists of a solution of commercial fuchsin, 50 centigrams to 100 grams (1½ to 3½ oz.) of distilled water. A test-tube is filled to about one-third with the urine to be tested, which is previously filtered, and in a second tube a similar quantity of distilled water. In each tube two drops of the reagent are placed, and the discoloration is compared. The urine is changed to orange yellow when bilirubin is present. If the urine is deep in color it should be diluted with distilled water. The reaction is explained as follows: Bilirubin is feebly acid, as found in combination with calcium and sodium. Commercial fuchsin is a rosanilin hydrochlorate. When these substances are brought together they form calcium and sodium chlorid and rosanilin bilirubinate, which is of an orange color. A series of experiments of urine from cirrhotics, alcoholics, and cases of hepatic cancer containing large amounts of urobilin did not react to this test, nor did a second series of urine from advanced ataxies containing indican in abundance. [J.H.W.R.]

**The Present Status of the Determination of the Freezing Point of Blood and Urine, and Its Importance in the Question of Kidney Insufficiency.**—Roeder,<sup>5</sup> while attempting to make Vant' Hoff's theory of electrical dissociation serviceable to clinical medicine, talks most interestingly about the researches performed thus far in this domain. The osmotic pressure of a fluid and its freezing point may be changed at will by dissolving solids in it; the elevation of the pressure and the lowering of the freezing point are directly proportional to the amount of the dissolved molecules. Practically this is

noticeable only in the cases of crystalloid substances on account of their relatively low molecular weight in comparison with colloid substances: Example, albumen. The kidney's function is to separate from the blood a solution of definite density, that is to keep the blood in a state of average definite concentration. Should they as a result of disease be less able to perform this function, the concentration of both the urine and blood solutions are modified; this expresses itself in the form of a diminution, respectively increase of the osmotic pressure, as well as of a lowering of the freezing point of the solution. These theoretically deduced changes have been found true in a number of ways. Many investigators, in particular Koranyi, have found in diseases of the kidneys a lowering of the freezing point of the urine, an increase of the freezing point of the blood serum. Basing their conclusions upon the detailed studies of their material, many of these men have probably gone too far in their expectation, but in the province of kidney surgery much has been gained, as we may now by means of ureteral catheterization determine the exact functioning power of each individual kidney. The supposition, however, that the appearance of uremic symptoms, the signs of the highest kidney insufficiency depends directly upon the increased osmotic pressure of the blood, could not be maintained permanently. Other men's statements, as well as animal experiments with blood solutions of high concentration, show that this state of affairs is not to be explained so easily as Roeder hopes, that especially this question may be better illumined by the combination of the older methods, with the examination of the solutions concerning their electrolytic behavior; the former informs us regarding the quantity, the latter regarding the quality of the substances dissolved in the blood not excreted by the kidneys. [E.L.]

**Addison's Disease and Genital Tuberculosis.**—Vincelet<sup>1</sup> has analyzed 216 cases of Addison's disease with tuberculosis of the suprarenal gland and found accompanying tuberculosis as follows: Pulmonary, 122 cases; vertebral, 17; osseous, 12; ganglionic, 14; intestinal, 6; pleural, 6; cutaneous, 1; and finally, tuberculosis of the genitals in 9 cases. Although difficult to determine the exact time of beginning of the genital tuberculosis, the appearance of Addison's disease seems to follow very soon in males, after a longer time in females. The evolution of the disease is practically the same as in suprarenal tuberculosis of other origin. The suprarenal lesion is more marked on the side which is the seat of the genital lesion. The prognosis does not differ from that of other cases. Treatment consists of absolute rest in bed, substantial diet, and codliver-oil in large doses. Suprarenal extract may be given in the dose of 40 to 50 cg. [A.G.E.]

THE PUBLIC SERVICE

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 21, 1903:

Changes in the Medical Corps of the U. S. Army for the week ended March 21, 1903:

PEASE, FRANK D., contract surgeon, is granted leave for one month, from about March 26, with permission to apply for an extension of one month.

MCADORY, ROBERT J., contract surgeon, is relieved from duty at Camp McKinley, H. T., and will proceed to San Francisco, Cal., and report by telegraph to the adjutant-general of the Army for further orders.

MCCLURE, S. B., contract surgeon, is granted leave for one month.

DEWITT, First Lieutenant WALLACE, assistant surgeon, is relieved from further attendance at the Army Medical School, Washington, D. C., and will proceed to Fort McPherson for treatment and observation by the post surgeon.

SHAW, Captain HENRY A., assistant surgeon, will accompany First Lieutenant Wallace DeWitt, assistant surgeon, to Fort McPherson, for the purpose of rendering such medical assistance as may be required by Lieutenant DeWitt en route, and upon the completion of this duty will return to his proper station.

KENNEDY, Captain JAMES M., assistant surgeon, leave granted February 6 is extended one month.

GRAHAM, GEORGE, hospital steward, Philippine Islands, is relieved from further duty in the division of the Philippines. He will proceed to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty.

PAGE, Captain HENRY, assistant surgeon, is granted leave for one month, to take effect upon his being relieved from duty at Fort Monroe.

MORRIS, Major EDWARD R., surgeon, is detailed for duty as surgeon in charge of the base hospital, Iloilo, Panay, with station in Washington, D. C., relieving Major A. S. Polhemus, surgeon. Major Polhemus will proceed to Camp Bumpus, Tacloban, Leyte, for duty.

WOOD, H. L., contract surgeon, is granted leave for one month, with permission to apply for an extension of one month, to take effect upon being relieved by Captain Irving W. Rand, assistant surgeon.

MCWILLIAMS, JOSEPH G., hospital steward, now on furlough at San Diego, Cal., is relieved from further duty with the company of Instruction No. 2, hospital corps, Fort McDowell, and will report on or before expiration of furlough at San Diego Barracks, to relieve Hospital Steward Patrick McGloin. Steward McGloin will proceed to Fort Sheridan to relieve Hospital Steward George C. Doran. Steward Doran will proceed to Fort Wright to relieve Hospital Steward Harry Meade. Steward Meade will proceed to San Francisco, Cal., and report for duty aboard the Army transport leaving that city on or about May 1 for the Philippines.

SHOCKLEY, First Lieutenant M. A. W., assistant surgeon, is granted leave for one month, from about March 20, with permission to apply for an extension of fifteen days.

Changes in the Medical Corps of the U. S. Navy for the week ended March 21, 1903:

KAINES, A. W., acting assistant surgeon, appointment revoked, to take effect upon reporting of relief—March 14.

BENTON, F. L., passed assistant surgeon, ordered to the Naval Station, Cavite, P. I.—March 14.

LUNG, G. A., surgeon, detached from the Bureau of Medicine and Surgery, and ordered to the Naval Hospital, Philadelphia, Pa.—March 16.

STEPP, J., assistant surgeon, detached from the Isla de Luzon and ordered home to wait orders—March 16.

COOKE, P. L., acting assistant surgeon, ordered to the Naval Academy, Annapolis, Md.—March 17.

HESLER, F. A., surgeon, died March 11 on board U. S. S. Wilmington, en route from Cavite, P. I., to Yokohama, Japan—March 17.

Changes in the Public Health and Marine-Hospital Service for the week ended March 19, 1903:

WILLIAMS, L. L., assistant surgeon-general, to proceed to New York, N. Y., as inspector of purveying depot—March 13, 1903.

WICKES, H. W., passed assistant surgeon, relieved from duty at Cincinnati, Ohio, and directed to proceed to Reedy Island quarantine and assume command of the service at that port, relieving Assistant Surgeon T. F. Richardson—March 12, 1903.

DECKER, C. E., assistant surgeon, granted extension of leave of absence, on account of sickness, for fourteen days from March 7—March 12, 1903.

RUSSELL, H. C., assistant surgeon, to proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for temporary duty—March 19, 1903.

FRICKS, L. D., assistant surgeon, upon being relieved from duty at Cape Fear quarantine, to proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for duty—March 19, 1903.

KERR, J. W., assistant surgeon, relieved from duty at New Orleans, La., and directed to proceed to Cincinnati, Ohio, and assume temporary command of the service at that port—March 12, 1903.

RICHARDSON, T. F., assistant surgeon, upon being relieved from duty at Reedy Island quarantine by Passed Assistant Surgeon H. W. Wickes, to report to him for temporary duty. Upon expiration of said temporary duty, to proceed to New Orleans, La., and report to medical officer in command for duty and assignment to quarters—March 12, 1903.

KORN, W. A., assistant surgeon, to report to medical officer in command at Philadelphia, Pa., for assignment to special duty—March 17, 1903.

SCHERESCHEWSKY, J. W., assistant surgeon, relieved from duty at New Orleans, La., and directed to report to Surgeon G. W. Stoner, Immigration Depot, New York, N. Y., for duty—March 17, 1903.

GLOVER, M. W., assistant surgeon, relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Baltimore, Md., and report to medical officer in command for assignment to special duty—March 17, 1903.

WARREN, B. S., assistant surgeon, upon expiration of leave of absence, relieved from duty at Washington, D. C., and directed to proceed to Cape Fear quarantine, relieving Assistant Surgeon L. D. Fricks, and assume command of the service at that port—March 19, 1903.

STIMSON, A. M., assistant surgeon, relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to New Orleans, La., and report to medical officer in command for assignment to special duty—March 17, 1903.

ALEMAN, FERNANDO, acting assistant surgeon, granted leave of absence for seven days from March 8, 1903, under provisions of paragraph 191 of the regulations.

PATRIE, W. E., acting assistant surgeon, granted extension of leave of absence for seven days from March 13—March 11, 1903.

GIBSON, R. H., pharmacist, granted leave of absence for twenty-three days from March 9—March 12, 1903. Relieved from duty at the Gulf quarantine station, and directed to proceed to Vineyard Haven, Mass., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist L. P. Hall—March 12, 1903.

BROWN, F. L., pharmacist, upon being relieved from duty at Cape Charles quarantine, to proceed to Pittsburg, Pa., and report to medical officer in command for duty—March 12, 1903.

STEPHENSON, C. W., pharmacist, to report to chairman of board of examiners at Chicago, Ill., for the purpose of determining his fitness for promotion to the grade of pharmacist of the second class—March 18, 1903.

HALL, L. P., pharmacist, upon being relieved from duty at Vineyard Haven, Mass., to proceed to Cape Charles quarantine and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist F. L. Brown—March 12, 1903.

SPANGLER, L. C., pharmacist, granted leave of absence for twenty-five days from March 4—March 12, 1903.

\$5.00 YEARLY.

**The Extinction of Tuberculosis.**—In a capital lecture on this subject, published in the English journal *Public Health* of March, Dr. Alfred Hillier gives a striking chart showing that at the present rate of decrease in the deaths from pulmonary tuberculosis Prussia will reach the zero point about the year 1927, whereas in England at that time there will still be about 8 deaths per 10,000, and the total extinction will take place only about 20 years later. In Prussia, whose statistics do not deal with the phthisis rate alone, but with the whole of the deaths from tuberculosis, the only decline—and that is a rapid one—of which the statistics furnish a record has occurred since 1886. From 1876 to 1886, a period during which our tuberculosis rate was steadily diminishing, the Prussian rate remained stationary at about 31 per 10,000. But in 1887 the drop in the Prussian rate began, and it has continued comparatively steadily down to 1900, when it had fallen to 21 per 10,000. In England in the same period the drop in the tuberculosis deathrate has only been from 24 to 19 per 10,000. The rapid fall in the Prussian rate is ascribed (1) to the precautions against infectious diseases due to the discovery of the tubercle bacillus; (2) to the improved conditions of the working classes caused by the Workmen's State Insurance laws; (3) the establishment of sanatoriums.

**The Microbe-laden Spray of the Tuberculous Patient.**—In the address of Dr. Hillier he quotes Professor Koch as having reached the conviction that the spread of the tubercle bacilli is far more by means of the tiny droplets or spray emitted with every cough, sneeze or effort at speech by the patient in the last stages of the disease, rather than by the dry, pulverized sputum. These tiny drops penetrate more deeply into the deeper recesses of the lungs than the coarser particles of pulverized sputum. The experiments of Flügge and his assistants demonstrate this, but the following test by Flügge and Heymann is particularly convincing: Guineapigs were brought into a disinfected room of the hygienic institute and tuberculous patients with disinfected clothes were then admitted. The guineapigs, with their heads fixed facing the patients, were coughed at a distance of from 20 to 45 centimeters every other day for 3 hours. Out of 25 guineapigs 2 died in 4 weeks, 2 in 7 weeks, 1 in 2 months, and 1 in 4 months, all

showing symptoms of inhalation tuberculosis. The advanced cases of pulmonary tuberculosis are therefore the dangerous ones and the public health control of them therefore becomes the dominant duty and the best method of bringing about the extinction of the disease. In England and Wales there are about 60,000 deaths from this cause each year and 120,000 patients require State supervision. The expense of this care is estimated at about \$30,000,000 per annum. Half of this immense sum would be saved out of the poor-rate and the amount would be a rapidly diminishing one.

**Social Progress and the Extinction of Tuberculosis.**—When the world went wild with enthusiasm over the supposed discovery of a method of extinguishing pulmonary tuberculosis by means of tuberculin injections, an unknown and now forgotten writer said that had Professor Koch succeeded in his aim it would have been the greatest curse imaginable to the human race. The reason given for this seemingly extravagant statement was that the moral and social origins of the disease would have been neglected, and the relation of moral and physical disease can never be safely ignored. *Malum* and *morbus* are often the same, at least so intimately connected that one cannot be eliminated from human life without the other. The most striking proof of this now comes out in the fact that Koch himself admits and even preaches that the great decrease in the deathrate from tuberculosis has been due and will still be due to sanitary and social betterment, but chiefly to the improvement in the condition of the workmen's lives through government insurance, etc. In other words, what may be called the morals of infectious disease are being recognized. The conditions that breed and scatter physical contagion are precisely those that degrade and morbidize the soul and character. Rightness of physical living is necessary to righteousness, and *vice versa*. Koch, the author of tuberculin, forgot this truth; Koch, the sanitarian, now preaches it.

**The business aspect of the practice of medicine** is discussed by Dr. Patten in the *Northwestern Lancet*, and with logical principle the reprint is sold at ten cents. The epitome of the advice is to systematize and push collections. This is certainly wise counsel, but every one who has thought on the matter knows that it

is a small part of what is needed to make the practice of medicine pay. In the first place we should enter a decided protest against the old and stupid and musty error echoed and reechoed since there has been a medical profession, that doctors are business idiots. According to this silly blunder doctors never charge and never collect for their services, and always end their lives in poverty and will their widows and children nothing but debts and mortgages. We think that for the investment made, that on the original "plant" of intellect, culture, skill, etc., doctors realize as good an interest as blacksmiths, preachers, shopkeepers, promoters, or farmers. All quackishness, and there is plenty of that left in the profession, surely rests upon an appreciation of the value of the dollar and upon an ability to get hold of it. But every quack also in his own person demonstrates the lack of intellect and ability to make money without the poor attempt at stupid cunning. It is noteworthy that those who make great financial successes of their professional lives, who by many years of sharp attention to the monetary side of the practice of medicine, often live a large part of their life, at least they are certainly sure to die, despised by their colleagues because of certain methods of thought and practice, and one may add that this contempt is merited.

**The Spaces About Hospitals.**—A bill has recently passed the House of the Pennsylvania Legislature worded as follows:

Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania, in General Assembly met, and it is hereby enacted by the authority of the same, That there shall be on all four sides of hospitals hereafter constructed or erected in this Commonwealth a clear space of at least 25 feet, and no hospital shall be extended beyond its present limits by the construction of new buildings, unless a clear space of at least 25 feet shall be preserved on the side or sides so extended, and no permit shall be issued for the construction and erection of a hospital or any extension of a hospital already erected by the proper authorities having charge of the issuing of permits, unless the plans for said building or extension show that the number of feet space mentioned in this act is fully complied with.

Now, why is there such a requirement to be made of hospitals, while factories, asylums, hotels, restaurants, etc., may do as they please concerning crowding and surrounding spaces? The omission of such institutions and the single mention of hospitals throws suspicion both on the motives and the intellects of the legislators. But the suspicion is greatly increased when we note that it is not the requirement of fresh air and open spaces that is demanded, but only that the space shall be of a certain kind and location. If the provision of fresh air and light had been aimed at the act would simply demand this by means of open courts, air wells, the construction of wings, etc. The profound injustice of the act is shown by the limitations imposed on already existing hospitals, which are thus prevented from enlarging their wards and buildings because the adjacent property cannot be obtained, while complying with the arbitrary requirement of the 25-foot space at the outer edges. The act should be entitled, An act to prevent existing hospitals from carrying out desirable enlargements and betterments of their wards, and for crippling the useful-

ness and beneficence of these institutions. This blundering bit of needless legislation is a relic of the old superstition as to the harmfulness of hospitals to the neighborhoods in which they are located. The act should not become a law.

**The new Colorado law as to regulation of the practice of medicine,** drafted and pushed through the Legislature by Dr. Van Meter, only awaits the Governor's signature to become a law. By its provisions a State Board of nine examiners appointed by the Governor is established. Graduates of chartered medical schools of the State of the standard recognized by the State Board of Medical Examiners are certified by the board as entitled to practise. Nongraduates of such schools are required to pass the examinations by the board in anatomy, physiology, chemistry, toxicology, pathology, surgery, obstetrics, and symptomatology, exclusive of materia medica and therapeutics. Those thus examined shall specify the school or system they purpose to practise, and shall file a certificate from the State Association of that school or system designated by the applicant, stating that he is qualified to practise that school or system. Licenses may be refused or canceled for the following reasons:

The employment of fraud or deception in applying for license on diploma or in passing the examination provided for in this act; conviction of crime involving moral turpitude; habitual intemperance in the use of ardent spirits, narcotics or stimulants; unprofessional or dishonorable conduct. The words "unprofessional or dishonorable conduct," as used herein, are hereby declared to mean: First, the procuring or aiding or abetting in procuring criminal abortion; second, the obtaining of a fee on the assurance that a manifestly incurable disease can be permanently cured; third, the betrayal of a professional secret to the detriment of a patient; fourth, causing the publication and circulation of advertisement of any medicine or means whereby the monthly period of women can be regulated or the menses can be reestablished, if suppressed; fifth, causing the publication and circulation of advertisements of any kind relative to the diseases of the sexual organs tending to injure the morals of the public.

As to who is a practitioner the act sets forth that:

Any person shall be regarded as practising medicine, within the meaning of this act, who shall attach to his or her name the title "M.D.," or "Surgeon," or "Doctor," or "D.O.," in a medical sense, or advertise in any manner or hold himself or herself out to the public in this State as a physician, surgeon, doctor, or as a person who shall diagnosticate, or offer to diagnosticate, any physical or mental disease of any person, or suggest, recommend and prescribe any form of treatment for the attendant palliation, relief or cure of the same, with the intention of receiving therefor, either directly or indirectly, any fee, gift or compensation whatsoever. It is further provided that the doing of any of the things hereinbefore set forth or the maintenance of an office for the reception, examination and treatment of any one as hereinbefore set forth, or the exposure of signs, circulars or advertisements, or any other device or information indicating thereby the occupation of the person or persons as that of being engaged in the practice of medicine as hereinbefore defined, shall be considered as prima facie evidence in any prosecution brought under this act. Nothing in this act, however, shall be construed to prohibit gratuitous service in case of emergency nor to the practice of the religious tenets of any church whatsoever, but in no event shall such person practise in contagious and infectious diseases recognized as dangerous to the public health subject to quarantine regulations, unless they have passed the examinations required by this act, nor shall it apply to commissioned surgeons of the United States Army, Navy, or Marine-Hospital Service while so

engaged, nor to regularly licensed physicians in actual consultation from another State or Territory, nor to regularly licensed physicians actually called from other States or Territories to attend specified cases in this State, nor shall it apply to the practice of dentistry or dental surgery.

While this law is not all that could be desired it will, properly administered, prove greatly superior to the older one. Dr. Van Meter, his associates, and the profession should be congratulated.

**The Public Baths Association** of Philadelphia in its success should encourage the wisely charitable of other cities. On Wednesday last there was opened a second public bath house at 718 Wood street. The new bath house is equipped with twenty-four shower baths for men and six for women. Separate entrances lead into attractive waiting-rooms, where the bathers exchange their nickels for a clean towel and a fresh cake of soap. Hot and cold water is provided, and everything necessary for the comfort of the patrons. The bath house has a capacity of eighty-four baths an hour, and will be open every day in the year. At the Gaskill street bath house, which was opened in 1898, more than 60,000 baths were taken last year. Since opening over 200,000 baths have been taken there, and over 5,000 women have patronized the public laundry connected with the establishment. The receipts from bathers have not so far paid the running expenses of the bath house, but from present prospects both places will some day become very nearly self-supporting. An actual count of a typical block near the Gaskill street bath house, made a year ago, showed:

Men, women and children . . . . .	1,713
Living rooms . . . . .	659
Bathtubs (several used for storing coal) . . . . .	11
Saloons (in and opposite the block) . . . . .	5

One bathtub for each 155 people explains why the public bath house has prospered. The establishment of such places should be encouraged, and the philanthropist will find in such work a noble opportunity for doing real good to those less fortunate than himself.

**Nutritive Value of Desiccated Vegetables.**—

One of the most remarkable peculiarities of the lower organisms, as exhibited in seeds and other vegetal bodies, is the fact that they are capable of withstanding desiccation for very considerable periods without losing capacity for germination and development. The vitalized crystalloids and colloids which possess the power of assimilation and metabolism appear capable of having all uncombined water removed by evaporation without undergoing molecular disruption by the loss of their combined water. They appear to retain the combined water much as crystals retain water of crystallization. If the ordinary drying of seeds, corms, rhizomes, bulbs, etc., does not destroy the integrity of their protoplasm or alter the availability of their stored-up albumin, starch, or sugar, it would appear that they should retain all their nutritive value, and that the same should hold true of most, if not all, vegetables used for food by man as well as it does for forage crops preserved by drying. It is curious that the desiccation of culinary vegetables should be so much neglected nowadays in view of the

universal use of dried fruits from prehistoric times and the practice of drying such vegetables as the pumpkin, in vogue among early New Englanders, in evidence of which the shiny pumpkin poles are still to be seen hanging on hooks in the ceiling in front of the fireplace of many an old homestead. Experiments made in Germany, and more recently in California, have demonstrated that desiccated vegetables suffer no loss of nutriment, and that they remain savory and wholesome. Here is a splendid opportunity for the utilization and conservation of potatoes, beets, parsnips, cabbage and the like at the season of their greatest abundance and in years of over-production, whereby there may be added to the regular supply a line of familiar food concentrated so as to admit of economic transportation for army rations and for those who cannot afford such fresh vegetables out of season. While it may not pay to can such vegetables as we have mentioned, it would be a boon to many if they were put on the market dried.

**The art of refraction**, if of any value whatever, is only so when absolute accuracy in it is attained. This accuracy requires such exceptional skill and training, is so dependent upon a rare combination of personal characteristics, conscientiousness, delicacy, tact, judgment, keenness of observation, etc., that it is seldom attained. To make the crudity more striking it has become the habit of textbook writers, of schools, of teachers, and of students to suppose that this most difficult of all medical technical work can be learned by anybody without application, and perhaps in a few weeks. On the contrary, no one ever learned it except by years of the most intense devotion. Indeed many men can and do never learn it. This fact accounts in part for much of the pessimism which exists as to the pathologic influence of eyestrain in producing systemic diseases. The patient is not cured because his disease has not been diagnosed and he has had no scientific treatment. In all the world there is no school which will train a student to do the perfect refraction work which conditions the relief of the sufferings of at least one-tenth or one-twentieth of civilized people. Bacteriology, chemistry, carpentering, electrical engineering, surgery, nursing—in any other calling or occupation years must be given to the acquirement of the requisite knowledge and the training of hand, eye, and nerve, but in an art demanding far more subtlety and skill and intellect than any of these, a few pages of theory in a textbook, or a few didactic lectures, are at most held to be necessary. And while the useless lectures are being delivered the drug stores in every town of the United States are dealing out tons of “head-ache powders” and the tramp spectacle peddler is at his farcical humbuggery, each making the diseases worse which they pretend to cure.

**Dose Measures.**—From time to time the subject of the dose measures in common use forms the topic of discussion in medical and pharmaceutical journals, but with apparently no practical result. Physicians continue to direct the administration of medicines in teaspoons, dessertspoons, tablespoons, wine glasses and teacups, notwithstanding the fact that these domestic measures are

respectively very likely to differ very much in capacity. The ordinary graduated medicine glasses afford no greater assurance of accuracy or uniformity and are employed to a very limited extent. The explanation of the matter would appear to lie in the fact that in the use of all ordinary remedies it makes very little difference whether there is a discrepancy of a few cubic centimeters one way or the other. The practitioner can scarcely gauge the exact dose of any given remedy to suit the exact susceptibility of each patient, and finds the ordinary capacities of spoons and glasses sufficiently accurate for everyday use. Particularly potent drugs may be administered in drops, and then notwithstanding the very considerable variation in the size of drops from the same dropper, drugs thus prescribed are usually administered in diluted form, and there appears to be no sufficient ground for alarm over the inequality in the doses. The suggestions of some writers that carefully graduated measuring glasses, standard or official droppers, or decigram pipets should be required, is not likely to meet any considerable amount of enthusiasm on the part of physicians or patients, as absolute accuracy in dosage by the mouth is rarely essential.

## EDITORIAL ECHOES

**Diet and Dyspepsia.**—The discovery that there are at Harvard 15 sufferers from insomnia, 100 sufferers from headaches, and 372 sufferers from indigestion has at once started a discussion of the proverbially fantastic and unwholesome things that students eat. In several places actual bills of fare of academic luncheons have been brought to light. Such as this: "Two 'hot dogs,'  $\frac{1}{2}$  apple pie, with whipped cream, 2 chicken sandwiches, 1 cup chocolate, 1 vanilla éclair, 1 glass orangeade, 1 hard boiled egg." This is said to be the frequent choice of an undergraduate in the University of Pennsylvania. Any college man can read of equally ungodly mixtures in the tablets of his memory. A few years ago a professor in a western university undertook to obtain from every student an actual week's dietary and a general summary of personal habits in regard to eating and drinking. He had little success, partly because he asked a number of extraneous questions which were thought amusing. "How many hours is your oatmeal boiled?" became a college joke, and but few answered the questions seriously. Of course nobody will dispute that the average college boy's diet is not selected on the lines marked out by the food chemists. But is this a peculiarity of college boys? Statistics from only one side will never determine this, and it should be in order to suggest a few virgin fields for investigation. First, there are the lines of muddy complexioned men who line up every noon at the drug store counters for stomach tonics before luncheon. The college big eater is a dyspeptic *in posse*. These men are dyspeptics *in esse*. What percentage of them have the bachelor's degree, and how many of them are self-made men? Certainly a good number in that melancholy line never clutched a diploma. Second, there are the restaurants in the larger college towns. Ask their head waiters who are the eaters of lobsters and milk, or cherries and ice cream. Then look over the provision bills of the restaurants to which the average city clerk gives his noonday patronage. How many times is "a cup of coffee and a piece of hot mince pie" the sole sustenance of an ambitious young man in business? Until these matters are investigated, as well as the mere prevalence of indigestion in the colleges, the student, as a class, should not be slandered.—[*N. Y. Evening Post*.]

## BOOK REVIEWS

**The American Year-Book of Medicine and Surgery for 1903.**—Arranged under the editorial charge of GEORGE M. GOULD, A. M., M. D. In two volumes—**General Medicine and General Surgery.** Philadelphia, New York, London: W. B. Saunders & Co.

This Year-Book is not an indiscriminate collection of extracts clipped from any and every journal; the matter is carefully selected, edited, and in numerous cases commented upon by the well known authorities whom Dr. Gould has enlisted as his assistants. Every new theory and scientific discovery worthy of the consideration of the profession has found a place in this unusually complete Year-Book, and the names of the several editors are sufficient guarantee of a proper discrimination. The volumes are sold separately if desired. As usual the illustrative feature is well taken care of, there being eleven full-page inserts, besides many excellent text-cuts.

**Therapeutics of Infancy and Childhood.**—By A. JACOBI, M. D., LL. D. Third edition. Philadelphia and London: J. B. Lippincott Company, 1903.

Unlike most medical writings of the day Jacobi's great book has an individuality of style as marked as its author's personality. It is truly personal, intensely so. The man, the teacher, talks to his colleague, his student, directly, familiarly; with egoism, if you please, but never egotism. He has no mock modesty, but neither is he vainglorious. He is strong in knowledge, firm in judgment, keen in observation, pointed in expression. He knows what he wishes to say, and he says it so that it sticks. He then clinches it with an illustration or an argument drawn from his long and broad experience. The discussion of artificial substitutes for mother's milk is illuminating. The author traces for us—perhaps unconsciously—the prodromes, development, acme, and slow—alas too slow—decline of what we might term laboratoryism among physicians in general and pediatricists in particular. Jacobi approves the theory, the scientific ideal, of accurate individual mixture of components for a given infant's food, but not the practice of having the prescription written and filled by "the barmaid in charge" of the factory's dispensing shop. He points out the necessity of giving infants sufficient water, therefore he dilutes the cow's milk well, increasing the total quantity proportionately. And he adds cereals—thus, oatmeal or barley water—to supply necessary elements in nutrition. Of "expectant treatment" he says: "My responsibility is not lessened by my busying myself with subcutaneous injections of brandy when a collapse has set in, which I ought to have foreseen and prevented, or with giving digitalis when on the fifth or sixth day of a pneumonia the pulse is flying up to 160 or 200. Anybody can perform that sort of perfunctory expectant treatment extending from the first call to the writing of a death certificate. Many a case might be saved by a few grains of digitalis or a few efficient doses of camphor or musk if administered in time." To those who do not wish to interfere with a whoopingcough because it finds its natural termination after several months he says: "That is true, but many of the children also find their natural termination during these months." The book is a treasury of good advice; it is replete with the lessons of skill and method in diagnosis, of practical experience in treatment. It teaches a rational empiricism based on profound appreciation of all the facts of science, and especially of the relations and relative weight of laboratory investigation and of bedside study. Etiology is the keynote. The third edition is rewritten, enlarged, brought abreast of the times, but never departs from the historic path of age-long wisdom.

**Atlas and Epitome of Diseases of the Mouth, Pharynx, and Nose.**—By Dr. L. GRÜNWARD, of Munich. Second edition. Edited, with additions, by JAMES E. NEWCOMB, M. D., of New York City. W. B. Saunders & Co., 1903.

Perusal of this little volume is a distinct mental pleasure. Its conciseness without sacrifice of clearness and thoroughness, as well as the excellence of text and illustration are commendable. The illustrations are copious, and with the exception

occasionally of the tints in the colored plates, especially where cartilage is represented, good. The subject arrangement of the text is based upon pathologic processes instead of regions, and while this does not permit of as ready reference, it is perhaps more scientific and makes more pleasant systematic reading. Pathology is given ample attention and space, and therapy is sound and modern. Particularly good are the general considerations as to the maintenance of health and prevention of catarrhal disorders. The book maintains a nice balance between the scientific and the practical, and is a distinct and valuable addition to the armamentarium of the worker in rhinologic fields, be he expert or tyro.

**A Textbook of the Diseases of the Ear.**—By Professor Dr. ADAM POLITZER, of Vienna. Edited by MILTON J. BALLIN, Ph.B., M.D., and CLARENCE L. HELLER, M.D. Fourth edition. Lea Brothers & Co., 1903.

The German original has been thoroughly revised and brought up to date by the distinguished author, and the translation was made by men who worked with Politzer for some time in the capacity of assistants, and were therefore thoroughly in touch with his ideas and habits of thought and work. An added advantage is that the translation was read by the author, who expresses himself as much pleased with it, so that it can be fairly taken as being a full and accurate expression of his ideas. It is pleasing to note that our American co-laborers are given credit for their work, and while naturally European authors are the more freely quoted, yet American otologists are not neglected. The book should be in the hands of every otologist, as it is unequalled in elaborate and scientific minuteness, and it is as easy to conceive of working without a head mirror as without having at hand a copy of this masterpiece of otologic science and practice. The publishers have done their work well in giving us a clear type on good paper and handsomely bound.

**A Manual of Otology.**—By GORHAM BACON, A.B., M.D., with an introductory chapter by CLARENCE JOHN BLAKE, M.D. Third edition. Lea Brothers & Co.

This little manual is essentially for the use of the beginner or the general practitioner who needs guidance in his otologic work. While it can be read with interest by the specialist it is of almost too elementary and rudimentary a character to be of much value to him. Bacon's book is clear and concise, and as regards treatment rather conventional; it contains a number of short illustrative case histories. The cuts in the main are satisfactory, although several of Gray's antiquated plates are used. One is disappointed in finding but the briefest notes on leukocytosis and lumbar puncture, when attention has been called to both of these subjects in the preface as being new to the present edition. Among the newer instruments Burnett's modification of Ziegler's otoscope is ignored, as well as the very useful little practical manner of anointing the end of the otoscope before introduction, in order to facilitate the securing of an airtight connection. The various operations for the cure of catarrhal deafness are described, but we are glad to say strongly condensed. The section on the mastoid is clear and full. For the purpose for which the book was evidently intended it should answer admirably, and that it has is evidenced by the fact that the present edition is the third in four years.

**Photographic Atlas of the Diseases of the Skin.**—Parts XI, XII, XIII, XIV, XV, XVI. By GEORGE HENRY FOX, M.D. J. B. Lippincott Company, Philadelphia and London, 1902.

These, the concluding parts of Dr. Fox's Photographic Atlas of the Diseases of the Skin, contain 47 portraits of various cutaneous diseases, and are fully up to the high standard set in the previous parts. Among the more important affections shown are *dermatitis herpetiformis*, several varieties of *eczema*, *lichen ruber*, *trichophytosis*, *lepra*, *mycosis fungoides*, *psoriasis*, and *dermatitis exfoliativa*. The author does not seem to us to have been altogether happy in his selection of a case of *dermatitis herpetiformis* for illustration, since the face is much less frequently affected than the trunk and extremities and the

eruption in this situation is much less characteristic than elsewhere. The plates representing *psoriasis exfoliativa* and *dermatitis exfoliativa* are especially fine; we can recall nothing finer in the way of pictorial representation of cutaneous diseases. The descriptive text accompanying the excellent portrait of *mycosis fungoides* seems to throw some doubt upon the diagnosis of the case from which the portrait was made, since it is stated that at the autopsy, made in a distant city, the *lepra bacillus* was found: This the author explains by supposing either a subsequent infection, or a mistake upon the part of those making the autopsy. A considerable portion of the text is devoted to the consideration of the therapeutics of skin diseases. We note that the author advises extraction of the hairs as a useful procedure in ordinary *sycosis*. This has always seemed to us an exceedingly barbarous treatment, a remnant of the days of the *calotte*, a remedy much worse than the disease. In our experience just as favorable results may be obtained much less painfully by frequent shaving. In the section devoted to the consideration of *pityriasis* we are told that "the *pityriasis rosea* of Gibert, the *pityriasis maculata*, *circinata*, and *marginata* of Vidal and Duhring, the *pityriasis simplex* of older writers, and most cases of so-called *eczema seborrhoicum*, or *dermatitis seborrhoica* . . . are simply clinical forms of one disease." The so-called *eczema marginatum* is regarded as a variety of *pityriasis*, and is described under the name *pityriasis marginata*. These statements are so entirely at variance with the teaching of today that they should not be allowed to go unchallenged. There is no demonstrable relationship, clinically or pathologically, between *eczema seborrhoicum* and the *pityriasis rosea* of Gibert, and the presence of the *trichophyton* has been so often demonstrated in the so-called *eczema marginatum* that the parasitic nature of this affection can no longer be doubted. For those who do not have the opportunity to study diseases of the skin upon the living subject this Atlas will be of great value, since the portraits are well chosen and beautifully executed.

**The Nose and Throat in Medical History.**—By JONATHAN WRIGHT, M.D. Published by Lewis S. Matthews & Co., St. Louis, Mo.

There can be but one opinion as to this book. The reader is filled with wonder, gratitude, admiration and respect; wonder at the vast amount of trouble that Dr. Wright has gone to in order to secure his facts, gratitude that he has collated so much of historic interest from the highways and byways of medical lore, admiration for the willingness to give up the vast amount of time that only the intensest love of his profession could prompt a man to grant, and respect for the thoroughness, logical presentation and careful culling which is everywhere in evidence. Back of all this one cannot fail to appreciate the breadth of education which must be an essential part of the author's equipment, for without this such a task would have been impossible. The book is a broad and thorough, yet succinct, account of the development of the armamentarium, anatomy, pathology and therapeutics appertaining to the parts of the body falling within the field of the rhinolaryngologist. It is difficult to resist the temptation to quote, but should one yield to this temptation the quotations would be limited only by the size of the book. While comparatively small the book is truly monumental, and should be in the hands of every worker in the field of laryngology who aims to be anything more than a skilled mechanic. It is regrettable that the publisher has not put into the type and bookwork the same care and elaborateness that characterizes the work of the author.

**Diseases of the Eye: A Handbook of Ophthalmic Practice.**—By G. E. DESCHWEINIZ, M.D., Professor of Ophthalmology in the University of Pennsylvania, Philadelphia, etc. Fourth edition. Pp. 773. Cloth, \$5.00 net; sheep or half morocco, \$6.00 net.

In the new fourth edition of this popular handbook the text has been thoroughly revised, and the entire work has been reset. Many new chapters have been added, such as Thomson's Lantern Test for Color-blindness; Hysteric Alopecia of the Eyelids; Metastatic Gonorrhoeal Conjunctivitis; Grill-like Kera-

titis (Haab); the so-called Holes in the Macula; Ocular Signs of Diseases of the Sphenoid and Antrum; Recurring Oculomotor Paralysis; Conjunctivitis Petrificans; Educative Treatment of Strabismus; Divergence-paralysis; Convergence-paralysis, and many others. A large number of therapeutic agents comparatively recently introduced, particularly the newer silver salts, are given in connection with the diseases in which they are indicated. The illustrative feature of the work has been greatly enhanced in value by the addition of many new cuts and six full-page chromolithographic plates.

**The New International Encyclopædia, Vol. VII.**—Dodd, Mead & Co., New York.

The chief articles upon medical subjects in this volume are:

Excretory System	Fever
Exercise	Filaria
Expectoration	Filth-disease
Eye	Fish as Food
Facial, Nerves, Neuralgia, and Paralysis	Fœtus
Faith-cure	Food
Fallopian, and F. Tubes	Foot
Fast	Foot-rot
Fatigue	Forceps
Fats	Foundling Hospital
Favus	Fowl Cholera
Femur	Freckles
Fermentation	Frostbite

Omitted or not cross-referenced are:

Fontanelle	Formalin
Forearm	Facies
Formaldehyd	Extrauterine

*Exanthemas* is cross-referenced to *Fever*, but there is no mention there of the subject. *Excision* deserved a cross-reference to *Amputation*. *Fatness* is not referred to *Obesity*, and *Fetus* is not referred to *Fœtus*. *Exophthalmic Goiter* should have been chosen as the proper title instead of *Basedow's Disease*. Under *Explosives* no mention is made of the medical significance of the term, and under *Fish as Food* there is no account of *Fish Poisoning*. Under *Expert* there is no account of the highly important medical aspect of the subject and no reference to *Medicolegal*. *Mathematic Exhaustions* are treated to exhaustion, but the physiologic types are not held worthy of a word. The *Magnetic Field* is spoken of, and the *Field of View in Microscopy*, but no hint of the physiologic *Field of Vision*. There is a capital article on *Food*. *Faith-cure*, of course, must get three columns.

#### BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

**Laboratory Textbook of Embryology.**—By CHARLES SEDGWICK MINOR, LL.D. (Yale), D.Sc. (Oxford), Professor of Histology and Embryology in the Harvard Medical School. With 218 illustrations, chiefly original. Price, \$1.50 net. P. Blakiston's Son & Co., Philadelphia, 1903.

**Surgery of the Head.**—By BAYARD HOLMES, B.S., M.D., Professor of Surgery in the University of Illinois, Professor of Clinical Surgery in the American Medical Missionary College, Chicago, Attending Surgeon the Chicago Baptist Hospital. D. Appleton & Co., New York, 1903.

**The Concise Obstetric Book:** Designed for Systematic Recording of Obstetric Work.—Published by the Systematic Record Publishing Company, Detroit, Mich.

**Manual of Bacteriology.**—By ROBERT MUIR, M.A., M.D., F.R.C.P. (Ed.), Professor of Pathology, University of Glasgow, and JAMES RITCHIE, M.A., M.D., B.Sc., Reader in Pathology, University of Oxford. American edition (with additions), revised and edited from the third English edition, by NORMAN MACLEOD HARRIS, M.B. (Tor.), Associate in Bacteriology, Johns Hopkins University, Baltimore. With 170 illustrations. The Macmillan Company, New York, 1903.

**A Practical Treatise on Materia Medica and Therapeutics.**—By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Professor Emeritus of Materia Medica, General Therapeutics, and Hygiene, in the Jefferson Medical College of Philadelphia, formerly Professor of Materia Medica and Therapeutics and of the Practice of Medicine in the Medical College of Ohio, etc. Eleventh edition, revised and enlarged. D. Appleton & Co., New York and London, 1903.

**Cutaneous Blastomycosis.**—A Summary of the Observations of JAMES NEVINS HYDE, A.M., M.D., and FRANK HUGH MONTGOMERY, M.D., Rush Medical College, Chicago.

**The Surgical Diseases of the Genitourinary Organs.**—By E. L. KEYES, A.M., M.D., LL.D., Consulting Surgeon to the Bellevue and the Skin and Cancer Hospitals, etc., and E. L. KEYES, JR., A.B., M.D., Ph.D., Lecturer on Genitourinary Surgery, New York Polytechnic Medical School and Hospital, etc. A revision of Van Buren's and Keyes' Textbook. With 174 illustrations in the text and 10 plates, 8 of which are colored. D. Appleton & Co., New York and London, 1903.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**Smallpox**, as officially reported in the United States from December 27 to March 27, amounts to 12,744 cases and 379 deaths, as against 25,574 cases and 739 deaths for the corresponding period of last year.

**Hospital Benefactions.**—NEW YORK CITY: Mrs. A. A. Thomas and her two children have presented \$50,000 to the Manhattan Eye, Ear, and Throat Hospital for the endowment of a new ward to be known as the Samuel Thomas Memorial Ward.

**The Samuel D. Gross prize** of \$1,200 will be awarded January 1, 1904. This prize is awarded every five years to the writer of the best original essay on surgical pathology or surgical practice founded upon original investigation. Candidates must be American citizens.

**Congress of American Physicians and Surgeons.**—At the sixth triennial session to be held in Washington, May 12, 13 and 14, 16 societies of specialists will be represented, and the attendance will doubtless be very large. The session will convene May 12 at 3 p. m., and in the evening Dr. W. W. Keen, president of the Congress, will deliver an address and will later receive the delegates at the Arlington Hotel.

**Improvement in the Plague Situation at Mazatlan.**—At the present writing there have been no deaths from plague and no new cases reported. In view of the fact that the number of plague cases have greatly diminished of late, the authorities of Laredo, Tex., have decided not to enforce the rigorous quarantine which has heretofore prevailed. Persons can leave and enter this port after 48 hours under observation and careful disinfection. It is confidently expected that within a very short time the pest will be entirely stamped out.

**Leprosy in Hawaii.**—It is stated that a plan proposed by the sub-committee of the Senate on the Pacific Islands that visited Hawaii last year for the establishment of a national leprosarium on the island of Molokai is meeting with determined opposition from the inhabitants. The Legislature has even passed a remonstrance, which is expected to influence the President against the measure. Some even urge the complete abandonment of the colony planned, claiming that leprosy is gradually subsiding with the progress of civilization, better hygiene, etc. On the other hand those in favor of the leprosarium claim that within certain limits leprosy is a curable disease. Hence the necessity for a leprosarium where the disease can be promptly and scientifically treated.

**Miscellaneous.**—MARION, OHIO: The late Dr. Elizabeth L. McMahon, of this city, has left \$8,000 to found a scholarship in Vassar College for the daughters of deceased physicians. FAULKLAND, DEL.: Dr. Louis Heisler Ball, who was recently elected to the United States Senate, is said to be the second physician in active practice to become a member of that body. ST. PAUL, MINN.: Dr. Justus Ohage has been reappointed health commissioner of the city for a term of four years. BALTIMORE, MD.: The University of Maryland Medical School will receive a sum aggregating \$25,000 from the estate of the late Dr. William H. Crim. MILWAUKEE, WIS.: It is reported that Dr. G. V. Brown, a dentist of this city, will act as a representative of the American Medical Association and the National Dental Association at the International Medical Congress to be held in Madrid, Spain.

### EASTERN STATES.

**An epidemic of grip** is reported at Yale University. It is said there are between 200 and 300 cases among the law students.

**Anticigaret Bill.**—A bill which makes it a misdemeanor to sell cigarettes to any person under 21 years of age and provides for a fine of \$100 to 300 for violations has passed the Pennsylvania Legislature.

**Deathrate of Massachusetts.**—The deathrate of Massachusetts has shown a steady decrease for the last ten years. According to the State Board of Health, all the conditions are changing for the better and the mortality from tuberculosis and infectious diseases also shows an encouraging decrease. The improvement is attributed to the coming of sound, healthy immigrants.

**State Boards and Commissions.**—According to the biennial report of the Connecticut State Board of Charities recently presented to the General Assembly, the board has visited 90 institutions, including the State Prison; 11 county jails, reform and industrial schools; 14 institutions for the insane, including those under private management; schools for the feeble-minded, the deaf and blind; 18 hospitals, 8 county temporary homes for children, and 30 private homes and asylums for children and old people. As a general rule these institutions were reported to be in good condition.

## NEW YORK.

**St. John's Riverside Hospital.**—The Cochran Surgical Pavilion, an addition to the St. John's Riverside Hospital at Yonkers, N. Y., was formally dedicated March 21. The building is three stories in height and is said to be one of the best equipped in the country.

**Relief for Incurable Cancer.**—The Women's Committee having in charge the work connected with the Dominican Cancer Hospital, New York, have planned to establish a country home for the relief of afflicted patients. They make an appeal to the public for funds to assist in this charitable work. Contributions should be sent to Mrs. M. M. Alphonsa Lathrop, Rosary Hill Home, Hawthorne, West Chester county, N. Y.

**Appropriation Asked for a New Bronx Hospital.**—The Board of Trustees of the Fordham Hospital, New York, have asked for an appropriation from the \$500,000 authorized by the Hennessey bill, so that a site may be secured and plans drawn up for a new hospital for the borough of Bronx, with a view to securing its construction before the lease of the present Fordham Hospital expires. This hospital is a small emergency institution containing only 44 beds, and is declared to be entirely inadequate to care for the sick of a steadily increasing population.

**Contagious Disease Hospital for New York.**—Ground was recently broken for a new Contagious Disease Hospital, to be erected at Sixteenth street and the East river, New York City. This hospital, which will cost \$350,000, is the first one to be built on the plan of Dr. Lederle of the Department of Health to provide for cases of contagious disease. Hospitals on North Brother's Island are being repaired, and with the additional hospitals in the different boroughs, the sick suffering with contagious diseases will be more adequately provided for than ever before in the history of the city.

**The Late Dr. T. Gaillard Thomas.**—At a meeting of a committee appointed by the Medical Board of the New York Infant Asylum held March 30, 1903, the following resolutions were adopted:

WHEREAS, The late Dr. T. Gaillard Thomas for several years and at the time of his death was consulting obstetrician of the New York Infant Asylum, and president of the Medical Board, an office in which he exhibited wise counsel and charming geniality; and

WHEREAS, Dr. Thomas was a man of great eminence, well known to the medical profession throughout the world, by virtue of whose character and renown much honor was reflected upon this institution; therefore

Be it resolved, That the Medical Board of the New York Infant Asylum record the death of Dr. Thomas with a sense of deep regret and inexpressible loss; and further

Be it resolved, That a copy of these minutes be sent to the bereaved family, and to the principal medical journals, and inscribed in the records of the New York Infant Asylum.

## PHILADELPHIA, PENNSYLVANIA, ETC.

**Whipping of Children Restricted.**—A statute which recently became operative in New Jersey makes it a misdemeanor punishable by six months in jail or a fine of \$100 to punish a child to such an extent that its health is endangered.

**Sanitary Legislation.**—A bill has passed the New Jersey Assembly which prohibits any person who is believed to be suffering from any infectious or contagious disease from appearing in a public street or place, and it also prohibits persons from renting or leasing any building or room that has been infected.

**New Frankford Hospital.**—A charter has been obtained for the new hospital which is to be erected in Frankford and to be known as the Frankford Hospital. The board of directors will be assisted in superintending and managing the hospital by a woman's auxiliary corps, which is to be organized in the near future. Many civic, beneficial, and industrial organizations in Frankford have offered to contribute to the hospital fund, and others are offering to raise money by holding entertainments.

**Smallpox at Stevens Point.**—News comes that 21 of the 54 persons in the little village of Stevens Point, near Susquehanna, Pa., were stricken with smallpox before the nature of the malady was discovered. It appears that the disease was brought to the locality by a man who had been working in New Jersey. Returning to Stevens Point he developed what was termed the "itch." No physician was called and many persons in the community were exposed. Later when a doctor was called in the true nature of the malady was discovered.

**Erection of Contagious Disease Hospitals.**—Governor Pennypacker has approved a bill permitting cities of the second class to acquire grounds outside of the city limits on which to erect a hospital for the care of contagious disease cases. The approval of the bill will enable Philadelphia to have its Municipal Hospital outside of the city limits within any of the adjoining counties, and the authorities in these counties will have no power to stop the location of the Philadelphia pesthouse within their boundaries. It appears that this feature of the bill was not recognized except by a few until after it had passed and been signed by the Governor.

## SOUTHERN STATES.

**The Texas State Board of Medical Examiners** will meet in Austin, Texas, April 20, 21, 22 and 23.

**Diphtheria at Norfolk Navy Yard.**—It is reported that 20 cases of diphtheria have developed among the 1,500 men stationed at the Norfolk Navy Yard on the receiving ships "Franklin" and "Richmond." Both of the ships have been placed in quarantine, and the men suffering from the disease have been transferred to the naval hospital.

**Antispitting Crusade in Washington.**—There is a movement under way in Washington for the enactment of a law prohibiting expectoration on the sidewalks. It is made an offense to spit on any sidewalk in the city, and violations are punishable by fine and imprisonment. Policemen are authorized to arrest for the offense any person they see committing it. The law will permit persons who want to spit to step to the curb to do so.

**Legislation in Florida.**—A bill is now being prepared by the committee on legislation of the Florida Medical Association providing for a general medical examining board, and an earnest effort will be made to secure the passage of the measure. Circular letters have been sent to all the members of the association throughout the State requesting their active cooperation and support in the effort to substitute a central State board of examiners for the district boards provided for under the present system, which has proved to be unsatisfactory in its operation. A similar measure was defeated at the last session of the Florida Legislature largely through the efforts of an irregular so-called medical institute.—[*New York Medical Journal.*]

## WESTERN STATES.

**Cigarets Barred Out of Wisconsin.**—An anticigarette bill has passed the Assembly. It prohibits the manufacture of or the sale of cigarettes or cigarette paper in the State, and becomes operative July 1.

**Augustana Hospital, Chicago.**—It is reported that a new building will be added to this hospital some time in the near future. It will be a fireproof structure six stories in height and it is estimated will cost \$100,000.

**Hospital for Epileptics at Gallipolis, Ohio.**—The report of the board of trustees of this hospital, which was recently filed with Governor Nash, severely criticises the former boards of the hospital. Dr. Fuller, the former superintendent of the hospital, will ask for an investigation into the charges contained in this report.

**California State Board of Health.**—Governor Pardee has formed the new State Board of Health. Its members are Dr. O. Stansbury, of Chico; Dr. Wallace Briggs, of Sacramento; Dr. Martin Regensburger, of San Francisco; Dr. N. K. Foster, of Oakland, and Dr. A. C. Hart, of Sacramento. On March 17 a case of plague was discovered in San Francisco. The patient was a Japanese girl.

**Hydrophobia Among Horses.**—It is asserted that hydrophobia exists among cattle and horses to an alarming extent throughout Wisconsin. The State Veterinarian has refused to order the killing of any more animals, stating that it would end in bankruptcy to the State, as under the law owners of diseased cattle killed are paid for them. The disease was started by mad dogs that ran through the State.

**An antismoke ordinance** has been passed by the Chicago City Council. The ordinance requires the department for the inspection of steam boilers and steam plants to pass on smoke devices and plans for constructing steam plants, and also requires the supervising engineer to give the owner of a smoke-making plant such advice and assistance as will in his judgment prevent the emission of dense smoke.

**Nottingham Bill.**—The measure known as the Nottingham bill, which was introduced into the Michigan Legislature, is designed by its author to raise the standard of examination, and requires graduates to pass examination before the medical board, regardless of the medical college from which they were graduated. It favors reciprocity with other States and raises the standard of entrance into the medical colleges. It is stated that a vigorous protest has been entered against the bill by the students of the three medical colleges of Detroit. These sent a delegation to Lansing to present their protest to the proper committee.

**Mortality in Chicago.**—According to the Bulletin of the Health Department of Chicago at the close of record hours on Saturday, March 21, there had been registered a total of 679 deaths from tuberculosis, and of 1,455 deaths from pneumonia since the first of the year. During the corresponding period of 1902 the respective totals were 619 from tuberculosis, and 1,095 from pneumonia. These figures show increases of 9.6% of tuberculosis mortality, and 32.8% of pneumonia mortality. And they also show that the excess of pneumonia mortality over tuberculosis mortality—which was 76% in 1902—has risen to 114% this year.

## FOREIGN NEWS AND NOTES

## GENERAL.

**Miscellaneous.**—The University of Halle has conferred a gold medal on Professor J. P. Pawlow, of St. Petersburg, for his research on digestion.

**Plague in India.**—The number of plague cases throughout India is steadily increasing. During the week ended March 14 there were 25,882 cases, as against 25,870 for the week previous and 12,695 cases for the corresponding week of last year.

**Plague and Rats.**—According to the *Allahabad Pioneer*, of Bombay, the municipal committee appointed to take precaution against the spread of the plague has had to desist from the extermination of rats on account of the violent protest of the native population against the killing of animals, particularly rats. In consequence the committee was compelled to offer a reward for rats taken alive, to confine them and to pay a certain sum for their sustenance until the plague should be combated.

## GREAT BRITAIN.

**A Sanitary Congress** to consider matters of international importance will be held at Bradford, Eng., from July 7 to 11. United States representatives are invited to attend.

**Medals for American Nurses.**—It is asserted that instructions have been given to issue war medals for presentation to the five American women nurses who served on the hospital ship "Maine" in South African and Chinese waters.

**Mistakes in the Diagnosis of Infectious Diseases.**—The committee of the London Metropolitan Asylums Board has issued a most interesting report showing the cases of mistaken diagnosis sent to their board's hospitals during the last three years. In 1899 1,583 cases were sent which were not notifiable diseases—a percentage of mistakes of 6.3. In 1900 the number was 1,706, a percentage of 7.9; and in 1901 the number was 2,365—a percentage of 9.2. The percentage on the total cases for scarlet fever, 5.6; diphtheria, 12.8; and typhoid fever 25.5. Among the diseases diagnosed as scarlet fever were measles, rubella, tonsillitis and erythema. Measles was returned as diphtheria in 47 cases, and tonsillitis as diphtheria in 880 cases. Among the cases wrongly certified as typhoid fever were 13 of influenza, 22 of febricula, 9 of bronchitis, and 86 of pneumonia. Of notified cases of smallpox the diagnosis was mistaken in 13% of the cases.—[*Journal American Medical Association.*]

## CONTINENTAL EUROPE.

**Comparison of the Physicians' and Lawyers' Incomes in Germany.**—In Berlin the average income is higher in the legal than in the medical profession. Eight per cent of the barristers and 4.7% of the medical men have incomes from \$3,750 to \$5,000, while 8% of the barristers and 7% of the physicians have incomes exceeding \$5,000.

**Paris Academy of Sciences Elects Dr. Koch.**—Dr. Robert Koch has been elected a member (associate foreign) of the Academy of Sciences of Paris to fill the vacancy created by the death of Professor Virchow. The candidates voted for were Koch, Agassiz (Harvard), Langley (Washington), and Van der Vaals (Amsterdam). The votes received by each were respectively 26, 18, 6 and 1.

**The Tenth Congress of the Polish Physicians and Scientists**, which was to meet in Lemberg, Austria, in July, 1903, has been postponed until the same month in 1904, on account of the several international meetings which have either taken place recently or will occur during the current year. Dr. Francis E. Fronczak, of Buffalo, has been appointed delegate for the United States to interest the Polish physicians and scientists in America to take part in the congress. Several have already promised to do so, and out of the 80 physicians of Polish descent here in America it is hoped that at least 10 will travel to Austrian Poland to assist actively in the proceedings.

## OBITUARIES.

**Robert S. Newton**, a well-known alienist and neurologist, died at his home in New York City, March 25, aged 45. He studied at the Eclectic Medical College and the New York College of Physicians and Surgeons, afterward studying and practicing in Paris, Vienna, London, and Berlin. In 1892 he received the degree of Doctor of Medicine from the New York University. He was a member of many American and foreign societies, among them the County Medical Society, the Neurological Society, and the Society of Medical Jurisprudence, and was attending physician at St. Mary's Hospital, Brooklyn, and at the Presbyterian Hospital, of which he was appointed class head in diseases of the nervous system. Dr. Newton has often figured as an expert witness at criminal trials.

**Walter S. Leaming**, of Cape May, N. J., March 29, aged 49. He was graduated from the Jefferson Medical College, Philadelphia, in 1882. He was a member of the New Jersey Assembly in 1888 and State

Senator for the three years following, and was three years president of the Cape May City Council and one year city treasurer.

**Charles H. Jones**, in Brooklyn, N. Y., aged 85. He was graduated from the Long Island College Hospital in 1899. He served as a captain in the One Hundred and Fourteenth Regiment, New York Volunteers, during the Spanish-American war and was captain of the Third Gatling Battery at the time of his death.

**Samuel W. McJunken**, in Terrell, Texas, March 8, aged 48. He was graduated from the Medical College of the State of South Carolina, Charleston, in 1875. He was assistant physician at the North Texas Hospital for the Insane and a member of the Dallas Medical and Surgical Society.

**John G. Giles**, of Athens, Ont., died at the General Hospital in Brockville, Ont., March 12, aged 69. He was graduated from the faculty of medicine of Queen's University and Royal College of Physicians and Surgeons, Kingston, Ont., in 1860.

**Alvin J. Cole**, in Fort Madison, Iowa, March 6, aged 65. He was graduated from the University of Michigan, Ann Arbor, in 1860. Throughout the Civil war he served as surgeon of the Fourteenth Michigan Volunteer Infantry.

**Herbert McAuley**, of Chicago, died at Joliet, Ill., March 24, aged 32. He was graduated from the Kentucky School of Medicine, Louisville, in 1889. He was the organizer of the Chicago hospital corps which served in the Boer war.

**James O. Berlin**, of Bath, Pa., died at the University of Pennsylvania Hospital, Philadelphia, March 24. He was graduated from the Jefferson Medical College, Philadelphia, in 1874.

**Nathan Udell**, of Centerville, Iowa, died in Denver, Col., March 6, aged 86. He was graduated from the College of Physicians and Surgeons, Keokuk, Iowa, in 1855.

**Norman H. Getman** died recently at his home in Richfield Springs, N. Y. He was graduated from the Homeopathic Hospital College, Cleveland, in 1854.

**Patrick N. Kelly**, of Wabasha, Minn., died at Pine Island, Minn., March 14, aged 46. He was graduated from McGill University, Montreal, in 1884.

**D. Gilbert Gordon**, of Toronto, Can., died in Baltimore, Md., March 28. He was graduated from the Trinity Medical College, Toronto, Ont., in 1886.

**Walter W. Bunyan**, in Chicago, Ill., March 16, aged 26. He was graduated from the Northwestern University Medical School, Chicago, in 1901.

**Lavoisier H. Gratigny**, in Cincinnati, Ohio, March 7, aged 62. He was graduated from the Starling Medical College, Columbus, Ohio, in 1864.

**Fostus A. Snear**, in Bryan, Ohio, March 10, aged 53. He was graduated from the Cincinnati College of Medicine and Surgery in 1872.

**James Douglas**, of Jamestown, N. Y., March 22. He was graduated from the medical department of the New York University in 1880.

**Charles F. Parker**, at Boston, Mass., March 26. He was graduated from the medical department of the University of Vermont in 1883.

**Charles D. E. Ball**, of Boston, Mass., March 29, aged 45. He was graduated from the University of Maryland School of Medicine in 1880.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

COMPARISON BETWEEN ABDOMINAL AND VAGINAL SECTION FOR PELVIC DISEASE.<sup>1</sup>

BY

C. WILMOT TOWNSEND, M.D.,  
of New Brighton, S. I.

This paper includes my observations of 50 or more cases in which I have operated by vaginal or abdominal section. In looking over the figures one is struck by the fact that the mortality for the upper and lower operations is nearly two to one in favor of the latter.

The vaginal sections were made for the most part for the relief of suppurative processes of the tubes and ovaries, whereas the operations by the abdominal route included a number for the removal of newgrowths.

A classification of the operations under the head of the organ operated on or removed follows:

Hysterectomy, 12 . . . . .	vaginal, 7 abdominal, 5—1 death
Oophorectomy, 9 . . . . .	vaginal, 2 abdominal, 7—1 death
Salpingotomy, 13 . . . . .	all vaginal—1 death
Salpingoophorectomy, 8 . . . . .	vaginal, 2 abdominal, 6
Relief of ectopic gestation, 10 . . . . .	vaginal, 4—1 death abdominal, 6

Those cases in which the combined operation was performed are classed under the abdominal route. Considering them by groups we find that hysterectomy was performed 12 times for the relief of the following conditions: Chronic metritis, 1; uterine fibroids, 2; carcinoma of the uterus, 4; puerperal septicemia, 3; prolapse of the uterus, 2. The one fatal case was that of a severe form of puerperal sepsis and the hysterectomy apparently did not affect the result one way or the other. The patient lived for two days after the operation, running a continuous temperature of 106°.

In choosing the route for performing the hysterectomy I found that for sepsis and complete proclitania the vaginal method is much preferable; as in the former group of cases the patient is usually much debilitated by parturition and septicemia and it is very important to avoid the shock of opening the abdomen. The vaginal section save time and provides an efficient means of drainage. In the latter group the age of the patient suggests the lower operation on account of the saving of time and of shock. For uterine fibroids and chronic inflammatory conditions of the uterus so severe as to necessitate an operation I prefer to do an abdominal hysterectomy leaving in the cervix as affording a more perfect pelvic floor.

*Oophorectomy* for chronic oophoritis and cysts of the ovary demands in almost all cases an abdominal section as affording a more thorough removal of the diseased organ. The two operations through the vagina were for ovarian cyst lying in Douglas' culdesac. The cysts were punctured, pedicles ligated, and were then removed by means of scissors. However, in my opinion, the abdominal method will, as a rule give better results as it enables a more complete removal of the diseased tissue. The one death was due to the untying of a catgut ligature, allowing a large hemorrhage to occur in the pelvis before it was discovered.

*Salpingotomy.*—The 13 cases reported under this head were all for the relief of pus in the tubes and frequently also in the peritoneal cavity. This is by far the most brilliant field for vaginal section. A pus tube taken early and thoroughly drained through the vagina will heal, and a few months later it will be hardly possible to discover by examination or even by inspection, if the abdomen perchance be opened for some other condition, that the tube ever contained pus. Indeed, the cure is so perfect that the fallopian tube will be able to resume its functions as an oviduct, and normal uterine pregnancy has occurred

<sup>1</sup> Read at the annual meeting of the Richmond County (N. Y.) Medical Society, January 14, 1903.

after such an operation. This really wonderful restoration is consummated as a rule only in early cases. Those of long-continued suppuration will not give such excellent results, but by an operation, comparatively free from danger, we can make our patient so well that she will consider herself cured. The one death in this group was due to shock and sepsis in a patient much debilitated by prolonged suppuration and with an exudate which extended to her umbilicus.

*Salpingoophorectomy.*—Here again the abdominal route is, as a rule, preferable. In two cases the tubes and ovaries were removed through the vagina, but there is always more or less difficulty in controlling the hemorrhage by ligatures. The abdominal method gives a cleaner and more surgically perfect result.

*Ectopic Gestation.*—For the relief of this condition six patients were treated abdominally and four by the vagina, with one death from sepsis by the latter method. It seems to me that a very definite rule can be laid down for the treatment of these patients: When hemorrhage from the ruptured tube has ceased and the blood settles in Douglas' culdesac a vaginal section is the proper method of relief; but when active bleeding has not ceased and the blood has accumulated among the intestinal folds above the pelvis an abdominal section, and that only, will avail. I can recall a case in which, after opening through the vagina and drawing out a large quantity of blood, the patient was about to leave the operating-room when my attention was called to her rapidly increasing pulse. I had her returned to the table, rapidly opened the abdomen and found a bleeding vessel above my pelvic packing, which in no possible manner could have controlled the hemorrhage. The vessel was tied and the patient made an uninterrupted recovery.

In view of the cases cited I feel justified in stating that while each operation has its special field neither operation will ever supplant the other. The ease of its performance and the excellent drainage it affords will ever recommend the vaginal route for a certain limited number of cases, but the abdominal method holds in my estimation a superior place in the field of surgery, as it allows a more perfect visual examination and consequently a more finished result.

GUNSHOT WOUND OF ABDOMEN.

BY

R. E. L. BARNUM, M.D.,  
of Richland, Ga.

On November 25, 1902, Milton Crump, a negro man, aged 35, received a gunshot wound of the abdomen. I was called in consultation with Dr. C. E. Pickett. The wound was made by a revolver at close range in a hand-to-hand fight. The ball entered the abdomen about one inch above the umbilicus and a little to the right. On introducing a probe it took a downward course pointing toward the right iliac region. The probe passed 1½ or 2 inches through the abdominal parietes, obliquely, before it pierced the peritoneum, then, as a matter of course, the track of the bullet was lost. I advised laparotomy at once. The wound was received about 4 p.m., and by 7 p.m. everything was in readiness for the operation. There was but slight evidence of shock or hemorrhage. The patient was given hypodermically 16 mg. (½ gr.) morphia and .4 mg. (⅙ gr.) atropin. His surroundings were very unfavorable for asepsis. The size of room was about 14x14 feet, with dingy cobweb walls and dirty floor. The bedding was also in a deplorably soiled condition. I had the floor swept and wiped up with a damp cloth. The walls were left untouched. While other preparations were going on, the instruments were being boiled in a kettle on the stove. A clean sheet was spread over a small table upon which were placed the instruments and dressings. The patient was anesthetized by Dr. Pickett, and with the assistance of Dr. W. F. McCurdy the operation proceeded. The abdomen was well scrubbed with soap and shaved, and then washed with bichlorid solution, 1-3,000. Clean towels wrung out of hot water were then placed about the field of operation. The incision was made from a point just beneath the umbilicus in the median line and extended 3½ or 4 inches downward. There was little evidence of hemorrhage in the abdominal cavity, and none whatever of the escape of intestinal contents. The intestines were then thoroughly examined so far as they could be well withdrawn, and no puncture could be found. Not being satisfied with this, the incision was extended 2½ or 3 inches upward to the right of the umbilicus, where the remaining portion of the upper intestine was easily reached. Here were found three ugly wounds of the intestine; two of them being

on opposite sides of the gut, the ball having passed through and through, the other about 6 inches distant and about 2 inches long being longitudinal with the axis of the gut. The upper intestines were found perfectly empty, and on inquiry it was ascertained that the patient had not eaten a mouthful of food since breakfast, an incident very much in his favor. The edges of the wounds were then carefully pared, all shreds and bruised tissues being cut away. They were then closed with a double row of sutures, the Czerney-Lembert stitch being employed. Common black silk sewing thread No. C with round sewing needle No. 5 was used. The intestines were then thoroughly washed with plain hot water and the abdominal cavity well flushed out with the same. The intestines being replaced the abdominal wound was then closed with surgeon's silk, the through-and-through or mass suture being employed. No drainage. A superficial row of sutures was also used to thoroughly coaptate the outer edges. Adhesive strips of zinc oxid plaster were placed over all. The application of iodoform gauze, cotton, and roller bandages completed the dressing. No search was made for the bullet. A second shot was received accidentally in the thigh, the ball entering the anterior aspect, and was found under the skin at the opposite point posteriorly. This was removed by a small incision, which was closed by sutures and dressed aseptically. The operation was completed in about one hour, four hours from the time of receiving the wounds. The patient was then placed in bed, which meanwhile had been replenished with clean sheets, etc. He rallied well from the operation. Next morning his temperature was 101.4°, pulse 90 with good volume. The second day after operation temperature 99.4°, pulse 86. Pulse and temperature continued about the same until the sixth day, when his temperature went to 98.4° and his pulse was 84. No food of any kind was allowed for the first 24 hours. Dressing was changed for the first time on the fifth day, when the wound was found united throughout. The deep row of stitches was removed and adhesive strips reapplied. An occasional dose of morphia had been given to keep the bowels locked. On the fourth day an enema of soapsuds was given, which cleared the lower bowel of a large quantity of fecal matter. On the seventh day no spontaneous movement of bowels having occurred one ounce of olive oil was given, which resulted about 4 p.m. in a good, free, through-and-through movement. After the first 24 hours the patient was allowed soup and milk at stated intervals and kept on a simple liquid diet for about two weeks. The wound was dressed the second time on the ninth day, when the superficial row of sutures was removed. At this time the patient complained of sharp pain at the crest of the right ilium. On examination the bullet was found just beneath the skin. A small incision was made without anesthesia, a No. 38 bullet removed, and the incision closed with a couple of sutures and dressed aseptically. The locality of the bullet accounted for the direction taken by the probe and demonstrated the fact that the patient was in a stooping position and his body almost horizontal with the revolver when it was fired. Neither of the small incisions gave any trouble, both uniting by first intention. At the time of second dressing a small stitch-hole abscess had developed around one of the superficial sutures. This was opened up and thoroughly washed out with bichlorid solution 1-3,000. Adhesive strips were kept on for several weeks and reinforced by pad and roller bandage until union was firm. The patient made a complete recovery and is now engaged at his usual occupation, farming.

This operation, done by the dim light of a smoky kerosene lamp and with the assistance of untrained negroes, is reported to show what results can sometimes be obtained under the most unfavorable surroundings and under the most trying difficulties, and in the hope that it may encourage some other young surgeon, when, like myself, he comes to do his first laparotomy.

## ATROPIN POISONING FROM OCULAR INSTILLATIONS.

BY

S. EDITH IVES, M.D.,  
of Middletown, Conn.

The patient, a girl aged 5, had internal strabismus. After making a preliminary examination I ordered atropin sulfate, 65 mg. (gr. 1), with distilled water 8 cc. (dr. 2), one drop in each eye three times a day. I saw the patient on Sunday and gave orders for her to return on Tuesday, the drops to have been used as directed. Before she left the office, I instilled one drop in each eye to show the father how I wished it done. On Tuesday the child returned to me, having had altogether six drops in each eye. My first thought on seeing her was that the pupils were not sufficiently dilated for a thorough retinoscopic examination, on which I was depending for determination of the refractive error, as the child did not know her letters. However I retinoscoped her, and during the examination noticed that she was quite restless, pulling at her dress and occasionally addressing her cousin (a girl of 13) as "mamma." I did not think, however, that her condition amounted to anything, so

told the cousin to continue the drops and bring her to me the following day, expecting the pupils to have been fully dilated by that time. In the evening of the same day, Tuesday, the mother of the child came to me in great alarm, saying the little girl was "entirely crazy." I went to the house and found the child in an active delirium. She was in her father's arms, and he had difficulty in restraining her. She wanted to get up and walk around, picking up imaginary articles off the floor, jerking her hands and feet. This condition lasted until seven o'clock the next morning, so that she had active delirium for 12 hours. During the next 12 hours she slept off and on and gradually quieted down.

The mother told me the child had not been herself since her first visit to my office. She was restless, not sleeping at night, so evidently the first instillation of atropin affected her. During the period of poisoning there was no fever and no rash; delirium seemed to be the only symptom. The peculiar feature of the case was that after six drops of the atropin solution in each eye there should not be full dilation of the pupils.

I thought there might possibly have been a mistake in putting up the prescription, but a chemist who analyzed it for me pronounced the drug atropin.

## SALIVARY FISTULA CAUSED BY STENOSIS OF THE PAROTID DUCT; OPERATION; RECOVERY.<sup>1</sup>

BY

FREDERIC GRIFFITH, M.D.,

of New York City.

Surgeon Bellevue Dispensary; Fellow of the New York Academy of Medicine.

The following is the history of a case of obstruction of Stenson's duct, due to the inflammatory reaction of the soft parts of the cheek to a ragged molar tooth:

The patient, a male of 17, called at the hospital for treatment of a salivary fistula upon the left side of his face. Upon examination I found a well marked sinus which admitted the end of a probe, upward and backward for a distance of about an inch. The probable cause of the sinus was an ulcerated tooth from which he had suffered some six months before I saw him. Saliva flowed continuously from the sinus causing excoriation of the skin of the cheek. Various measures for the relief of the condition had been tried, such as suturing the opening and the application of lunar caustic.

My treatment consisted in carrying out the method suggested by Hayes Agnew, namely, ligation of the sinus within the mouth. With a curved needle, threaded with silk, a puncture was made below the duct, at a point inside the mouth, about opposite that of the opening of the duct upon the right side. The needle was passed onward well in (toward the skin surface of the cheek), then brought out above; the ligature, drawn through, was tied tight and cut short. The new opening cut through during the course of three or four days. The lower sinus had meanwhile closed. A perfect outlet was thus secured for the saliva, within the mouth, and the cheek healed with no indentation, and but little scarring.

## TO CUT SURGEONS' BANDAGES.

BY

L. W. SPRADLING, M.D.,

of Athens, Tenn.

Take the whole width and length of a piece of muslin or bandage material, roll it on the table into a tight roll the width of the material; hold the roll in the left hand and cut off end sections of the width wanted with a sharp knife after sticking a pin through the section to be cut, which keeps it from slipping and unwrapping. In this way bandages are already rolled for emergency and do not unravel.

DR. B. H. MCCALLON'S SOLUTION OF STRYCHNIN SULFATE.

Strychnin sulfate . . . . .	.5 gram (gr. 8)
Diluted acetic acid . . . . .	4 cc. (31)
Alcohol . . . . .	30 cc. (31)
Mix.	

This solution is permanent and readily miscible and contains 1 mg. ( $\frac{1}{100}$  grain) to each drop. It is very convenient and much more active than the tablet method or solutions of the United States Pharmacopoeia.

<sup>1</sup> Presented at the New York Academy of Medicine, Surgical Section, 1903.

THE USE OF COMPRESSED AIR TO ENHANCE AND PROLONG THE ACTION OF REMEDIES UPON THE CEREBROSPINAL AXIS: SYNOPSIS OF EXPERIENCES IN APPLYING THE METHOD OVER SIX THOUSAND TIMES.

BY

J. LEONARD CORNING, M.D., LL.D.,  
of New York City.

To squeeze within a definition or a formula the significance of some chosen field of human activity, some dignified pursuit or discipline, seems perennially to commend itself to two quite opposite types of mind—to the philosopher, because of its hair-splitting possibilities; to the humorist by reason of its mirth-making opportunities. Even such serious business as the practice of medicine has not been able to defend itself against these warring propensities. Only recently I have been reminded of the humorous aspect of the incursion. Loitering amid the miscellany of a medical publication, my eye was halted by this bit of facetious wisdom: "Neurology is the art of giving sedatives and stimulants!" Shades of Æsculapian propriety! The very proposition made the wits jump; each syllable exhaled a unique fallaciousness. And yet, even extravagance may have its uses. Masked by the cheap clatter of the sophistry, a temperate discernment may find the modicum of truth. Yes, sedatives and stimulants, while but a part, are certainly an important part of our neurotherapeutic resources. So long as, in the management of disease, it shall be deemed worth while to exalt or depress the functions of the nervous system, just so long this tenure is secure. Holding, then, a high place in the regard of the profession, their usage sanctioned by invincible necessity, it becomes a matter of high importance to render their exhibition as secure and effective as possible.

Agreeable to this conclusion, I have sought, in the present paper, to embody in a brief synopsis the results of my investigations and experience with compressed air, as a means of focalizing the action of remedies upon the brain and spinal cord.

Condensed air has been extensively used in the profession to facilitate the introduction of gases, medicated or nonmedicated, by way of the lungs. This, however, was not the purpose I had in mind when, in 1891,<sup>1</sup> I published my first paper on the neurotherapeutics of compressed air. In contradistinction to my predecessors, what I then sought to demonstrate was the possibility of enhancing and perpetuating the effects upon the cerebrospinal axis of certain stimulants and sedatives, when exhibited while the subject remained in air condensed more or less beyond that of the normal atmosphere. As the experiments and arguments brought forward were originally set forth with considerable attention to detail, I cannot do better than recall their more important features.

By proceeding in this fashion—following in some sort the first shaping of the idea—those who read will win, I hope, an appreciation of the position maintained by me without undue strain upon forbearance or attention.

The fundamental proposition of the argument may be thus stated:

The pharmacodynamic potency of certain stimulants, sedatives, analgesics, and probably of all remedies which possess a chemical affinity for nervous matter, is enhanced by exhibiting them (the remedies) in solution or soluble form—hypodermically, by the mouth, or per rectum—

while the subject remains in a condensed atmosphere. And, as a corollary, it may be stated that this increase, this enhancement of the action of the remedy is, within certain limits, in the ratio of the atmospheric condensation.

To express this truth mathematically is not difficult. Thus, when  $a$  represents the amount of blood of the whole body,  $b$  the amount of the remedy,  $e$  the amount of atmospheric compression, and  $x$  the pharmacodynamic potentiality which we are seeking, we shall then have the simple formula

$$x = \frac{b \times e}{a}$$

A definite conception of the truth of this proposition will, I think, be more readily attained by the presentation of the steps which led me to its discovery.

Let me begin, then, by stating that my attention was attracted several years ago by that unique complex of symptoms known as the "caisson or tunnel disease." As most physicians are aware, the caisson disease is an affection of the spinal cord, due to a sudden transition from a relatively high atmospheric pressure to one much lower. Hence, those who work in caissons or submerged tunnels under an external pressure of two atmospheres or even more are liable to be attacked by the disease shortly after leaving the tunnel. The seizure never, however,

FIG. 1

occurs while the subject is in the caisson, or in other words, while he remains under pressure. Moreover, when the transition from the condensed atmosphere to that of ordinary density is gradually accomplished, which may be done by letting the air escape from the lock very slowly, caisson disease is rarely if ever set up. It is the systematic disregard of this principle by those who work in compressed air that is responsible, or largely responsible, for the occurrence of the disease.

The chief clinical features of caisson disease are pain, which may be relatively mild, as when confined to a circumscribed area of one extremity, or of frightful intensity, as when it appears in the ears, knees, back, or abdomen; anesthesia and paralysis, usually of paraplegic type; bladder symptoms, assuming the form of retention or incontinence; and, more rarely, rectal disturbances (usually incontinence).

These phenomena, or, rather, some of them, appear some time within half an hour after the subject has left the compressed atmosphere. It was while investigating this most interesting affection as it occurred in the course of the construction of the Hudson river tunnel that I was able at the same time to study the effects of compressed air upon the organism, and especially upon the

<sup>1</sup>"The Use of Compressed Air in Conjunction with Medicinal Solutions in the Treatment of Nervous and Mental Affections." *The Medical Record*, August 29, 1891. Also amplified in my monograph, "Pain," J. B. Lippincott Company, Philadelphia, 1894.

nervous system, as exhibited in a large number of persons.

Without anticipating, however, let me state that the first thing which impressed me about compressed air was the extraordinary effect upon cerebral and cerebrospinal function.

Those who remain for a certain length of time—not too long, however—in the condensed atmosphere exhibit a most striking exacerbation of mental and physical vigor. They go up and down ladders, lift heavy weights, are somewhat exhilarated, and, in short, behave as though slightly under the influence of a stimulant.

Hardly had I observed these things, which are perfectly well known to those who have been able to familiarize themselves with the ordinary effects of compressed air as used in caissons and submarine works of various kinds, when my attention became attracted by what at first appeared to be a phenomenon of trivial importance. In a word, I observed that some of the men exposed to the effects of the compressed air were more exhilarated by it than others. Upon superficial reflection one might have supposed that this discrepancy in physiologic effect was to be accounted for merely on the basis of constitutional idiosyncrasy; maturer thought, however, convinced me that the exaggerated effects of the condensed air were both too numerous and too constant to be amenable to such an explanation. This led me to study the habits of the men; and thus it was that I arrived at a discovery of real practical value to neurotherapy. Briefly, I found that certain of the men were accustomed, before entering the compressed air, to drink a moderate quantity of alcohol. So long as they remained outside the tunnel, where the atmospheric conditions were normal, they were not visibly affected by their potations. When, however, they entered the compressed air of the tunnel, but a short time elapsed before they became exhilarated to an inordinate degree, acting, as one of the foremen graphically expressed it, "as though they owned the town."

On the other hand, when the customary draught of alcohol was withheld from them, these evidences of motor and mental exhilaration were entirely wanting.

The effects of alcohol, then, are enhanced by exposing the subject to the influence of air condensed to a considerable degree beyond that of the normal atmosphere.

Acting on the hint derived from this discovery, I administered ether, champagne, ammonia, and other stimulants, before exposing the subject to the influence of the condensed air, and invariably observed analogous effects, *i. e.*, palpable augmentation of the physiologic effects of the remedy.

Upon what principle does this augmentation of physiologic effect depend? How is it to be accounted for?

In my opinion, the answer to this question may be given as follows: In the first place, we know that the primary effect of the compressed air upon the organism must be to force the blood from the surface of the body toward the interior, and especially into the cerebrospinal canal. Or to express it more succinctly, the blood will be forced in the direction of the least resistance—that is, into the soft organs enclosed by bony walls, which latter completely shut out the element of counter-pressure. Now, when the bloodstream is freighted with a soluble chemical of some sort—let us say, for the present, with alcohol—this medicated blood will exert its greatest chemical effect where the tension—the pressure—is greatest; that is, in the cerebrospinal canal. The reason for this is found in the fact that endosmosis is most pronounced where the blood-pressure is greatest. This explanation of why the effects of alcohol are enhanced by exposing the individual who has taken it to the effects of a condensed atmosphere will, I believe, appeal to the physiologic conceptions of most medical men. It was the above course of reasoning which, at this stage of the argument, led me to the idea that, just

as the effects of stimulating substances are enhanced by exposing the subject to the influence of compressed air, so inversely sedatives and analgesics, when brought in solution into the bloodstream, either hypodermically or by the stomach, might be greatly enhanced in effect by causing the subject to remain, while under their influence, in a condensed atmosphere.

When I came to investigate the validity of these predictions, as I did shortly after the introduction of antipyrin, phenacetin, and other related compounds, I found my predictions verified, and, indeed exceeded. To summarize the whole matter, I ascertained that not only could therapeutic effects be obtained from much smaller doses by exposing the subjects to the influence of a condensed atmosphere, but, what was of equal interest, I found that the analgesic influence of the remedies was much more permanent, was prolonged, in short, by this mode of administration. With regard to the latter point—the prolongation of the effect of the remedy—there is a notable fact in connection with the physiologic action of compressed air that will help to a rational explanation. It is a matter of experience that the heart beat increases in frequency and the blood-pressure is raised while the subject remains in compressed air. On coming once more, however, into the normal atmosphere the conditions are reversed; the frequency of the heart's action is diminished and there is a notable falling off in the fullness of the pulse. These two factors—decreased frequency of the heart and diminished arterial tension—while asserting their influence throughout the organism, are bound to exert their greatest sway in the realm of the cerebrospinal circulation. The functional efficiency of the brain and spinal cord is especially dependent upon adequate oxidation and elimination of waste products. The evidence on this point—clinical and experimental alike—is overwhelming. Here activity of the circulation, even more than in the muscle, means enhancement of function; while sluggishness is no less certainly followed by decline. And it is worth remembering that this decline of function is contingent upon inadequate elimination of waste no less than upon curtailment of oxidation. These considerations, though perhaps a little aside from the argument, will help, none the less, to an intelligent answer of the chief question: Why are the effects of certain remedies upon the cerebrospinal axis perpetuated beyond the usual by this exhibition while the subject remains in a compressed atmosphere?

Briefly, we have merely to think of the decreased elimination consequent upon retardation of the circulation after the emergence of the subject from the compressed air to realize that the deportation of the medication from the tissues must share in the delay. Allowed thus to linger beyond the ordinary in the field of action the effect of the remedy is proportionately prolonged. I can conceive of no other explanation, and pending the arrival of something better, it may be accepted as the true one.

*The Power of Compressed Air to Increase the Effect of Remedies Upon the Cerebrospinal Axis May be Heightened by the Simultaneous Exhibition of Substances Which Dilate the Capillaries.*—I desire to draw attention now to a supplementary expedient in connection with the neurotherapeutic use of compressed air, an expedient which experience has taught me is of no little practical value in the management of various morbid conditions of intraspinal or intracranial origin, and more especially of the painful crises of ataxia, intractable insomnia, spinal irritation, melancholy of the simple, nondelusional type; headache, especially megrim, and impairment of memory due to functional causes.

It has long been known to me that when agents which cause relaxation of the capillaries—nitroglycerin, amyl nitrate—are exhibited jointly with sedatives or stimulants while the subject remains in compressed air an increased pharmacodynamic effect ensues, an enhance-

ment over and above that obtainable from the compressed air alone. Nor does the phenomenon stop here, for I have observed that after exit from the compressed air persons treated in this way are under the dominion of the remedy for a much longer time than when treated in the compressed air with sedatives or stimulants, but without the simultaneous exhibition of vasomotor relaxants. This observation I conceive to be of no little practical moment; I have set it down, because again and again it has served me well, and I trust in other hands may do no less.

As to forming a conception touching the *modus operandi* I conceive there need be no embarrassment. We have only to conceive of the retarded blood current in the cerebrospinal organs consequent upon the widening of the vessels to realize that such lethargy must mean a commensurate slowing of the processes of elimination. This means that the medicinal substance will linger longer in the tissues; that its action will be intensified and prolonged.

Certainly in the management of the painful phases of ataxia and spinal irritation the procedure is most serviceable. When we picture to ourselves the artificial lensor caused by this relaxation of the vessels, to which must further be added the sluggishness naturally prevailing in the circulation of the lower cord,<sup>1</sup> we shall then understand why remedies given to influence the sensory mechanism of the cord are enhanced and prolonged in their effects when exhibited with an arterial relaxant like nitroglycerin, while the subject remains in a condensed atmosphere.

The method just described, though not achieving an absolute localization of remedies, certainly *focalizes* their effects. I have used it during the past 10 years upward of 6,000 times, and have never witnessed ill effects of any kind.

But besides attaining in this way to a more effective focalization of remedies upon the cerebrospinal axis, and more especially upon the cord, I have also especially sought to direct their influence upon the contents of the cranium. To give practical effect to the idea I have with appropriate appliances moderately compressed both jugulars, after the administration of a sedative or a stimulant combined with nitroglycerin, the subject remaining meanwhile immersed in the condensed air. This expedient, born of the promptings of pure theory, has been amply justified by the practical event. It has again and again justified the claim that it is a means of subduing a severe attack of megrim. In the management of the lesser sorts of head pain, however, such clamping of the vessels is superfluous.

I am told that I should give a description of the apparatus employed by me in carrying out the various features of the treatment whose advantages have been already sufficiently set forth. Though this has been done with much detail, in my first paper, and still more explicitly in my monograph on "Pain," I suppose to give a practical climax to this writing I really ought to do it again. Not needlessly to expatiate, then, but merely to prod the memory, the apparatus I have made use of may be thus briefly described:

(1) It consists, in the first place, of a cylindrical steel chamber, six feet in diameter and something over that measurement in length (Fig. 1). To this access is had by a heavy door of the same material, hinged at the center and opening inward. A packing of rubber, carried around the edge of this door insures an air-tight enclosure, an accurate coaptation being made easy by means of a cross-bar and screw, as shown in the diagram.

Two port holes, protected by thick glass, give a view of the interior, which is brilliantly lighted by electric lamps. By the aid of a gauge it is possible to be at all times informed of the amount of pressure in the cham-

ber; while an adjustable valve, opening at the predetermined pressure, removes the possibility of accident from carelessness.

The walls of the chamber are hung with light drapery to remove the sense of confinement; and a semicircular couch comfortably cushioned enables the occupant to lie at ease.

(2) Into the chamber the air is driven by a large pump, actuated by an electric motor (two-horse power) (Fig. 2). Both pump and motor are installed in the cellar, and the air is led up by a stout iron pipe. To start or stop the motor, the turn of a switch, located near the chamber, is sufficient.

Pressures of two atmospheres fulfill, as a rule, all ordinary needs.

I have already alluded to the *exceptional* expedient of pressing upon the jugulars. This is done by fastening two small metal cups over the veins and connecting them by means of a narrow rubber tube with a stopcock, which, when opened, places the interior of the cups in direct communication with the external atmosphere. As a result of the difference in density of the air inside the cups and that in the chamber the tissues are both drawn up and pressed upon, whereby a decided venous turgor is produced.

It cannot, however, be sufficiently insisted that com-

FIG. 2.

pression of the jugulars is an exceptional device, a device invocable in severe intracranial pain only.

Parenthetically, I would remark that the pneumatic principle invoked by me to compress the jugulars is also applicable to all forms of dry cupping, and, indeed, has been so applied by me for years. When, however, such use is intended—and the same may be said of compression of the jugulars—the air pressure in the chamber should be kept low; a concentration of three or four pounds above that of the normal atmosphere being sufficient to cause the cups to cling tenaciously to the integument. It is self-evident that communication is established between the interiors of the cups and the external atmosphere by means of india-rubber tubing carried outward to the small stopcock in the wall of the chamber. The manipulation required is infinitely simple, *i. e.*, (1) to raise the pressure; (2) to adjust the cups—this may be done by the patient or by an attendant with him in the chamber; (3) to open the stopcock, whereupon the cups immediately attach themselves.

#### CONCLUSIONS.

It has become something of a habit of late among medical writers to append to their papers a formal synopsis of opinion, a kind of ultimate extract of what has gone before. This, we are told, helps to a consistent grasp of essentials, and to that extent lightens the task of the reader.

<sup>1</sup> This lethargy of the circulation in the lower segments of the cord has been alluded to by Brown-Séguard in his papers on paraplegia.

Yielding, then, to the sway of a fashion, amply justified, no doubt, by such a consummation, I would shortly summarize my conclusions:

1. *Limitations of the Method.*—The plan of treatment previously described is of no use whatever in the management of the inflammatory and degenerative conditions of the cerebrospinal axis. True, the painful crises of ataxia may be averted by it, but the progress of the disease is not arrested. Upon such diseases as disseminated sclerosis, spastic spinal paralysis, poliomyelitis, its influence, as one might naturally infer, is nil. In disease of the bloodvessels and all cerebral accidents arising therefrom its use is absolutely counterindicated. Nor is neuritis an affection which lends itself to this mode of treatment, the increased pressure at the surface serving rather to augment than diminish the pain. The same may be said of articular rheumatism, whether recent or of long standing, even an added pressure of a few pounds being sufficient to cause discomfort in an old arthritic joint.

2. *Legitimate Sphere of Application.*—What, then, are the affections in which compressed air may be invoked as a means of focalizing the action of remedies upon the brain or spinal cord or both? Speaking generally, it may be said that cerebral and cerebrospinal affections of a functional character, in which pain, exhaustion, insomnia or depression are prominent features, are the most amenable to this plan of treatment. Here its effects are striking, and indeed, quite beyond those obtainable in any other way.

Finally and causally, compressed air, by increasing the pressure in the renal bloodvessels, gives rise to diuresis. This effect, obtainable from the air alone, becomes exceedingly pronounced when a diuretic is given, even in insignificant doses.

## HERNIAL COMPLICATIONS.<sup>1</sup>

BY

JOHN BRUCE HARVIE, M.D.,

of Troy, N. Y.

Gynecologic Surgeon, Troy Hospital, Troy, N. Y.; Abdominal and Gynecologic Surgeon, St. Peter's Hospital, Albany, N. Y.; Consulting Surgeon, Leonard Hospital, Lansingburgh, N. Y.

Most operators of experience have found in hernial sacs almost any portion or even the entire floating contents of the abdominal cavity. I have found in my own operations for strangulated hernia in the inguinal region, in addition to the commoner contents, bowel and omentum, twice the ovary, once tube and ovary, twice a strangulated sloughing vermiform appendix, and once an adherent vermiform appendix. In one instance a kidney, which was exceedingly movable (after reduction of the mass of bowel), was found at the hernial ring, but did not constitute a portion of the hernia.

In two cases which came under my observation at the Troy Hospital the hernias, which were of the inguinal variety, contained the entire intestinal tract, and in one of these instances a portion of the stomach. These persons had been under observation for some months, and it was known that a large portion of the bowels had been down in the hernial sac in an irreducible way for several years. These patients died from intercurrent troubles, and upon autopsy the exact condition was confirmed. Incidentally, I would say I have knowledge of a case of umbilical hernia in which all the intestines escaped and were only partly reducible.

In a case of ventral hernia, following an operation for an appendicular abscess, all the coils of small intestine were found agglutinated and bound down in the sac, constituting a condition which would make one wonder how the contents ever passed through, and why obstruction did not occur at once. The intestinal coils were reduced

with difficulty, and it was evident that the long absence from their natural quarters had permitted a shrinking of the cavity, which caused a notable crowding of the contents after their return. This patient died three days after operation with all the phenomena of intestinal obstruction.

From the histories of these cases and many others which have been reported, it is very evident that large portions of bowel may escape from their natural quarters and continue for years without interfering particularly with the ordinary physiologic function; whereas one often finds that a small band or adhesion will frequently be associated with very marked discomfort and actual pain, and is more prone to become the seat of obstruction than in the former condition.

An unusual circumstance to which I desire to refer more particularly is one with which I was not familiar:

On July 5, 1900, I was asked by Dr. Hanratta, of Watervliet, N. Y., to see a patient whose condition he had diagnosed as strangulated inguinal hernia, requiring immediate operation. The left side of the scrotum presented a large tumor, contracted in its center, giving it an hour-glass shape. The upper part of the mass was tender, sensitive on manipulation, the lower part not so tender. The upper portion was hard and resisting; the lower elastic, evidently containing fluid. I suggested to Dr. Hanratta that the case was probably one of strangulated hernia complicating a hydrocele. The patient was sent to the Troy Hospital and in the afternoon of the same day I operated upon him.

*Operation.*—The ordinary incision was made, rather liberally; the hernial sac well exposed and opened, a small quantity of bloody serum escaping. Between 7 and 8 inches of small intestine was found within the sac tightly grasped and devitalized. The hernial ring was well divided, adhesions liberated, and the intestine drawn down into the wound until healthy portions presented. The entire gangrenous bowel was resected and an end-to-end anastomosis made with a Murphy button, reinforced with mattress sutures of very fine silk. The hernial sac was clamped with a pair of ordinary artery forceps after reduction of the bowel, and an investigation made of the remaining mass, which evidently contained fluid. A rather close examination failing to determine its exact identity, a small incision was made 1 cm. in length, permitting the escape of between 5 and 6 ounces of clear urine. The moment the incision was made and not until then did I suspect that we were dealing with the urinary bladder; and in order to satisfy myself that it was actually the bladder, I explored its interior with my finger and found that the bladder had escaped into the scrotum in its entirety. This was clearly seen by those present—Dr. Hanratta, the attending physician; Dr. William Kirk, my first assistant, and others. The mucous membrane of the bladder was healthy, the escaping urine was of clear amber color and of normal odor. The bladder was sutured with No. 2 plain catgut after its thorough evacuation. Considerable difficulty was experienced in effecting its reduction, but after more or less prolonged manipulation and continuous pressure with gauze sponges the whole organ slipped back into its normal position below and to the inner side of the hernial sac. The wound was closed partially with silkwormgut sutures and the unclosed portion packed with iodoform gauze. Instructions were given to pass a catheter every hour for the twenty-four hours immediately following the operation. A good quantity of urine was secreted and no pain or discomfort experienced.

*History.*—The patient had had a reducible hernia for about 10 years and never wore a truss. The hernia invariably came down in an erect posture and assumed a fair size. He could effect its reduction in a standing position and it always disappeared on lying down. On the morning of July 4, after being about the house for a short time, he found that his hernia caused him some pain, and its reduction could not be accomplished as on former occasions. Considerable colicky pain ensued during the day. He laid down, kept quiet, made ordinary pressure, but without success. He made several unsuccessful attempts to evacuate the bowels, and toward morning in straining at stool, he felt that the mass had suddenly increased very materially and the pain correspondingly. He sent at this time for his physician (Dr. Hanratta) for the first time, and the doctor recognizing the importance of the case, secured surgical assistance as soon as possible. Attempts at urination from this time on were frequent, but not more than a few drops were passed. Vomiting became frequent, there was moderate abdominal distention, paroxysmal pain and all the evidences of obstructed bowel.

The history of this case points very strongly to the fact that the entire bladder had descended into the scrotum from the severe muscular straining made in attempting to move the bowels.

The *British Medical Journal* for October 24, 1896, contains a report by W. Thelwell Thomas, F.R.C.S., under

<sup>1</sup> Read before the New York State Medical Society, January 20, 1902.

the title, Two Complicated and Unusual Hernias, One Containing Bladder, the other the Fallopian Tube.

B. T., aged 50, admitted to the Royal Infirmary for a strangulated hernia. The rupture had become strangulated 24 hours previous to admission to the hospital, the swelling was large, tense and irreducible.

*Operation.*—Sac exposed, looked like figure 8, the upper part was whiter than the lower and tightly nipped by the internal ring, and a loop of small intestines three inches long reduced, and the sac separated from the larger part lower down, and drawn up "a la MacEwen." The larger swelling clearly contained fluid which pressure could reduce into the abdomen through the usual place for a direct hernia, quite half an inch of the back wall of the inguinal canal intervening between it and the reduced hernia. A tiny puncture was made in it and a stream of ammoniacal urine poured out. The edge of the puncture was clamped and a catheter passed through the urethra which emptied the bladder and this pouch. After dissecting off a portion of the transversalis fascia which was stretched across the posterior wall, the finger could be introduced into the abdomen, but outside the peritoneum which was now detached toward the pelvis to prepare a place for the herniated portion of the bladder. A continuous Lembert suture closed the puncture in the bladder, and after reducing the hernia, the fascial covering alluded to was ligated as one would the peritoneal sac of a hernia in Czerny's operation, and the redundancy cut away. One remarkable feature of this very interesting case was the existence of a hernia for 25 years, disappearing on lying down; during the last five years the rupture was present when he awoke in the morning and disappeared on urinating.

Rose<sup>1</sup> reports a case of inguinal hernia associated with hernia of the bladder in a young woman of 24 who had a reducible hernia. Urination was often painful and sometimes not performed for from 24 to 36 hours, during which time the swelling increased. The bladder was opened and sutured with fine catgut, the patient recovering.

Curtis<sup>2</sup> attributes the frequency of wounds of the bladder to the altered methods of operating for hernia. The attempts to effect a radical cure necessitates complete dissection of the neck of the sac in order to ligate it, and for this reason the bladder is more apt to be injured, the tissues of the herniated bladder being recognized with difficulty.

Three varieties of bladder hernia are distinguished anatomically, according to the relation of the peritoneum to the bladder. 1. The extraperitoneal, in which the bladder lies wholly without the hernial sac. 2. The pariperitoneal, in which it lies partly within and partly without the hernial sac. 3. The intraperitoneal, in which the bladder lies fully within the hernial sac.

Hernia of the bladder has been known to exist ever since Sala, master and friend of Bartholini, sounded a man for stone in 1520 and failed to find one, but post-mortem examination showed it to be in a pouch of the bladder in the inguinal canal.

Macready found 51 cases recorded, and ferreted out 59, the greater majority being of the inguinal variety. This form of hernia is, however, quite rare, and the diagnosis surrounded with considerable difficulty; so that the condition is not usually considered until shown to exist on the operating table. Many surgeons have injured the bladder during operation accidentally, or have cut into it prior to recognizing what it was.

During operation the bladder may be recognized by the unusual amount of prevesical fat. The appearance and position of the bladder may be decidedly misleading; the wall of the bladder may be stretched so that its identity would be impossible. In about 40% of hernial operations the bladder was recognized before injury. In some the bladder was not seen until it was wounded—in others the injury was not recognized at the time; in quite a large percentage it was taken for the hernial sac, and in others for a cyst. In my own case the bladder resembled an independent cyst and on manipulation the size of the mass remained unchanged. The bladder was covered with a layer of fat—the bladder wall was nor-

mal in thickness, and its presence was unsuspected until an incision was made allowing the escape of the contents, about 200 cc. of urine.

My object in reporting my case is on account of the keen realization of the necessity of operators keeping constantly before them the possibility of such a complication. That such a condition occurs frequently is not at all appreciated, and in looking up the literature of the subject I have been astonished to find that while a goodly number of bladder hernias have been reported there are very few instances in which the entire organ had slipped out of its normal quarters.

Most of the cases reported have been instances in which only a portion of the bladder was included in the hernia, and very often formed no part in the hernial mass. Under the latter condition the organ lying in close proximity to the hernial sac, being included with the sac in the ligature, has frequently escaped notice and been injured. The recognition of the bladder is a matter of very great importance, and should not be surrounded with particular difficulty in instances in which its presence is suspected. The almost invariable presence of the fatty covering, which was a distinctive feature in my case; the origin of the cyst or sac traveling, as it always will, through the hernial ring; and the almost invariable possibility of emptying the cyst, particularly when the entire bladder is not prolapsed, should lead to its ready detection.

## CASE OF BUBONIC PLAGUE, WITH EXHIBITION OF THE BACILLUS.<sup>1</sup>

BY

JUDSON DALAND, M.D.,

of Philadelphia.

Instructor in Clinical Medicine at the University of Pennsylvania  
Assistant Visiting Physician to the University Hospital; Professor of Clinical Medicine at the Philadelphia Polyclinic; Visiting Physician to the Polyclinic Hospital, and Consulting Physician to the Kensington Hospital for Women.

While in Honolulu, in September, 1902, I learned that for some months previously sporadic cases of plague occurred chiefly among Hawaiians in widely scattered portions of the city. Three such cases occurred during my short visit, and it is highly probable that the annual number is greater for the reason that unless the disease is serious the poorer class does not seek professional advice, and if recovery ensues, such cases are not reported to the health officers. As will be observed by examination of the statistics, all of the reported cases were fatal. During the present year plague occurred in the Cape of Good Hope, Hongkong, Japan, Mexico, New York and other places. Between January and September of the year 1902, 5,550 deaths from this disease occurred in India. For the week ended December 6, 1902, 12,400 deaths were recorded, as against 12,039 for the previous week, and 8,878 in the corresponding week of 1901. These facts show that plague is largely increasing in India.

Between December, 1901, and September 9, 1902, 10 cases of plague were reported to have occurred in the Philippine Islands, of which 9 were fatal. From December 11, 1901, to November 18, 1902, 40 deaths from the plague occurred in the Hawaiian Islands.

Between December 11, 1901, and November 18, 1902, 38 cases of plague were reported to have occurred in San Francisco, Cal. Recently new cases are reported in Honolulu, and three cases were brought to Swinburne Island, in New York harbor, by a ship from Durban, South Africa.

The widespread distribution of this disease, which is

<sup>1</sup> London Lancet for July 28, 1894.

<sup>2</sup> Sajous' Annual, for 1896, p. 164, sec. C. B. F.

<sup>1</sup> Read before the Pathological Society of Philadelphia, February 12, 1903.

favored by the close communications now existing between all parts of the world, together with the recent acquisition of the Philippine and Hawaiian Islands and the occurrence of this disease in Mexico, San Francisco, and New York, adds new interest to the study of this disease by physicians of the United States.

The case that I wish to relate is that of a native Hawaiian woman, aged 60, rather small in stature, who fell ill six days before her death. During the first three days of her malady she was without medical assistance, and when first visited no satisfactory history was obtainable. It was learned that she had been suffering from the symptoms of fever. Her temperature when first examined was 105° F., pulse about 130, tongue heavily coated, breath offensive, delirium moderate, and the abdomen tympanitic.

Upon the fourth day of the disease the temperature was 105° F., the delirium became more marked, and the abdomen more distended. In the left inguinal region an enlarged lymphatic gland was discovered, which was moderately painful. On the fifth day the temperature rose to 106° F., and the inguinal gland was slightly larger.

A diagnosis of plague was made, and the following day the temperature rose to 108° F., with a corresponding rapid pulse. The left inguinal gland was about the size of a hen's egg. No other symptoms were noted by the attending physician, and the patient died a few hours subsequently.

Through the kindness of Dr. J. T. MacDonald, of Honolulu, I was invited to assist at the autopsy, which was held two hours after death. The cadaver was still warm, and there was no rigor mortis. The body was rather small, more especially the upper and lower extremities and the neck, and the emaciation of these parts was in striking contrast to the remarkably enlarged and protuberant abdomen, upon the walls of which could be seen the cicatrices produced by former pregnancies. The skin was of a normal dark hue, and of a color common to the Hawaiian. In the left inguino-femoral region there was a small swelling produced by a moderately enlarged inguinal gland a section of which measured one inch by three fourths of an inch, and presented a whitish-gray appearance. This gland was partially disintegrated and softened, and a smear preparation showed numerous plague bacilli. The tissues surrounding the enlarged gland were edematous, and the serum flowed freely from the incision, but was not blood-stained, as has been so frequently observed in rapidly fatal cases of plague. Excepting one or two enlarged glands in the right axilla, no other glandular enlargements were discovered, nor was anything of importance noted in the thoracic or abdominal cavities, excepting the presence of an enlarged spleen measuring 4 inches by 2½ inches, and upon section presented a mahogany-brown appearance. A thermometer placed in the center of the spleen registered 109° F.

An autopsy of a rat that was found in the house in which this individual lived revealed no enlargement of the spleen nor of the glands. The lungs showed no inflammatory changes, and the bacteriologic examination gave negative results. A careful inquiry failed to show the exact manner in which the patient had become infected.

The occurrence of isolated cases of plague in the various portions of the city of Honolulu during the summer of 1902 has caused the health officers considerable concern, and the fact that these cases are not found in one particular quarter of the town, but on the contrary are scattered all over, leads them to believe that this malady is widely disseminated. It is more than probable that this disease was imported into Honolulu from China.

In most cases of plague that have occurred in Hawaii, the clinical diagnosis is based upon the existence of fever, adynamia, delirium, and enlarged lymphatic glands, and the existence of an endemic or epidemic in the community. The diagnosis is considered to be established when the plague bacillus is discovered in the liquid removed from an enlarged gland by means of the Pravaz syringe, or when found in the urine, sputum or feces. The cultural peculiarities are considered diagnostic, and the successful inoculation of mice, rats, or guineapigs often establishes the existence of the disease in doubtful cases. The mortality among the natives of Hawaii is very great, and all the cases thus far reported have been fatal, but it is probable that in many of the milder cases the patients recover without having been reported to the Board of Health.

The prognosis is particularly unfavorable when the plague bacillus is found in the blood, especially if the number of bacilli are greater in each succeeding examination. When a number of bacilli are included within

the leukocytes in the fluid obtained from a bubo, the prognosis is considered to be more favorable.

The physicians in Honolulu were unable to give any definite opinion as to the effects of Haffkine's inoculation. In India, during the month of October, 1902, 120,000 people were inoculated with the antiplague serum, which should go far toward determining its value. The inoculations were temporarily suspended because of the unfortunate occurrence of 17 deaths from tetanus, probably due to contamination of the serum employed.

The specimen under the microscope is a smear preparation from the enlarged inguinal gland already described. It was stained with anilin and showed an enormous number of short, thick, cocco bacilli with transparent centers and round ends. The bipolar portions are deeply stained. Certain of the microorganisms appear to be encapsulated, and a few are seen within the leukocytes.

### AMYOTROPHIC LATERAL SCLEROSIS IN A BOY OF 15 WITH A HISTORY OF ACUTE ANTERIOR POLIOMYELITIS IN INFANCY.<sup>1</sup>

BY

ALFRED GORDON, M.D.,

of Philadelphia.

Instructor in Nervous Diseases, Jefferson Medical College, Philadelphia.

The disease which is known under the name of infantile spinal paralysis or acute anterior poliomyelitis we usually consider as one in which the paralysis, the amyotrophy, the secondary deformities and the arrest of development in the affected limbs are confined to a certain portion of the body and remain there during the entire period of life.

When the myelitic focus is replaced by a cicatrix the patient is left with irremediable infirmities which, however, have no influence upon the duration of life nor upon the integrity of other portions of the cord. This is the rule. Nevertheless there are exceptions. We are now in possession of a certain number of facts which prove that the presence of an old myelitic focus, though healed up, is not an indifferent factor for the future of the patient so far as his spinal cord is concerned. On general principles a *locus minoris resistentiæ* can be a point of departure for new inflammatory processes either in the old injured place or in the immediate vicinity, or at a distance in the same cord. A concussion, circulatory disturbances, infectious diseases, exposure, trauma, are all factors for awakening an old extinguished focus.

That the acute symptoms of anterior poliomyelitis after a long interval of a few or many years may repeat themselves in the portions of the body previously affected is well known, but that the acute poliomyelitis may be followed by other diseases of the cord is a fact not altogether frequent, as the cases on record are comparatively few. Among the spinal diseases following spinal infantile palsy, progressive muscular atrophy is the most frequent. The perusal of the meager literature on the subject shows that the spinal diseases recorded made their first appearance a great many years after the initial symptoms of anterior poliomyelitis, consequently in adult or in middle life (Dutil, Ballet, Langer, Laehr, Charcot, Hirsh and others).

The case that I am about to report is of a special interest from this point of view. It occurred at a very early age. After a typical onset of infantile palsy at the age of one year, the disease remained typical until the age of eight, when a series of infectious diseases developed. Shortly afterward gradual loss of weight and strength was noticed. Still later two fractures occurred in one of the affected limbs. The two circum-

<sup>1</sup> Read, and patient exhibited, before the Philadelphia Neurological Society, December 23, 1902.

stances gave probably an impetus to the old diseased focus, with the result that the same pathologic process spread considerably and involved also the pyramidal tract.

The latter fact makes the case still more unusual, because if progressive muscular atrophy was reported, amyotrophic lateral sclerosis was reported only in one case, that of Hirsh.<sup>1</sup> The case I report presented *ad*

*vitam* a typical amyotrophic lateral sclerosis. The postmortem examination showed vast degenerations of the white matter between the cornua, besides the cornua themselves.

Two more points deserve our attention. The majority of cases of progressive muscular atrophy present the well known Aran-Duchenne's type, in which the small muscles of the hands are first affected. Our case presents the scapulohumeral type of Vulpian and Déjerine.

The second and last point of importance lies in the fact that the patient sustained two fractures of the right humerus, both in the same place, after a

trivial accident. The occurrence of two fractures in a limb affected with an infantile palsy, and the long process of healing (four months), is an indication that there is a defect of solidity dependent evidently upon a disturbed state of nutrition of the bony tissue, probably of the same origin as the muscular atrophy. As a matter of coincidence (perhaps more) the patient presents a large thyroid gland.

Our case is therefore one of amyotrophic lateral sclerosis with an atrophy of scapulohumeral type developed at a very early age in a patient who presents symptoms of an old acute poliomyelitis.

The case is as follows:

P. R., aged 15, was addressed to me through the courtesy of Dr. Saltzman, with the following history: When he was a little over a year old he became suddenly ill; fever, vomiting and diarrhea were the main symptoms. So soon as the fever, which lasted about 10 days, subsided, the parents noticed that the infant would not move his right arm and left leg, which soon became totally paralyzed. At the age of 5 he commenced to walk. Since then his general health was good until the age of 8, when he had measles and whoopingcough. Since then he became weaker, lost in weight and strength. Shortly afterward he sustained a fracture in the middle third of the right arm. It took about four months before a permanent callus was formed. About three years ago a second fracture occurred in the place of the old callus. It is interesting to state that both fractures took place after a trivial accident, while tying his shoestrings he stepped on them and fell. The paralysis which occurred in infancy remained confined to the two limbs and never improved. He was compelled to use the unaffected arm, and thus became lefthanded. This fact is significant, because under the circumstances we should expect if not a compensatory muscular hypertrophy at least well developed muscles.

Patient presents a normal height with an average intelligence. The two limbs which were primarily affected present a total flaccid palsy with a deformity of the foot (equinovalgus). The muscles in the lower extremity are contracted. The muscles of the right upper limb are almost totally atrophied; the hand on the same side has preserved some muscles. The scapulohumeral region, the supraspinatus and infraspinatus muscles are markedly wasted. The trapezius, however, is well preserved. The left lower extremity, which was primarily

paralyzed, presents also marked wasting. The muscles of the thigh, however, are not yet totally destroyed, although the difference in the size with the thigh of the opposite side is striking; the adductors are particularly flabby.

The interesting fact to notice is that the atrophy did not remain limited to the paralyzed limbs. The left upper extremity became invaded. The scapulohumeral region, the supraspinatus and infraspinatus, the triceps, the extensors of the forearm, the first interosseous space, and only to some extent the thenar and hypothenar are involved. The biceps is apparently preserved, but owing to the fact that the patient uses only the left arm and hand we should rather expect a biceps of larger size. The left scapula is very much receding from the thorax. The power of the left hand is below normal. The muscles of the thorax are also strikingly atrophied. There is a slight scoliosis toward the left. The right lower extremity is apparently normal as to size and power. However, the plantar arch is reduced to quite a marked degree.

The electric examination gives the following result: To faradism the right upper extremity does not respond at all. On the left the biceps and deltoid show some diminution of reaction, but much less response is obtained for the triceps, extensors, flexors of the forearm, muscles of the thumb, supraspinatus and infraspinatus muscles. On the left lower extremity the muscles of the thigh give an exaggerated response, no response whatever on the muscles of the leg and foot. On the right lower extremity is noticed a diminished faradic reaction for all the muscles. The muscles of the thorax present also diminished faradic reaction. The trapezeii muscles are normal on either side.

The examination with the galvanic current gave the following result: No response for the right upper extremity and the muscles of the scapula on the same side. On the left upper limb the deltoid and biceps give a weak reaction, but no reaction of degeneration. The triceps presents distinct reaction of degeneration, the extensors of the forearm, the thenar and hypothenar muscles present a much diminished irritability, the flexors are normal, the muscles of the scapula present the cathodal closure contraction equal to the anodal closure contraction. The pectoralis muscles on either side present also the cathodal closure contraction equal to the anodal closure contraction. On the left lower extremity no response for the muscles of the leg and foot, diminished response for the muscles of the thigh. The right lower limb presents also diminished reaction for some muscles, but the majority are normal.

The reflexes are as follow: The patellar, Achilles', cremasteric, abdominal are all exaggerated, more on the right than on the left. On the right upper extremity no reflex could be obtained, except Bechterew's, which is obtainable only in one spot. On the left upper limb Bechterew's reflex is exaggerated, also that of the biceps. The triceps reflex is entirely lost.

Babinski's reflex is distinct on the right side, doubtful on the left. No ankle clonus on either side. In addition to the atrophy and exaggerated reflexes the atrophied muscles present fibrillary tremor and increased mechanical irritability. The test for sensations to all the three forms (touch, pain, and temperature) gave negative results. At no time did the patient complain of pain. The sphincters are normal. He complains of occasional attacks of shortness of breath and difficulty in swallowing. These symptoms developed within the last year. Finally, it is interesting to notice that the thyroid gland seems to be enlarged. The family history of the patient is negative. He was born at term and delivered normally.

I wish to thank Dr. J. O. Arnold for the patient's photograph.

**Vacancies in the Army.**—There are over 40 vacancies in the junior grade of the medical department of the Army. An examination of candidates to fill these positions will be held in April. The first class to be examined will report at the Army Medical Museum, Washington, April 20.

## THE INFLUENCE OF ALTITUDE ON THE MORTALITY OF PNEUMONIA.<sup>1</sup>

BY

HENRY W. HOAGLAND, M.D.,

of Colorado Springs, Colo.

Visiting Physician to St. Francis' Hospital, Member of the American Climatological Association, American Medical Association, the American Association for the Advancement of Science, etc.

Pneumonia is a serious and common disease, attacking all ages and all walks of life, and despite the progress of therapeutics, is as fatal now as it was several decades ago. There have been some epidemics, if I may call them so, reporting a low deathrate and, from time to time, different methods of treatment have been put forth to lower the mortality, such as digitalis, antipneumonic serum, creasote, and the salicylates—but they have been attended with little or no success. We know when called to treat a patient that we cannot tell the outcome, and in any acute disease in which statistics prove that one in four die, any light, however feeble, thrown on the treatment of this condition either from drugs or climate is of interest. The popular impression among the profession generally and especially among those at sea-level is that this disease at high altitudes has a higher deathrate than elsewhere, and this is especially true among the laity, even in Colorado, their general impression being that it is practically fatal. For example, how often do we hear when called to the bedside of a patient suffering from influenza or bronchitis, "If I have pneumonia, doctor, I want to be sent at once to a lower altitude." With this opinion I was surprised to find on coming to Colorado Springs, several years ago, that the mortality, both in private and hospital practice, was no higher than, say, in Philadelphia, London, or Vienna. This impression has become a conviction, and for further proof I wrote a circular letter to the hospitals throughout the State, asking for statistics, and while not at all striking they bear out my general statement. I have taken hospital statistics instead of those of individuals, and consequently of private practice, for, while it is hardly fair to the disease, for we know there is a greater fatality in hospital practice, they are the only means of absolute and accurate comparison.

Through the kindness of Dr. A. A. Stevens, of Philadelphia, the following are the statistics from St. Agnes', the German, Episcopal and Pennsylvania Hospitals of Philadelphia for the past two years: Of a total number of 221 cases there were 58 deaths, giving a mortality of 26.2%. Osler puts the mortality of the Montreal General Hospital of 1,012 cases at 20.4%; New Orleans Hospital, 3,900 cases, mortality 28%. In the Massachusetts General,<sup>2</sup> during the past decade, there were 1,549 cases, with 172 deaths, making 31.3%. Albutt, with a record of 434 cases, gives a mortality of 25.5%. Taking these together to obtain a general average of the hospital mortality of pneumonia throughout the world, or at a low altitude, we have a total number of 6,116 cases, 1,640 deaths, making a percentage of 26.8. Of course it is impossible to get anywhere near this number of cases in Colorado, but the number reported is sufficiently large for a fair percentage. However, I do not want to appear dogmatic in my assertions, for I realize the fallacies when 700 cases are compared with 6,000, and until we can obtain statistics from several thousand can we gain a satisfactory conclusion?

The statistics from Denver, altitude 5,000 feet, for the past two years, taken from St. Joseph's, St. Anthony's and St. Luke's Hospitals follow: Of a total of 132 cases, they report 38 deaths, with a percentage of 28.7. Of St. Francis' Hospital, Colorado Springs, altitude 6,000 feet, statistics for the past two years, 66 cases, 17 deaths, 25.7%.

Of the D. & R. G. R. Hospital, at Salida, altitude 7,000 feet, 16 cases, 2 deaths, 12.2%. St. Mary's Hospital, Pueblo, altitude 4,800 feet, 120 cases, 32 deaths, 26.5%. Of Cripple Creek, altitude approximately 10,000, of 375 cases collected personally by Dr. B. F. Cunningham, the mortality was 18%. The latter are not hospital statistics, but they were collected during the winters of 1894, 1895 and 1896, when the Cripple Creek district had no hospital, when most of the patients were in shacks, with no nursing or hygienic surroundings, and were men, the majority of whom were alcoholics, so the objection can hardly be raised that they were from private practice, or that the surroundings were favorable. Taking these together, we have a total number of 709 cases of pneumonia, 157 deaths, with a deathrate of 22.1%, at an average altitude of 6,600 feet, against a percentage of 26.8 at sea-level. The following table may be of interest:

City.	Altitude.	Cases.	Deaths.	Percent.
Pueblo.....	4,700 ft.	120	32	26.5
Colorado Springs.....	6,000 ft.	66	17	25.7
Denver.....	5,200 ft.	132	38	28.7
Cripple Creek.....	10,000 ft.	375	68	18
Salida.....	7,000 ft.	16	2	12.5
Average.....	6,580 ft.	709	157	22.1

City.	Cases.	Deaths.	Percent.
Philadelphia.....	221	58	26.2
Montreal.....	1,012	207	20.4
New Orleans.....	3,900	1,092	28
London (Albutt).....	434	111	25.5
Massachusetts General.....	549	172	31.2
Average.....	6,116	1,640	26.8

The reason for this, I think, lies in a number of conditions. It has been proved by Herrera and Loupe that living at an altitude, say of 6,000 feet, respiration and heart's action are slightly increased. Dr. Maurice Kahn, of Leadville (altitude 10,000 feet), in a paper before the Colorado State Medical Association, states that in 100 cases examined he found a pulse-rate of 76.5%. Owing possibly to the rarity of oxygen the lungs are larger, expansion is increased, and there is a greater interchange of air. The heart is normally stronger, with possibly a certain amount of hypertrophy. Some keen observers in Colorado have decided that the right side of the heart is increased in size and contractile power by living at a high altitude. And if this supposition is true it may help to account for the lowered mortality, for as is well known so much depends on the integrity of the right heart in pneumonia. Then, too, we live more of an outdoor life. These conditions, taken together, obviously give a stronger activity of life, an increased metabolism, hence a greater resistance to toxins, which more than counteracts the possible lack of oxygen. Respiration after all is only one factor in the disease and not the most serious at that. A contributing condition may lie in the fact of this being a comparatively recently settled country, and hence fewer old people. Then we have few of the large factories so common in the east where large numbers of people are confined for eight or ten hours a day. On the other hand, Colorado is a health resort for many tuberculous persons, and they, in their proportion, suffer from pneumonia, which manifestly is more fatal than in the robust. Certainly a man with active tuberculosis, with lowered vitality, or one with but one lung left and half of it affected, with a pneumonic consolidation, has very little chance against this disease. This, I think, above all else, has caused the belief that pneumonia is more fatal here.

I know full well there is a line of demarcation as we ascend in altitude where pneumonia is certainly more fatal than at sea-level, but statistics must be obtained

<sup>1</sup> Read before the El Paso County (Colo.) Medical Society, June, 1902.

<sup>2</sup> Statistics collected by Dr. Edward F. Wells, in the American Medical Association Journal.

from other countries and at an altitude higher than 7,000 feet to reach any definite conclusions. This I have been unable to do, and while I grant that cases occurring in new arrivals (those not acclimated to the temporary increase of the heart's action), and the occurrence of such cases is rare, pneumonia has a high deathrate. In those who are acclimated, the disease is no more fatal, and in fact, by the statistics I have presented, it seems manifestly less so at an average altitude of 7,000 feet than at sea-level.

## THE PRESENT-DAY MORTALITY OF PNEUMONIA.<sup>1</sup>

BY

ALEXANDER G. BROWN, JR., M.D.,

of Richmond, Va.

Adjunct to the Chair of Practice of Medicine, University College of Medicine.

In the ancient history of disease no subject received more careful description and study than pneumonia. The physicians of antiquity, of Grecian, Roman, and Arabian nationality, set forth their knowledge of the pneumonia of that day in descriptions filled with many interesting conceits and queer observations. In the writings attributed to Hippocrates and Aretæus, among the symptoms mentioned we find these: "The tip of the nose is turned up;" "the white of the eye has a greasy luster," and others as curious, while the diagnosis "is made by the coating of the tongue." For many decades greatest confusion reigned with reference to pneumonia; in fact, pleurisy and pneumonia were not really differentiated until 1819, when Laennec pointed out these distinct and separate diseases, and to him is due the classification of the stages of pneumonia at the present time accepted as correct. However, through all the writings of history this fact is constantly set forth, though statistics are not given, that pneumonia is a deadly disease.

So great a factor in the deathrate has pneumonia become, and so rapid and terrible is its brief course, that I have deemed its consideration not an unprofitable pursuit. At the outset, I wish to comment upon two facts which have a direct bearing on this question of pneumonia mortality. First the advances of science have, during the last decade, raised the average of life in the United States 4.1 years. In the decade ending at 1890 the average life length was 31.1 years, while in the decade ending 1900 the average length was 35.2 years, a marked and gratifying increase. Second, the "great white plague" or tuberculosis, which up to recent date has exacted, of all diseases, the greatest toll of human life, even to one-seventh of the world's mortality, is conceded to be now on the decline. This may be explained by the worldwide fight which has been made recently against its progress: for the universal interest in civil, social, and scientific circles, as manifested in international conferences of scientific men, in popular education of the masses, and in State, municipal and private grants of large sums of money for the study, prophylaxis, and treatment of this erstwhile captain of death, has begun to have a most gratifying effect upon mortality tables. Now, pneumonia, as a swift destroyer, has appeared, according to the latest statistics, proving itself man's most formidable enemy, yielding to no other in the number of its deaths, and certainly effecting this end with swiftest brevity. Indeed, may not this ancient disease, treated through the ages with only this grave statistic result, justly claim the sober consideration now accorded it by the profession?

According to the Vital Statistics Report of the registered area of the United States in the *Twelfth Census Bulletin* of August 20, 1901, pneumonia holds leading place in the death column, having been the cause of death in 1900 in 55,296 instances, *i. e.*, 191.9 persons in

100,000 population. This fact is borne out in various particular localities, which I will cite to establish this point. In the report of the Department of Health of Chicago we find that between 1851 and 1890 there were 25,719 deaths from pulmonary tuberculosis and 16,577 deaths from pneumonia—that is, more than 35% excess of pulmonary tuberculosis deaths. Between 1891 and 1901 there were 22,957 deaths from pulmonary tuberculosis and 25,228 deaths from pneumonia, making an excess during this last decade of 9% in deaths from pneumonia. In the same report we find that in the decade 1861–1871 deaths from pneumonia formed 3% of the deaths from all causes; in the two succeeding decades it formed respectively 5% and 6.7% of the total deaths. In the last decade, 1891–1901, the proportion rose to more than 10% (10.2) of the total deaths from all causes. In Massachusetts also we find a great increase in the deathrate from pneumonia, it having risen from 7% to 8% in the late 70's to 9% and 10% in the last decade. In Rhode Island and Connecticut we find a similar increase in the pneumonia deathrate, and doubtless, as says the editor of the *Journal of the American Medical Association*, were the figures available we would probably find a corresponding increase throughout the Northern Atlantic and Lake States. In Virginia for the year ending May 31, 1900, there were 25,252 deaths from all causes; of this number there were 2,429 deaths from pneumonia—that is, about 10% of all deaths. In Richmond, Va., there were 2,523 deaths from all causes during the year ending May 31, 1900, and of this number 239, or 9.4%, were due to pneumonia. In order to explain this mortality I shall set forth some of the influences which seem to aid the occurrence of pneumonia: One of the chief factors operating as a recent causal agent may be the great fourth pandemic of influenza. It began, as Osler says, "October, 1899, in some of the distant provinces of Russia and by the November following it had reached Moscow. By the middle of November Berlin was attacked. By the middle of December it was in London, and by the end of the month it had invaded New York and was rapidly distributed over the entire Continent." Accordingly in the following year the pneumonia deathrate in Chicago doubled its former rate and throughout the entire country there was a marked increase in its mortality. Another factor in this increase of pneumonia fatalities may be the lessened deathrate of the newborn and infants from intestinal diseases. Many infants kept alive in delicate health may rapidly succumb before childhood is over to pneumonia. At the other end of life the number of aged lungs, sudden changes of weather, and exposure to atmospheric and microbic dangers may render the aged ready victims to pneumonia. The common use of alcohol in excess, the rheumatic and gouty diatheses of modern life, the concentration and overcrowded conditions in the cities, the dusty and filth-laden air of the city streets, all may tend to increase the deaths from pneumonia.

According to the latest authorities pneumonia is classified as an infectious disease, due to the pneumococcus of Fraenkel, in at least 95% of cases, the remaining 5% being accredited to other germs, namely, streptococci, Pfeiffer-bacilli, the pneumococcus of Friedländer. Fraenkel's pneumococcus is nonmotile; occurs in pairs, oval or lancet shaped; surrounded by a capsule of a substance like mucin. It grows in alkaline culture media, with or without oxygen, at a temperature of 35° to 38° C. Its life is self-limited in any medium in four to five days; however, in the dry state it possesses great latent virulence for a long time, especially when fostered in desiccated sputum.

In order to establish the communicability of this germ I will cite a few notable epidemics:

Tyson tells of a ship's crew of 815, of which 410 were attacked by pneumonia in rapid succession. Before the epidemic had subsided 720 had had the disease, and the appalling number of 298 had perished.

<sup>1</sup> Read before the Richmond Academy of Medicine and Surgery, November 11, 1902.

Dr. Cunningham, of Alabama, at the last meeting of the American Medical Association at Saratoga, reported a series of epidemics which had occurred during the last 15 years among prisoners under his charge.

In 1886 Darlington had 105 patients among laborers living in adjoining huts. In 1888 in Middleborough, England, 367 cases of pneumonia occurred in a population of 40,000. The history of epidemics in foreign prisons, garrisons and armies, and in native asylums, institutions and boarding schools, is too extensive—suffice it to say that pneumonia is an infectious and communicable disease, modified and influenced by such predisposing factors as age, sex, race, former attacks, unsanitary living, exposure to cold, occupation, rheumatic diathesis, anesthetization by chloroform or ether, and surgical operations.

Passing by the history of the treatment of pneumonia by blood-letting, blistering, tartar emetic, veratrum viride, calomel in large doses, by elimination of toxins, by the use of oxygen, care of the heart by stimulants and antipyresis, we take up that neglected phase of the question—prophylaxis. Dr. N. S. Davis, Jr., in a recent article, makes this pertinent inquiry in discussing this subject: "But is the medical profession altogether free from blame for its (pneumonia) prevalence?" And later he says: "Prophylactic measures have not been enforced as they should have been." Public education and professional teaching of the masses, followed in the masterly fight of the latter years against the increase of tuberculosis, may well be repeated in the fight that should be made against the further increase of the deathrate from pneumonia. As in pulmonary tuberculosis it must be not so much in the remedial measures as in the prophylactic agencies that we shall find the greatest results.

In the sick room the physician must intelligently teach its dangers and its preventive measures to the attendants. In the training school for nurses he must expound the truth of its deadly communicability and its successful prevention. He must advocate such laws of public sanitation, in regard to location, ventilation, disinfection of dwellings, as will best prevent the spread of this disease.

It should be the special care of the profession to guard the aged and protect infants from the prevailing evil conditions that so quickly cause them to succumb to this disease. With professional forethought in the treatment of influenza to avoid any lung complication, wise precautions in the administration of general anesthetics in the performance of surgical operations, and the most careful sanitary and aseptic measures in the treatment of patients with pneumonia, much will have been done toward lessening mortality.

In this day of medical enlightenment and the retrogression of fatality and frequency of all other infectious diseases, a masterful inactivity in the prophylaxis of pneumonia will but take from our day and time the glory of its wonderful progress. While if these seemingly overacting measures of prevention be adopted much will be done to annihilate the germinal cause, check the fatal progress and protect the stronghold of all future health against the devastating inroads of pneumonia.

## TETANUS.<sup>1</sup>

BY

ISAAC R. TRIMBLE, M.D.,  
 of Baltimore, Md.

Professor of Anatomy and Clinical Surgery, College of Physicians and Surgeons.

In 1884 Nicolaier described the bacillus of tetanus, and in 1889 Kitasato obtained it in pure culture. It is one of the most poisonous of known bacteria. The bacilli, when not in spore formation, are long and slender and have rounded ends. They are motile and seldom united in chains. At the temperature of the body they form spores, and when in spore formation there is an enlargement at one end of the bacillus, in the center of which there is a bright round spore. They have no flagella, and while in spore formation they are non-motile. They stain with the ordinary anilin dyes and by Gram's method.

It is a common, saprophytic organism and is found in garden earth, dust, especially of stables, and sometimes in the intestines and discharges of animals. It is difficult to isolate and grows only where oxygen has been displaced. Kitasato's method of obtaining it in pure culture is the one generally used. It consists of heating the cultures to 80° C. for an hour at a time. This is sufficient to kill all contaminating organisms, but does not kill the tetanus spores, which may be subsequently cultivated under suitable conditions. The cultures all have a peculiar, rather characteristic odor.

Verneuil has observed that tetanus rarely occurs at sea, and when it does it occurs on vessels carrying hay or dirt. Ledantec has noted the fact that the natives in the New Hebrides poison their arrows by dipping them in clay rich in tetanus bacilli.

The bacillus generally gains entrance into the body through a punctured wound or an open one that has been badly soiled. The period of incubation is from 7 to 28 days, and during this period the wound may heal and not be found on examination. Men, horses, mice and rabbits are very susceptible to this bacillus, while dogs and birds are but slightly so. Amphibians are immune, but frogs may be infected if the body temperature is raised.

The bacillus grows at the site of inoculation, but does not enter the blood-current and is very rarely found in the body. Its growth is most rapid and but few bacilli are required to produce a most powerful toxin. The following experiments need no word of comment:

Kitasato inoculated the tail of a mouse, and an hour later tail, skin and subcutaneous tissue about the root of the tail were cut away. In spite of this the mouse died of tetanus.

Nocard took three sheep and put under the skin at the root of the tail of each a splinter of infected wood. When the first symptoms appeared he cut off the tails of two of the sheep, keeping the third as a control. All three died of tetanus.

Mice may be killed by injecting into them the blood, urine, or cerebrospinal fluid of animals affected with tetanus.

Brieger separated from the blood of diseased animals and also from pure cultures of the tetanus bacillus two alkaloid substances which he calls tetanin and tetanotoxin. Both are poisonous and capable of producing convulsions. Brieger and Fraenkel later isolated an extremely powerful toxalbumin. Vaillard and Rouget found that when tetanus bacilli were injected into the body free from toxin, owing to the promptness with which the phagocytes took them up and destroyed them, there were no ill effects. If the tissues were injured, however, either from trauma or chemicals, the bacilli began to form toxins and symptoms resulted.

Behring and Kitasato, and subsequently many other observers, have produced a valuable antitoxin by the usual method of introducing into animals increasing doses of the toxin. A. Lambert has shown that a protective power of 1 to 800,000,000 can be obtained. Dr.

<sup>1</sup> Read before the Journal Club, November, 1901.

Welch has pointed out that antitoxin has not as yet been very successful in the treatment of human tetanus. In animals it has proved of great value as a preventive. In all laboratories where horses are injected with the various toxins there is invariably an outbreak of tetanus from time to time. If the animals are given tetanus antitoxin every three months these outbreaks are prevented. This has been shown to be so at the Mulford laboratories in Philadelphia.

Nocard's figures regarding protective inoculations are most striking. Of 2,727 animals inoculated not one developed tetanus, while during the same period in the same neighborhood 256 nonimmunized animals developed the disease. In the large lying-in hospitals where tetanus is present its spread may be prevented by giving the mothers an immunizing dose of the antitoxin.

The more acute the attack the less chance there is of cure. The prognosis depends on the period of incubation and the nature of the attack. Roux and Borelles assert that the mortality in severe cases is 50% when the injections are made in the subcutaneous tissue. Delayed cases may result in cure with or without the use of antitoxin. In those individuals in whom the disease develops before five days after infection, the prognosis is almost invariably fatal. I do not know of a case of the patient getting well when the disease developed within four days. All cases coming on after five days may be classed as delayed, and they have a correspondingly good prognosis, depending, of course, on the incubation period.

The treatment is to open the wound and cleanse it thoroughly, with the object of preventing the formation of more toxin. Blood may be drawn and the fluid in the body replaced by injecting normal salt solution. The antitoxin should be injected as soon as possible. It has been suggested by Rabbe that the antitoxin would be more powerful and quick in its action if it were injected directly into the cerebral cavity. To do this it would be necessary to trephine. A simpler plan is to inject it into the spinal canal, using the same procedure as for lumbar puncture. Subcutaneous injection seems, so far, to give about equally good results.

Carbolic acid has been recommended by many. The idea originated with Bacelli, and has attracted widespread attention in Italy, where the most brilliant results are claimed for it. It has not received very much attention elsewhere, although there are a few scattered reports, some by very good authorities, commending its use. The drug is given hypodermically, the dosage being about 0.2 cc. (3 minims) in 2% solution, given during 24 hours. Twice as much as this and even more has been given without bad results. The injections are usually given at two-hour intervals. I have had no personal experience with its use.

In former days the surgical treatment of tetanus consisted in cleansing the wound, nerve stretching, or even amputation of the member wounded, at the first sign of the disease. Today the treatment consists in thorough cleansing of the wound, administration of antitoxin, and the use of such drugs as may be deemed necessary for allaying unpleasant symptoms.

The dosage of antitoxin should be considered carefully and a sufficient quantity used. When tetanus first shows itself it has probably existed for some days in a latent stage, and with the use of antitoxin there is an alleviation of the unpleasant features in many cases, and in some of the delayed cases a cure may be effected. Let me refer briefly to my experience with this disease:

While I was a student of medicine at the Maryland University, a boy of 12 years came in with a crushed foot. The late Dr. J. E. Michael amputated the leg, and 10 days later the boy developed tetanus. We gave him whisky, milk and opium by rectum and by mouth. Chloroform was used to lessen the spasms. The case was one of delayed tetanus, and after an illness of three weeks the boy recovered.

In April, 1892, a stableman was kicked on the leg by a

horse. A compound fracture of the tibia and the fibula was the result. The wound was cleansed and dressed. Four days later tetanus developed. Six days after the injury I amputated the leg above the knee, but without effect on the course of the disease. The man died on the seventh day after infection.

In 1894 a man fell down an areaway and sustained a compound comminuted fracture of the left shoulder bones. The wound was carefully cleansed and dressed. Seven days later the first symptoms of tetanus showed themselves, and 36 hours later the man died. The ordinary treatment was without avail.

In 1898 a negro was admitted to the City Hospital suffering from a wound of the foot of five days' standing. Tetanus had already developed. The wound was opened and cleansed and he was given a full dose of morphia and tetanus antitoxin hypodermically. During the following week he was given 700 cc. of the serum. He recovered and was able to leave the hospital in a month.

In 1900 a white woman came into the City Hospital. She had had spasms of the jaws for two weeks, was emaciated, and much reduced in health. She was given antitetanic serum and improved. Unfortunately the spasm was never relieved entirely, and she died of exhaustion four weeks later.

During the same year I was called to see an old man who had fallen in the street two weeks previously, receiving a cut on the head. The wound had been dressed by the family physician. On the ninth day tetanus developed. When I saw him he had been having convulsions for five days. He was given three phials of the antitoxin, but without result. He died 12 hours later.

In 1901 a negro who had served in the U. S. Army at Santiago, and who had had both yellow fever and rheumatism at that time, came to my office. Two hours before he had been thrown from his wagon into the street. The palm of his right hand at the base of his middle finger was torn across exposing the tendons. There was dirt in the wound and in the tendon sheath. He regarded the wound as trivial and came only because urged to do so by his employer. The finger was cocaineized and laid open. It was cleansed thoroughly and then allowed to soak in 1-5,000 bichlorid solution for 15 minutes. As the wound did not heal readily and there was some suppuration, it was opened again and hydrogen dioxide used in cleansing it. Ten days later the wound was practically healed, only a small part of it granulating. On the thirteenth day the patient told me that his right shoulder pained him and that he thought he had a return of the rheumatism with which he had suffered while a soldier. Tetanus was not suspected at this time. I was called to see him two days later, and he presented all the characteristic symptoms of tetanus. He was moved to the City Hospital, and placed in a darkened room and kept absolutely quiet. The convulsions were very severe, some lasting so long that it was feared he would die from impeded respiration. Chloroform was used to relax him, and he was given three phials of antitoxin which relieved him in a half hour, so that he was able to take nourishment. For 10 days he was given the serum every six hours. At first three phials were given at a dose, later two, and at the end of the treatment only one. Within 10 days he was given 53 phials of antitoxin. His spasms ceased but the muscles remained stiff and sore. He continued to improve, and was discharged cured at the end of six weeks.

From the foregoing cases and those of other observers I am led to believe that the tetanus antitoxin is of very considerable value in the treatment of this disease, especially in the delayed cases.

## LOBAR PNEUMONIA AND ITS TREATMENT.<sup>1</sup>

BY

G. WEHRLI, B.S., M.D.,  
of El Paso, Tex.

Pneumonia has been defined as an inflammation of the parenchyma of the lungs. "The parts of the lungs involved are the alveoli, the air passages, and the smallest bronchi."

Of all cases of pneumonia 90% are caused by the pneumococcus of Fraenkel. The bacillus of influenza probably ranks second as a causative agent. The pneumococcus of Friedländer, streptococcus of suppuration, Klebs-Loeffler bacillus, fungus of actinomycosis, plague bacillus, colon bacillus, typhoid bacillus, tubercle bacillus, intracellular meningococcus, and perhaps other organisms are each capable of setting up pneumonia. Neusser, of Vienna, mentions a case in which a gonococcus-like organism seemed to have caused pneumonia.

The disease is most common and most fatal at the two

<sup>1</sup> Read before the El Paso County (Tex.) Medical Society.

extremes of life. Delafield says that of 7,873 cases occurring in New York City between 1871 and 1875 nearly one-half were in children under five years of age. Loomis states that 65% of all deaths after 75 are caused by lobar pneumonia. The fact that the mortality is so high at the two extremes of life renders statistics showing very favorable results in the treatment of a small number of vigorous adults of practically no value.

Pneumonia occurs about twice as frequently in males as in females. In youth and old age the sexes are about equally subject to the disease. Nephritis, diabetes, and alcoholism, measles, diphtheria, and other infectious diseases act as predisposing causes. Traumatism may also give rise to pneumonia.

In the United States pneumonia is more prevalent in the South than in the North. Colorado shows 60 deaths per 1,000 due to pneumonia, while Alabama has 123 per 1,000, and Arkansas 183 per 1,000. From January 1, 1895, to December 31, 1899, there were 1,736 deaths from all causes in El Paso. Of these 114 were due to pneumonia, which is 66 per 1,000. This includes all kinds of pneumonia.

According to the last census, pneumonia caused more deaths than any other disease. In New York City from 1890 to 1900, there were 56,062 deaths from this cause, and but 50,490 from tuberculosis. During the same period Chicago had 25,228 deaths from pneumonia and 22,957 from tuberculosis. The recent increase in mortality has been ascribed to influenza. Osler says that hospital records show a mortality of from 20% to 40%. He says that of 3,969 patients treated at the Charity Hospital, New Orleans, the deathrate was 28.01%. His analysis of 708 cases at the St. Thomas' Hospital shows that the mortality increases from the twentieth year on, rising from 3.7% under that age to 22% in the third decade, 30.8% in the fourth decade, 47% in the fifth decade, 51% in the sixth decade, and 65% in the seventh decade. A collection of 223,730 cases gathered from various sources gave a mortality of 18.1%. The mortality at El Paso is between 20% and 25%.

Hardship, alcoholism and extreme poverty make the prognosis bad. Pneumonia secondary to measles and the diarrheal diseases of children, is almost always fatal, circulatory failure being the common cause of death. There is generally an intense toxemia, partly due perhaps, to the great mass of infected tissue, through which a large part of the blood must pass with each circuit. The final effect of the toxins of pneumonia is to cause a vasomotor paralysis, to which the heart failure is due in most instances. The consolidated lung offers some resistance to the circulation, but while the affected part is impervious to air, the bloodvessels are, of course, open, or gangrene would result. Especially in pneumonia of the lower left lobe the consolidated and enlarged lung may press upon the heart and somewhat impede its action. In many cases tympanites embarrasses the heart movements by pressure from below. By preventing the descent of the diaphragm the circulation is also deprived of the aid of aspiration of the thorax with each respiration.

Of complications, meningitis is fatal. It is, however, not always easily made out during life. Ulcerative endocarditis is a common complication in cases terminating fatally. Pericarditis, the involvement of more than one lobe and pleurisy add to the gravity of the case. Edema of the lungs indicates a desperate, but not necessarily hopeless condition. A pulse of from 140 to 150 per minute, steadily maintained or gradually increasing in rapidity, generally means a fatal termination. High temperature has little to do with the prognosis. Marked leukocytosis is said to be a favorable symptom, as is also the reappearance of chlorids in the urine. Patients with a scanty excretion of urine do badly.

I will not discuss the morbid anatomy and symptomatology. Mistakes in diagnosis are very seldom made;

but lobar pneumonia in children is often overlooked if careful physical examinations are not made. A distinguished author has said "pneumonia is a self-limited disease and runs its course uninfluenced in any way by medicine. Patients are more often damaged than helped by the poisonous drugging, which is still only too prevalent." It is very evident however that some do not subscribe to this dogma.

Petresco gives from 4 to 12 grams of digitalis in powder daily. He reports 1,192 soldiers treated by this method, with a mortality of from 1.2% to 2.6%. The crisis occurred in general as early as the third day. Anders, in his textbook, says that this treatment is rational, but warns against the use of large doses of digitalis after the lung has become consolidated. It must be remembered that Petresco's cases were in young and healthy individuals, at an age when the deathrate is normally low. Corin has had similar results with large doses of digitoxin. He treated 54 patients with digitoxin with but four deaths. These cases occurred in private practice and in 24 the process ran its course completely in from 24 to 36 hours.

Dr. T. G. Stephens, of Sidney, Iowa, a practitioner of forty-two years' experience, says that veratrum viride is more efficacious in pneumonia than quinin is in malaria. His deathrate is 8%. He gives three-drop doses of Norwood's tincture, and increases the dose one or two drops each time until the desired effect is produced. Hare thinks veratrum viride sometimes capable of aborting a beginning pneumonia. H. C. Wood believes that in the early stages of sthenic pneumonia, veratrum viride offers the best known method of reducing the pulse-rate and temperature, and of ameliorating the disease. Dr. J. Paffrath asserts that he has never failed to abort a beginning pneumonia in three or four days, and the severest double pneumonia in five or six days by administering .39 gram to .45 gram (6 or 7 grains) of acetanilid with .19 gram to .26 gram (3 or 4 grains) of Dover's powder every four hours day and night. He has never seen collapse or other dangerous symptoms from acetanilid. De Becker recommends salicylic acid, and believes that, if administered early it is a sure preventive. Eleven out of twelve patients thus treated by him were cured quickly. Of seventy-two cases of pneumonia occurring in Austria, the patients were treated with 8 grams (120 grains) of sodium salicylate daily, and all recovered. Dr. Sebering, of Kingston, N. Y., treated seventy-five patients in this manner with but one death.

Within the last few years creosote carbonate has been highly commended, it being claimed that in the form of creosotal it is an antidote for the toxins of pneumonia. The dose advised is from 2 to 12 grams (.5 to 3 drams) a day. Excellent results are reported, but the statistics that I have seen only included patients between the ages of 10 and 45, a period during which, as has been already shown, the mortality is not high.

Dr. Thomas J. Mays, of Philadelphia, believes in treating pneumonia by the application of ice bags over the lesion in the lungs. He has collected a large number of statistics showing a mortality of but 3% when his method has been followed.

Dr. Simon Baruch urges the great value of hydrotherapy in the treatment of pneumonia. He advises the wet compress, which consists of several folds of old linen covered with flannel and cut in the form of a vest so as to fit accurately the whole chest. This is to be wrung out of water at 60° F., and changed every half hour; if the temperature is below 102.5°, every hour, and when it is 99.5° it is discontinued. He has not lost an uncomplicated case of pneumonia since adopting this plan of treatment. To combat collapse he has depended largely upon strychnin used hypodermically. In connection with the compress externally, he has insisted upon large quantities of fluid being taken internally.

Regnaud, of Marseilles, has bled pneumonia patients, at the same time injecting normal salt solution. It is

said that by this plan cyanosis disappears, arterial tension improves, and the energy and regularity of the heart are increased. Wells, of Chicago, has reported good results from this procedure.

Venesection performed early has produced striking results in some cases. The symptoms calling for venesection, according to Broadbent, are distended jugular veins, cyanosis and a strong apex beat with a weak pulse, showing that the right ventricle is unable to overcome the obstruction in the lungs. Late venesection it would seem is a mistake. Out of 12 hospital patients upon whom Osler did the operation 11 died.

The specific treatment of pneumonia would be all very well if others could get the same results claimed by a few enthusiasts. In many cases the drugs mentioned cannot be used at all. For example in acute gastritis digitalis and ammonium salicylate are out of the question. And in the pneumonia complicating measles, the summer diarrheas of children, or typhoid fever, who would have the hardihood to use any of the drugs advised? And the same might be said of the old and feeble, and also of marasmic infants. And it is just these patients that give the highest mortality.

The best results on the whole seem to come from rational symptomatic treatment. *Absolute rest* in bed from the very beginning is imperative. The patient should not be allowed to raise himself in bed for food or medicine, and the bedpan should be used from the start. Anything that will add to the comfort of mind or body is a real and valuable aid to recovery. All visitors must be firmly refused admittance to the sick-room. Until these matters have received attention, we are not ready to begin the administration of drugs, which is a part of good nursing, but cannot be left to the nurse without detailed instruction from the physician. It is our first duty to see that the patient does not kill himself by his indiscretions; second, to prevent his friends from killing him by their misguided zeal, and third, to beware lest we ourselves snap the slender thread of life in our anxiety to give relief.

The diet should be nourishing and easily digestible. Milk serves a twofold purpose, as a food and as a diuretic. An abundance of plain or medicated water should be given to aid in carrying off toxins by the urine. Enemas of normal salt solution meet the same indication and form a valuable routine measure. Tympanites should be carefully watched for and promptly relieved by enemas or turpentine stupes. A dose of from .32 gram to .65 gram (5 to 10 grains) of calomel in the beginning is generally good, but too active purging does harm by carrying off fluid by the bowels that is needed for the elimination of toxins by the kidneys.

An abundance of fresh air will do much to prevent circulatory failure. Huxley once said that if the tissues of the human body were as well supplied with oxygen as are those of the gnat, an ordinary man could easily carry Newgate prison across the street on his back. The proper ventilation of the sick-room must come before the administration of cardiac stimulants. Of course the tissues can only use a certain amount of oxygen, but that ought to be furnished in an atmosphere that is pure and unvitiated. An oil stove, or worse yet, a swarm of visitors in the sick-room may be the means of killing a pneumonia patient by robbing him of fresh air and oxygen.

Fever, unless it causes restlessness or remains persistently high is best left untreated. If it becomes necessary to reduce it the wet pack, or ice bags, to the head and chest, or sponging with cold water are probably the safest measures. Circulatory stimulants are often needed but should only be employed when plainly indicated. A pulse that is poorly filled and gradually increasing in rapidity until 120 or 130 beats per minute are reached generally calls for heart stimulants. When the second sound of the heart at the pulmonary orifice begins to grow faint and poorly accentuated, failure of

the right ventricle is apparent, and it is the most valuable sign of heart failure. Strychnin, ammonia, ether, and camphor are most to be depended upon in desperate cases. The administration of 6 mg. ( $\frac{1}{10}$  gr.) of strychnin every hour for a few doses may be necessary at times; but ammonia and ether make the most prompt and decided impression upon the circulation. The administration of 15 minims each of ammonia and ether night and day every 15 minutes, as advised by Professor Elsner, has apparently saved life in some instances. His patients were in a desperate condition, with pulse from 130 to 150 per minute, cyanosis, tracheal rattling and edema of the lungs persisting for from one to three days. Still many patients will die under any form of treatment. What I wish to emphasize especially, and what seems to be generally overlooked or regarded of secondary importance, is the great value of fresh air, plenty of water, absolute rest in bed, and good nursing.

## SPECIAL ARTICLES

### ON THE CLASSIFICATION OF MUSEUM SPECIMENS.<sup>1</sup>

With an Exposition of a Decimal Classification of Museum Specimens Applied in the Pathological Museum of McGill University, After a Plan Suggested by the Late Professor Wyatt Johnston.

BY

M. E. ABBOTT, B.A., M.D.,  
of Montreal, Canada.

Curator, Pathological Museum, McGill University.

The progress of modern professional education being always toward more objective teaching in all departments, the importance of the medical museum in this connection increases constantly, and in a university the uses of the museum as a storehouse for the curiosities of medicine or for the materials of scientific research are naturally subordinated to its value in the practical assistance it can lend the teacher by placing at his hand the fullest illustration of the varying facts which he seeks to impress upon the student.

Further, in the department of pathology, museum preparations have of late years been made of infinitely greater value to the teacher by the introduction of methods for preserving the natural colors of organs. The discovery of these methods was announced in the year 1896 by three independent workers—Melnikow-Raswedenkow, Jore, and Kaiserling.<sup>2</sup> These methods, one or other of which is now the routine practice in almost all the leading museums, depend on the action of, first, formalin, and then alcohol, on the blood-coloring matter in the tissues, the formalin reducing the hemoglobin to brown acid hematin, and the alcohol changing this again to the red alkaline hematin, a substance closely resembling oxyhemoglobin in color, but which remains fixed in the tissues and does not undergo further change.

Under the right employment of these methods there is now no longer a "Museum Pathology" in which the peculiar appearances of the museum specimen must be acquired for examination purposes by the hard-worked student. Today a well prepared museum specimen, its colors preserved almost as in life, properly mounted to resemble as closely as possible its position in the body, and carefully dissected to display the extent and relations of the lesions, presents appearances very similar to those of the postmortem-room, and sometimes shows the morbid process even more clearly and with greater advantage to the student. At the meeting of the Berliner Med. Gesell., of July 8, 1896, at which Dr. Kaiserling first announced his method, Professor Virchow stated that he believed the use of this process for the preservation of the natural colors of organs would inaugurate a new era in the demonstrative teaching of pathology, and already it may be said to have done so.

Virchow's own institute—the new Pathological Museum of

<sup>1</sup>Read before the meeting of the Canadian Medical Association, Montreal, September 18, 1902.

<sup>2</sup>Puppe: Vierteljahrsschrift für gerichtliche Medizin, 2 Folge, xvii, 2.

Berlin—is a good example of the extensive use to which a large collection of fine specimens can be put in teaching. This museum, which was formally opened last year at the festival of Virchow's eightieth birthday, is a large, four-story brick building devoted entirely to pathologic museum specimens, to museum preparation rooms, and lecture theater, and contains about 20,000 specimens. Among these are many full series of the finest colored preparations. These are used singly to illustrate conditions studied for the first time, in groups for comparison and differential diagnosis, and also (and this especially) in large numbers for purposes of rapid review. In Virchow's own words, written at the time of the opening:

Thus will the student prepare himself for the difficult art of forming for himself, out of the confusing many-sidedness of pathologic appearances, a general idea of a diseased process, even in those cases in which direct observation is impossible.<sup>1</sup>

So soon as a museum collection becomes of any size the question of its scientific classification is of primary importance. This not only for the convenience of the teacher and the curator, but also for the sake of making the material as it stands on the shelves accessible and of most advantage to the student. For this reason a useful classification must be based on teaching principles.

Pathologic material will be approached by the teacher from the standpoint of (a) general pathology, the study of the same morbid condition as it appears in different organs and tissues; (b) special pathology, the study of the same organ as it is affected by different diseases, and (c) regional pathology, the study of a portion of the body, such as the head or abdomen, according as it is affected by different diseases.

Any classification will naturally be based on one of these divisions, and in a large collection where specimens are duplicated all three may be followed. Thus in the great Army and Navy Museum at Washington there are three full sets of specimens. First one finds diseases and injuries of regions, in which morbid processes involving the head, thorax, abdomen and extremities are grouped together; second, diseases of organs where groups of pathologic conditions affecting the different parts of the circulatory, nervous, digestive and other systems follow each other; and third, one sees illustrations of the same diseased process, *e. g.*, tuberculosis, syphilis, infarction, as it affects the different organs of the body.

In the great Museum of the College of Surgeons of London, as also in the small but beautifully ordered Museum of Charing Cross Hospital, an anatomic classification is followed throughout, specimens being subclassified pathologically under the main divisions of the organ in which they occur. For a smaller teaching museum, such as college museums are likely to be, where specimens are not often present in duplicate, this last named arrangement would seem to be the most practical. That is, that an anatomic classification be followed and the different morbid processes affecting each organ be subclassified under it, general and regional pathology being provided for by cross cataloguing. Especially characteristic groups of morbid conditions, such as calculi, parasites, etc., may be placed together as departments of general pathology.

The general plan of classification having thus been mapped out, a less prominent but no less important problem is the method in which the preparation shall be numbered so that it will remain in the order to which it has been assigned, perhaps after some study. The specimen must either bear the number of its shelf or its catalog number must be made to give an index to the place to which it belongs on the museum shelves. I have the honor to present in this paper a system of descriptive catalog numbers which has recently been applied in the Pathologic Museum of McGill University. These catalog numbers have a logical sequence and are based on a scientific classification of which the main grouping is anatomic and the subdivisions pathologic.

For the suggestion of this classification the museum committee is indebted to the late Professor Wyatt Johnston, with whom also the pathologic portion of the classification was original.

To devise a good working system of catalog numbers that

will not require frequent change is a problem that has exercised museum workers everywhere, and has nowhere as yet been satisfactorily solved. It has generally, indeed, been set aside as less important than the time which it would take to elaborate it. What is required is a system of numbers which will run in numerical rotation in the museum and will yet allow of the addition of new specimens in the division of the classification to which they belong without disturbing this numerical order.

In the College of Surgeons of London, as in the Charing Cross Museum, which has lately been completely recatalogued under Dr. Hunter, only one set of consecutive numbers is used, and these numbers follow each other in rotation all through the museum. Gaps are left in the series for new specimens, and new duplicate specimens are distinguished from the original by a small letter. Thus: 1001, Tuberculous Pericarditis, 1001a, ditto.

The objection to this method is that it does not allow for the growth of the museum. When new specimens have exhausted all the numbers of the gaps that have been left in the series or have occupied all the shelf room that has been left empty for them, an extension means a complete renumbering of the collection in order to preserve the rotation. A descriptive number is needed which will be common to each group of specimens, some additional letter or figure being added to distinguish the particular specimen from another of the same group. This has been attempted in the Army and Navy Museum, Washington. Here a descriptive number is used; it is made up of letters to represent the anatomic, and figures to represent the pathologic condition, while the particular specimen is indicated by a figure placed after a decimal point. Thus, for instance, capital D. would represent the circulatory system, little a. the heart, and 3 anomalies. All specimens showing anomalies of the heart are labeled Da3, the individual specimens of this condition would be Da3.1, Da3.2, Da3.3, etc.

If I may venture to criticize so excellent a museum, it appears to me that in the Army and Navy collection the ideal lying behind this descriptive number has not been systematically carried out in its application, so that it does not altogether answer the purpose for which it was intended. The classification on which the numbers are based does not attempt to be a complete one, only a few headings being used, and these not always exhausting the main divisions of the subject, nor following each other in the order in which we are accustomed to think of them. So that not only is it often difficult or even impossible to classify a specimen under the headings that the catalog numbers furnish, but also it is impossible to observe the numerical order in the different groups without disturbing the natural order in which the specimens should stand.

#### THE CLASSIFICATION OF SPECIMENS IN THE PATHOLOGICAL MUSEUM OF MCGILL UNIVERSITY.

In the year 1897 this museum was renovated and put in order under the direction of Professor Adami. At this time the specimens were grouped on an anatomic classification, with a pathologic subclassification, and a corresponding descriptive catalog number made up of letters and figures, as in the Army and Navy Museum, was used. The classification employed, however, as was necessary in any attempt to get the whole mass of material into order in a short time, was too broad to be adequate for permanent purposes. The few divisions made were soon found insufficient for classifying purposes, as they did not indicate the whole range of pathologic possibilities.

In the year 1899 the late Professor Wyatt Johnston laid the decimal system of classification and catalog numbers, which is the subject of this paper, before the Museum Committee. It was adopted and applied and the collection catalogued upon it.

In its application this system has been found to meet all the requirements of the case. Its decimal character admits of its being extended in any one direction or of its being modified in any one particular at will, and specimens can be kept in order on the shelves without the help of skilled labor.

The general principles of this classification may be summed up as follow:

A full classification, both anatomic and pathologic, is aimed at, in which there is a logical sequence of ideas. The anatomic

<sup>1</sup> Virchow: Das neue Pathologisches Museum zu Berlin, Berlin, 1901.

condition is made the main classification and the pathologic condition a subclassification under it. In the anatomic classification organs are made to follow each other, so far as possible, in their relations in the body. Thus, the respiratory system runs: 21, nose; 22, larynx; 23, trachea and bronchi; 24, lungs; 25, pleura, passing from the surface inward. So also in the pathologic classification, anomalies, circulatory disturbances, inflammations, progressive and retrogressive changes follow each other in the order in which they are generally presented to the student.

The descriptive numbers are made up of figures only. A decimal point is used, and the anatomic condition is represented by numbers before, the pathologic by numbers after the decimal point. The particular specimen is indicated by a small index figure to the right of the full number.

The Dewey system of library classification is followed. This is a decimal system. The set of numbers before and after the decimal point each represent a complete classification in themselves. In each classification there is a division into ten main groups, and each of these groups may be divided at will into ten or less subgroups, each of which may again be subdivided into ten, and so on indefinitely.

The Anatomic Classification.—This is the main classification. The numbers representing its divisions precede the decimal point in the catalog number. With a few insignificant modifications it is the work of Dr. Haviland Field, of Zurich, and was devised by him for use in medical libraries under the Dewey system.

- 1. CIRCULATORY SYSTEM:
  - 11. Pericardium.
  - 12. Heart and Myocardium,
  - 13. Endocardium,
  - 14. Arteries,
  - 15. Veins,
  - 16. Capillaries,
  - 17. Blood,
  - 18. Lymphatic Vessels.
- 2. RESPIRATORY SYSTEM:
  - 21. Nares,
  - 22. Larynx,
  - 23. Trachea and Bronchi,
  - 24. Lungs,
  - 25. Pleura.
- 3. DIGESTIVE SYSTEM:
  - 31. Teeth,
  - 32. Mouth, Tongue, etc.,
  - 33. Pharynx and Esophagus,
  - 34. Stomach,
  - 341. Stomach Contents,
  - 35. Intestine,
  - 351. Small Intestine,
  - 352. Appendix and Cecum,
  - 353. Large Intestine,
  - 354. Rectum,
  - 355. Intestinal Contents,
  - 36. Peritoneum and Mesentery,
  - 37. Liver,
  - 38. Gallbladder and bile-ducts,
  - 39. Pancreas.
- 4. LYMPHATIC SYSTEM AND DUCTLESS GLANDS:
  - 41. Special Lymphatic Glands,
  - 42. Thymus Gland,
  - 43. Thyroid Gland,
  - 44. Spleen,
  - 45. Suprarenals.
- 5. UROGENITAL SYSTEM:
  - 51. Kidney,
  - 52. Ureter,
  - 53. Bladder,
  - 54. Urethra,
  - 55. Penis,
  - 56. Prostate,
  - 57. Seminal Vesicles, Vas Deferens and Cord,
  - 58. Testes, Epididymus and Tunica Vaginalis,
  - 59. Scrotum.
- 6. FEMALE GENERATIVE SYSTEM:
  - 61. Vulva,
  - 62. Vagina,
  - 63. Uterus,
  - 64. Tubes,
  - 65. Ovaries,
  - 66. Broad Ligament,
  - 661. Parovarium,
  - 67. Mamma,
  - 68. Gravid Uterus,
  - 69. Ovum,
  - 691. Membranes,
  - 692. Placenta,
  - 693. Fetus.
- 7. NERVOUS SYSTEM:
  - 71. Dura Mater,
  - 72. Pia Mater,
  - 73. Brain,
  - 74. Medulla and Pons,
  - 75. Spinal Cord,
  - 76. Nerves,
  - 77. Sympathetic System,
  - 78. Eye,
  - 79. Ear.
- 8. TEGUMENTARY AND MUSCULAR SYSTEMS:
  - 81. Skin,
  - 82. Hair,
  - 83. Nails,
  - 84. Muscle and Fascia,
  - 85. Cellular Tissues.
- 9. OSSEOUS AND ARTICULAR SYSTEMS:
  - 91. Bones of Cranium,
  - 92. Bones of Face,
  - 93. Vertebras,
  - 94. Sternum,
  - 95. Ribs,
  - 96. Bones of Upper Extremity,
  - 961. Scapula,
  - 962. Clavicle,
  - 963. Shoulder-joint,
  - 964. Humerus,
  - 965. Elbow-joint,
  - 966. Bones of Forearm,
  - 967. Wrist-joint and Joints of Hand,
  - 968. Bones of Hand,
  - 97. Pelvis,
  - 98. Bones of Lower Extremity,
  - 981. Os Innominatum,
  - 982. Hip-joint,
  - 983. Femur,
  - 984. Knee-joint,
  - 985. Bones of Leg,
  - 986. Joints of Ankle and Foot,
  - 987. Bones of Foot.
- 0. REGIONAL:
  - 01. Head,
  - 02. Face,
  - 03. Neck,
  - 04. Trunk,
  - 05.
  - 06.
  - 07.
  - 08.
  - 09.

The Pathologic Classification.—This is the subclassification. The numbers representing its divisions follow the decimal point in the catalog number:

- 1. ABNORMALITIES:
  - .11 Persistent fetal structures,
  - .12 Defective closure of fetal openings,
  - .13 Fetal disease,
  - .14 Malposition of parts,
  - .15 Suppression of parts,
  - .16 Excess of parts,
  - .17 Duplication of parts,
  - .18 Reversions,
  - .19 Teratomas,
  - .20
- 2. CIRCULATORY DISTURBANCES: (Abnormal distribution of blood and lymph)
  - .21 Anemia,
  - .22 Hyperemia,
  - .23 Hemorrhage,
  - .24 Thrombosis,
  - .25 Embolism,
  - .26 Infarction,
  - .27 Edema.
- 3. INFLAMMATIONS:
  - .31 Parenchymatous degeneration,
  - .32 Cellular or catarrhal inflammation,
  - .33 Serous inflammation,
  - .34 Fibrinous or croupous inflammation,
  - .35 Diphtheric inflammation,
  - .36 Hemorrhagic inflammation,
  - .37 Purulent inflammation,
  - .38 Destructive inflammation,
  - .39 Productive inflammation.
- 4. INFECTIONS AND PARASITES:
  - .41
  - .42 Pyogenic cocci,
  - .43 Bacilli,
  - .44 Spirilla,
  - .45 Yeasts and molds,
  - .46 Protozoa,
  - .47 Verms,
  - .48 Verms,
  - .49 Arthropods.
- 5. GRANULOMAS AND GENERAL DISEASES.
  - .51 Tubercle,
  - .52 Lupus,
  - .53 Syphilis,
  - .54 Glanders,
  - .55 Actinomycosis,
  - .56 Diseases of the blood,
  - .57 Nutritional diseases,
  - .58 Gouty rheumatic group.
- 6. PROGRESSIVE CHANGES:
  - .61 Regeneration,
  - .62 Hypertrophy,
  - .63 Histoid tumors,
  - .64 Histoid tumors,\*
  - .65 Sarcoma,
  - .66 Sarcoma (mixed forms),
  - .67 Cyst formation and teratomas,
  - .68 Benign epithelial tumors,
  - .69 Carcinoma.
- 7. RETROGRESSIVE CHANGES:
  - .71 Atrophy,
  - .72 Necrosis,
  - .73 Gangrene,
  - .74 Degenerations,
  - .741 Parenchymatous,
  - .742 Fatty,
  - .743 Hyaline,
  - .744 Amyloid,
  - .745 Caseous,
  - .746 Calcification,
  - .747 Pigmentary,
  - .748 Cystic degeneration,
  - .75 Ulceration and abscess formation,
  - .76 Perforation and rupture due to disease,
  - .77 Dilatation due to disease.
  - .78 Stenosis due to disease.
  - .79 Calculus formation.
- 8. WOUNDS AND INJURIES:
  - .81 Wounds,
  - .82 Ruptures and lacerations,
  - .83 Gunshot wounds,
  - .84 Fractures,
  - .85 Dislocations,
  - .86 Sprains,
  - .87 Corrosion,
  - .88 Poisons,
  - .89 Foreign bodies,
  - .90 Abortions.
- 9. SPECIFIC ARTEFACTS:
  - .91 Amputation,
  - .92 Excisions,
  - .93 Plastic operations,
  - .94 Ligatures,
  - .95 Miscellaneous operations,
  - .96 Tattooing,
  - .97
  - .98 Gas formation,
  - .99 Postmortem changes,
  - .90

  - .08
  - .09

A glance at the details of this system as it is applied in the museum will illustrate what, although it may appear complicated, is really a very simple principle. The whole collection is divided into 10 main divisions, the 10 systems of the anatomic classification, and the organs of each system are arranged under it. Under each organ again the lesions affecting it are classified, while the individual specimens showing the same condition stand in the rotation of their index figures. Thus, the first department is lettered: 1. Circulatory System, and its first division: 11. Pericardium. The specimens showing inflammations of the pericardium read as follows on the shelves:

- 11.23<sup>1</sup> Ecchymoses into pericardial layers.
- 11.34<sup>1</sup> Acute fibrinous pericarditis, moderate degree of "Cor Villosum."
- 11.34<sup>2</sup> Acute fibrinous pericarditis. Fine example of "Cor Villosum."
- 11.34<sup>3</sup> Subacute serofibrinous pericarditis.
- 11.34<sup>4</sup> Acute serofibrinous pericarditis. Pericardial cavity enlarged. Both layers covered with a granular deposit having a flattened surface and peeling off in flakes.
- 11.34<sup>5</sup> Subacute serofibrinous pericarditis.
- 11.36<sup>1</sup> Hemorrhagic pericarditis.
- 11.37<sup>1</sup> Purulent pericarditis. Greatly enlarged pericardial cavity, which contained postmortem a pint of pus.
- 11.37<sup>2</sup> Subacute purulent pericarditis. Both surfaces covered with a phlegmonous sloughy bloodstained surface.

\* Where a term is repeated it signifies that the possible subdivisions being more than 10, 20 instead of 10 places are allowed for convenience in classification.

- 11.39<sup>1</sup> Chronic adhesive pericarditis, pericardium adherent anteriorly, the layers widely separated posteriorly to contain a large cavity. Both layers are thickened and lined by organized tissue.
- 11.39<sup>2</sup> Chronic adhesive pericarditis.
- 11.39<sup>3</sup> Chronic pericarditis with localized adhesions.
- 11.39<sup>4</sup> Chronic mediastinopericarditis. The outer surface of the parietal pericardium is adherent to the pleura covering the right lung, also firmly united to diaphragm below and anteriorly.
- 11.39<sup>5</sup> Chronic adhesive pericarditis. A filmy layer of organized tissue unites the opposed surfaces at all points. Etc., etc., etc., etc.

The anatomic classification is followed in the museum into all its details, and cards bearing the title of each division, with its corresponding number, are placed over the shelves where each organ is to be found. These subdivisions form the most convenient point in the whole system. Thus, after 34, Stomach, a compartment is found, 341, Stomach Contents; after 35, Intestine (under which are classed lesions affecting the intestine as a whole, such as "hernias"), comes 351, Small Intestine; 352, Appendix and Cecum; 353, Large Intestine; 354, Rectum; 355, Intestinal Contents. Again, the obstetric collection arranges itself naturally at the end of the gynecologic department.

In the pathologic classification, on the other hand, the intent has been to avoid subdivision wherever possible. Although a full table of possible conditions has been made out, the subheadings are used only in those cases in which there are many variations of a given lesion. Thus, "Anomalies" of the pericardium, being rare, would be all classed together, 11.1<sup>1</sup>, 11.1<sup>2</sup>, 11.1<sup>3</sup>, etc., while "Anomalies" of the heart itself, being many and varied, would be subclassified under this head as 12.11<sup>1</sup>, 12.12<sup>2</sup>, 12.13<sup>3</sup>, etc., according to the condition.

In working out this system in the museum, one or two possible alterations have suggested themselves. If the anatomic classification were altered to: 1. Digestive System. 2. Respiratory System. 3. Circulatory System. 4. Glandular System. 5. Urogenital, etc., the lymphatic vessels with which the circulatory system ends would stand next to the lymphatic glands, and the suprarenals, with which the glandular system ends, would stand next to the kidney, with which the Urogenital begins. But this is a minor point, and it seems not worth sacrificing to it the natural order which would certainly begin the open book which the museum aims at making itself to the students with the circulatory system.

The pathologic classification presents, in the nature of the subject, many difficulties. In the present state of our knowledge it is not like an anatomic classification, based on certain well-established facts, it is largely tentative, for our ideas of pathologic conditions change constantly with the increase of our knowledge. One has only to glance at the repeated changes that are being made, for instance, in the Bertillon classification of the causes of death, to realize how impossible a permanent nomenclature will be, at least for many years to come. All that can be done is to classify so far as possible on the actual pathologic changes known to be present, rather than on any supposed etiology.

The advantages of this system may be summed up as follows:

First. A careful classification is, as has been said at the outset, absolutely necessary to make a museum of thoroughly practical use to teacher or student. A careful system of catalog numbers which follows the classification into its details, so far as one wishes to push it, is of inestimable use to the curator in meeting this requirement. The catalog number chosen carefully and with study to describe the condition cannot fail of its numerical order in relation to other specimens of the same kind, and the preparations can then be kept in their appointed order by any boy who follows the one order that he is to watch the figures closely and place the specimens under their main group in the strict rotation of their index figure.

Second. The system allows of an indefinite growth of the museum, for it is expansive, permitting the addition of an indefinite number of specimens without any disturbance of either the grouping or the numerical order.

Third. It admits of subclassification to an indefinite extent in any one direction that may seem desirable. Thus, suppos-

ing that the museum is particularly rich in tumors, or that the curator devotes much time to working out this particular department, he can subdivide, *e. g.*, Sarcoma—65 Sarcoma; .651 Round-celled sarcoma; .652 Spindle-celled sarcoma; .653 Giant-celled sarcoma—and so on indefinitely. In short, this system is an aid to exact definition which is the basis of accuracy.

We believe that some form of decimal classification has been contemplated in several museums on this continent and has already been introduced in one or two places, as in the Museum of Biology and Zoology at Manchester, England; in the Pathologic Museum at Newcastle-on-Tyne, and in the Pathologic Laboratory of Professor Ira Van Gieson. But we do not know the details of the systems adopted or the degree of success which has attended them. The classification applied in the Pathologic Museum of McGill University, and given in detail in this paper, has now been in working order for more than a year and has proved itself thoroughly satisfactory in meeting the requirements alike of teacher, curator and student. In view of this fact we have thought it important to put it fully upon record in the hope that its utility might be increased by its adoption elsewhere, and that in time, if necessary by modifying and further simplifying wherever possible, a common system of museum classification based on the decimal system might be arrived at.

NOTE.—Dr. Johnston's plan, in its entirety, embraced the medical museum as a whole. The Museums of Anatomy, Pathology, Public Health and Legal Medicine were divisions I, II, III and IV under it, and the subject-matter of each had a decimal classification of its own. Thus, in the Medicolegal Collection the main divisions, 1. Criminology, 2. Thanatology, 3. Traumatism, 4. \_\_\_\_\_, 5. Tests, 6. Toxicology, 7. Sexual Relations, 8. Mental, 9. Jurisprudence, all precede the decimal point, while Dr. Field's anatomic classification (used as the main headings in the Pathologic Museum) follows the decimal point. But the only one of these classifications that had been fully worked out and applied by us in Dr. Johnston's lifetime was that in the Museum of Pathology. This is therefore the only portion which we feel competent to publish now, deprived as we are of his active cooperation through his recent sad and untimely death.

**Tuberculosis in Prison.**—Dr. J. P. Ranson, resident physician of the Clinton State Prison, Dannemora, New York, states that one-fourth of the inmates are afflicted with tuberculosis. An appropriation is urged for the construction of a special building at the prison for the cure of persons thus afflicted. It is said that from 40 to 200 tuberculous cases are being discharged every year from this prison, to carry infection broadcast into the outside world. At present there are 200 tuberculous inmates in the institution. Of these 195 were transferred from other institutions.

**Mortality of Indiana.**—The total number of deaths returned to the Department of State for February was 2,677, making an annual rate of 13.8 per 1,000. Pneumonia caused 339 deaths; tuberculosis, 342; cancer, 92; influenza, 56; diphtheria, 53; smallpox, 50; and typhoid fever, 49. The city deathrate was 17.3, which is 3.5 higher than the average rate for the whole State. The country deathrate was 11.9, which is 1.9 less than the State average, and 1.7 less than in the same month last year. Pulmonary tuberculosis prevailed more extensively in the cities than in the country, the rate being respectively 195.4 and 137.8 per 100,000. Pneumonia also prevailed more extensively in the cities, with rate of 236.4, and country 190.4. Of the smallpox deaths 43 occurred in the cities, 38 of these were in Indianapolis and 7 in the country. Of the 92 deaths from cancer 44 occurred in the cities and 48 in the country.

**Medical Expert Testimony.**—Judge Cary D. Davie believes that the value of evidence given by an expert depends upon his honor, experience and sound judgment. Much depends upon his personal appearance and conduct as a witness. He is called upon to testify as to what he may actually know regarding the matter in controversy, and to express his opinion founded upon such knowledge. An expert should be thoroughly conversant with his subject; he should avoid technical terms. In New York State an expert may decline to give evidence until satisfactory arrangements have been made for his fee. It is the court's duty to protect an expert in the exercise of this right. It is the duty of the court to decide whether an expert is competent or not. The only use an expert can make of quotations from textbooks is as follows: The counsel may ask a witness whether he agrees with the statement read from a textbook. He believes the creation of a State commission of experts is impracticable; and the present method of using hypothetical questions in the examination and cross-examination of witnesses is farcical and dangerous. He believes the defects in the present system of expert testimony are more the fault of the system than of the doctor.—[*Buffalo Medical Journal.*]

8. The Recognition and Prompt Removal of Postnasal Adenoids in Children. LOUIS J. LAUTENBACH.
9. Cyclic Vomiting in Children: With Report of Cases. THOMAS C. ELY.

1.—Iodized Catgut.—N. Senn thinks there is little doubt that catgut will eventually render silk and metal obsolete for buried sutures. He advises the method of preparation devised by Claudius. A 1% aqueous solution of iodine destroys anthrax spores in eight days. The solution for the catgut is made by dissolving potassium iodide in a little water, adding finely powdered iodine, and diluting to 1%. The solution and catgut are kept in a glass-stoppered bottle with the date on the label. Before using the catgut it is immersed in a sterile solution to remove the iodine from the surface of the threads. The catgut not used is returned to the bottle. The thread is pitch black, pliable, and almost as strong as silk. Absorption occurs in from 12 to 16 days. The iodine not only sterilizes the catgut but inhibits the growth of pyogenic microbes in the tissues around the suture. The raw material prepared in this country is more suitable for this method of sterilization than imported catgut. [H.M.]

2.—Calcium Salts for Uric Acid Calculi.—A. C. Croftan notes that the uric acid of the urine is held in solution by disodium phosphate and is precipitated by monosodium phosphate. For the prevention of uratic calculi the increase of diphosphate and the decrease of monophosphate is therefore a desideratum. The object can be accomplished either by decreasing the phosphoric acid or by increasing the sodium of the urine. Calcium salts decrease the excretion of phosphoric acid through the kidneys by binding the preformed phosphates of the food and preventing their absorption and by binding the phosphates of the blood and causing their elimination through the bowel. The administration of sodium salts that can also produce an increase of the diphosphate and a corresponding decrease of the monophosphate is to be condemned, chiefly because sufficiently large doses render the urine permanently alkaline, thus favoring the deposit of concretions other than uric acid stones. They also interfere with gastric digestion and affect the corpuscular elements of the blood. Calcium salts have none of these deleterious effects. The author recommends the carbonate in 15 or more grains three times daily. The good results obtained in four cases of nephrolithiasis encourage further trial. [H.M.]

4.—See *American Medicine*, Vol. III, No. 25, p. 1039.

5.—See *American Medicine*, Vol. III, No. 24, p. 993.

6.—Intracellular Toxins of Pathogenic Bacteria.—V. C. Vaughan has studied the cell substance of the colon, diphtheria and anthrax bacillus, the micrococcus prodigiosus, and lemon and orange sarcines, and in all these organisms has found it more or less toxic to guinea-pigs and rabbits, the toxicity varying with the virulence of the culture employed. By the use of sulfuric acid he has split off, in the case of the colon bacillus, a soluble toxin, which, when injected into animals causes symptoms and lesions identical with those obtained after injection of the unbroken cell. The part which remains is also toxic, but much less so than that split off by the acid. He believes that he has isolated the specific toxin of the anthrax bacillus by the same method. He reviews the work of other men along this line, and believes his own investigations show the toxin cannot be obtained except by chemical disintegration of the cell substance. From other experiments he concludes that the intracellular toxin of diphtheria is not identical

with the soluble toxin. Commercial diphtheria antitoxin protects against the latter but not against the former. This offers a plausible explanation for that natural immunity to diphtheria toxin possessed by animals which are not immune to diphtheria infection. [H.M.]

7.—See *American Medicine*, Vol. III, No. 25, p. 1048.

8.—See *American Medicine*, Vol. III, No. 25, p. 1049.

9.—Cyclic Vomiting in Children.—T. C. Ely describes the mechanism of vomiting, and the attacks which occur in gouty and neurotic children, due to faulty metabolism and elimination. He reports several illustrative cases, differentiating them from cases of bilious vomiting. The toxin probably acts directly on the vomiting center. He emphasizes the importance of being on one's guard for the vomiting of this gastric neurosis, distinguishing it from that due to kidney, brain, and other diseases. In severe cases he advises hypodermics of morphine and atropine with elimination by high saline enema and gavage, and in extreme cases hypodermoclysis and even intravenous injections of saline solutions. In less severe cases calomel and cocaine or Fowler's solution may be sufficient. [H.M.]

## Boston Medical and Surgical Journal.

March 26, 1903. [Vol. CXLVIII, No. 13.]

1. Extensive Cavity Formation in the Central Nervous System, Presumably Due to *Bacillus Aerogenes Capsulatus*. EMMA W. MOOERS.
2. *Bacillus Shiga* in an Epidemic of Diarrhea. LAWRENCE W. STRONG.
3. Systemic Infection Due to Natural Teeth Conditions. D. D. SMITH.
4. Suppuration of the Frontal, Ethmoid and Sphenoid Sinuses: With Brief Report of the Treatment of 237 Cases. EDGAR M. HOLMES.

1.—Cavity Formation in the Central Nervous System, Presumably Due to the *Bacillus Aerogenes Capsulatus*.—E. W. Mooers reports the case. A man of 49 had advanced general paralysis, having been in the hospital for nine years. He was profoundly demented, with extensive paralytic evidences and confined to bed. He was well nourished and weighed 168 pounds. The patient's condition continued unchanged until a few days before death, when an increased restlessness was noted. On the morning of the day he died there was discovered a marked abdominal distension, a temperature of 104°, and respirations 48 to 58. He rapidly failed, and died in the evening. Necropsy performed 20 hours after death showed the abdomen and intestines enormously distended with gas, and there was gaseous emphysema of the subcutaneous structures. The most marked feature was a series of cavities in the brain substance, in both white and gray matter, and the meninges of the brain and cord were pigmented. Microscopic examination showed the presence in both brain and cord of a bacillus, presumably *B. aerogenes capsulatus*. The gaseous distension as well as the cavities in the brain were presumably caused by this bacillus. It was believed that death was produced by the entrance of the germ into the blood and the elaboration of a toxin. [A.B.C.]

2.—*Bacillus Shiga* in an Epidemic of Diarrhea.—L. W. Strong reports an epidemic on the Maine coast due to untraceable causes, and presenting several types of diarrhea. Simple diarrhea, which is nonbacterial, may, by increasing susceptibility to invasion, pass over into an infective type. This may be fermental, acting high up in the alimentary tract, or an ileocolitis may be produced if the bacterial action or absorption of toxic substances is delayed till the ileum or colon is reached. On this theory the same organism, whether a normal inhabitant of the intestine or introduced with the food, might produce either a fermental diarrhea or an ileocolitis. No definite relation has been found between any special form of bacteria and variety of diarrhea. In this epidemic the bacillus of Shiga was isolated from several cases of ileocolitis. The only way of determining the cause in various cases is by the serum reaction, as there is no way of separating them clinically. This organism is viable in the soil longer even than the typhoid bacillus and this suggests the means of distribution and production of epidemics. The stools and presumably the urine of all cases of infective diarrhea should be disinfected. [H.M.]

4.—Suppuration of the Frontal, Ethmoid and Sphenoid Sinuses.—After an elaborate paper dealing with the entire

subject, E. M. Holmes gives the results of his treatment. In the 16 cases of suppurative frontal sinus, 7 were relieved by removing obstructions in the middle meatus and draining the ethmoid cells. Four of these were cleansed through a cannula, but into the other three not even a probe would pass. Eight persisted after all internal treatment had been applied. Upon six of these he performed the external operation, and obtained good results in all but one. Ethmoid suppuration is in a labyrinth of cells, any one of which may be diseased. Fourteen in this series were discharged well in three weeks. Of the others 23 were well within two months, and 16 others within three months; 24 were apparently well after periods varying from three to six months, and 11 others after longer periods. The sphenoid cavity though large can be so thoroughly exposed and drained that the great majority of cases when not complicated are cured in a comparatively short time. In the 182 cases of pus in the sphenoid cavity there were only five of the non-complicated which were not cured by the end of six months. Eighteen cases were apparently well by the end of three weeks, 15 by the end of four weeks. Fifty-one cases were free from symptoms by the end of two months. Sixty-seven cases were under treatment between two and three months. Of the 26 remaining cases, 8 were discharged during the fourth month, 11 during the fifth month, and 7 during the sixth month.

#### Medical Record.

March 23, 1903. [Vol. 63, No. 13.]

1. Renal Decapsulation for Chronic Bright's Disease. GEORGE M. EDEBOHLS.
2. Specific Treatment of Diphtheria. GEORGE B. PHILHOWER.
3. The Psychic Element in Hay-fever. RAYMOND WALLACE.
4. On the Biologic Relationship of Proteids and on Proteid Assimilation. P. A. LEVENE.

#### 1.—Renal Decapsulation for Chronic Bright's Disease.

—George M. Edebohls' conclusions after operating on 51 cases for chronic Bright's disease are summed up: In 47 instances double renal decapsulation was performed in every instance at a single operation; in four instances a unilateral renal decapsulation was done. Seven patients died within 17 days after operation; 7 patients died at periods varying from 2 months to 8 years after operation, the average being 20 months. Two patients do not show satisfactory improvement. Twenty-two are in various stages of satisfactory improvement, varying from 2 months to 15 months after operation. The urine of several of these is entirely free from albumin and casts, but they have not passed the probationary period of 6 months of normal urine, before which they are not entitled to a place in the list of cured. One patient, after a cure lasting 4 years, again has chronic Bright's disease, one kidney only being operated upon. Nine were cured of chronic Bright's disease and remain cured at periods after operation varying from 21 months to 10 years, the average duration being over 4 years. Three patients disappeared after leaving the hospital and no trace of them can be found. Attention is called to the fact that a number of these patients were operated upon in the very late stages of the disease, when little hope of benefit could be had. Of all patients who applied only two were refused operation. No surgeon should attempt the operation who is not familiar by experience with renal surgery. The operation for double renal decapsulation should in no case exceed one hour in duration, as the anesthetic is the dangerous factor. Rapidity and dexterity are prime requisites. The histories of heretofore unreported cases are detailed at some length, and the article is a rather exhaustive discussion of the operation, which the author has introduced into surgery as offering practically the only relief to those suffering from chronic Bright's disease. The most noticeable feature after operation is the prompt increase in urea. An increase from 6 grams previous to operation to 35 grams within a month after operation has been observed, the greatest relative gain being in the first two or three months. Casts, such as the waxy, fatty, epithelial and pus casts, which denote destruction of the secreting structure, disappear first, usually requiring 1 to 12 months or more. Granular and hyaline casts next disappear, albumin usually persisting for some time after all casts have disappeared. [A.B.C.]

#### 2.—Specific Treatment of Diphtheria.—G. B. Philhower

emphasizes the importance of medical societies pronouncing against the misleading statements of cheap medical journals as to the value of antitoxin in diphtheria, and would have every physician who treats a fatal case without its use prosecuted for malpractice. He believes that severe cases are just as surely controllable with large doses as are mild cases with small doses if given early in the disease. The growth of the membrane should be arrested in the first 24 hours, its edges caused to loosen and turn up during the second 24, and it should crumble and come away in the third 24, or else the dose has not been large enough. Tonsillar cases do well with 2,000 units, nasal require from 4,000 to 6,000 units, laryngeal cases should receive from 6,000 to 10,000 units. When there is much glandular swelling the doses should be from 4,000 to 6,000 units. [H.M.]

4.—The Biologic Relationship of Proteids.—P. A. Levene has observed that if the serum of an animal acquires the power to form precipitins with one proteid of an animal it has the power to form them with other proteids of the same or closely related animals. Chemically different albumin, globulin, casein, etc., derived from the same animal have at least one part common to all of them, or, perhaps, may be regarded as derivatives of one substance, which is the nucleus of all the proteid material of that animal. We may look on them as isomers. He has also observed that a precipitin for a given proteid is capable of forming precipitins with the primary digestive products of the latter and vice versa. This property of forming precipitins against food proteids shows that the molecules of foreign proteids have to be reconstructed before they can be assimilated. The place of this reconstruction can be found only experimentally. It is not improbable that in pathologic conditions these proteids pass the digestive organs unchanged. [H.M.]

#### New York Medical Journal.

March 21, 1903. [VOL. LXXVII, No. 12.]

1. The Development and Ultimate Result of Medical Science. ANDREW F. CURRIER.
2. The Treatment of Felon. EDWARD WALLACE LEE.
3. Report of a Case of Epidemic Parotiditis, with Fatal Termination. W. J. S. STEWART.
4. A Study of Tuberculous Infection: Special Susceptibility of Childhood; Causes and Methods of Infection; Factors of Development of the Disease. F. M. POTTENGER.
5. The Intravenous Injection of Formaldehyd. WILLIAM L. BANER.
6. The Hemorrhagic Diathesis as a Factor in the Production of Hemorrhage Following Removal of Tonsils and Adenoids. FRANK H. WASHBURN.

1.—Development of Medical Science.—A. F. Currier in this address takes up the development of medical science from its beginning to the present time and calls attention to some of the work which remains unfinished. The article is interesting and instructive and should be read in the original as it does not lend itself to valuable abstract. [C.A.O.]

2.—Treatment of Felon.—E. W. Lee states that a general anesthetic is indicated in the severe forms. The hand and forearm should then be placed as near as possible in an aseptic condition and measures taken to control hemorrhage so that the extent of the disease may be clearly defined. An incision should be made from a few lines back of the inflamed area to the tip of the finger, down, if necessary, to the bone. All pus and sloughing debris should be removed with hydrogen peroxid, and the wound cavity washed with a 1-1,000 bichlorid of mercury solution. All diseased tissue should then be thoroughly removed, the wound cleansed again with peroxid and washed with bichlorid, and the whole cavity swabbed with pure carbolic followed by alcohol. After again washing with bichlorid an aseptic dressing should be applied. [C.A.O.]

3.—Epidemic Parotiditis.—A fatal case is reported by W. J. S. Stewart as occurring in a man of 27. Death occurred on the fifth day of the disease, and before the inflammation of the second infected gland had reached its height. The infection was exceptionally severe, as evidenced by the continued high temperature and delirium. He believes that the fatal termination was due to sudden failure of the heart, caused by the excessive strain to which that organ had been subjected by reason of the difficulty to respiration, from which the patient had been suffering for eight or nine hours previous to his demise. [C.A.O.]

#### 4.—Tuberculous Infection.—F. M. Pottenger has thor-

oroughly reviewed the literature on this subject, and quotes statistics to show that although children are, with few exceptions, born free from tuberculosis, it is common in childhood, causing about 25% of the deaths occurring during the last quarter of the first year, and quite a large proportion of those during the second and third years. Nearly all cases of tuberculosis show involvement of the lymph glands; and if the fact that the process is furthest advanced is an indication, they are in a large percentage of cases to be considered the primary foci. Nearly all children show enlarged glands during the period of infancy and early childhood, of which investigation seems to show from 60% to 70% to be tuberculous; and of those chronically enlarged, even a larger per cent are so affected. A large proportion of those patients who, although infected, do not show acute symptoms during childhood, develop active tuberculosis in later life. In seeking the cause of this frequent infection, aside from the habits of the child and the carelessness of the parent bringing it in frequent contact with the bacillus, all those things which lower vitality at this time must be considered; and the author calls special attention to the fact that there is a connection which seems more than coincidence in the time that tuberculous infection takes place and the time that the child is most apt to suffer from catarrhal conditions of the stomach and bowels. [C.A.O.]

**5.—Intravenous Formaldehyd Injection.**—W. L. Baner gives a brief review of the case reported by Barrows, an account of which appeared in *American Medicine*, Vol. V, No. 6, and also of a case treated by Waitzfelder which was also one of puerperal sepsis and had been cured. The blood showed the presence of streptococci. The temperature, averaging about 105.5° F., had three separate times fallen below normal following a hypodermoclysis of normal saline solution, but within 24 or 36 hours in each instance had risen as high as ever. An intravenous injection of 750 cc. of a 1-5,000 formalin solution was then given. The temperature again fell below normal, but in 24 hours had regained its former height. A second injection was ordered, but by mistake the solution was made double strength, and the patient became rapidly cyanotic, so that the formalin had to be stopped. A saline infusion was given in its place, and the result was the same as from the first formalin injection. Forty-eight hours later her temperature was 101° F., pulse 120, and respirations 48. The author reports a case of pure streptococcus bacteremia occurring in a woman of 42, admitted to the hospital suffering from a scalp wound, and was also found to have a bronchopneumonia. Twenty-two days later she had a chill, after which the fever fluctuated daily between normal and 104° F. to 105° F. Streptococci in great numbers and pure culture were found in the blood. An intravenous injection of 250 cc. of a 1-5,000 formalin solution was then given. The following day the patient was better, but on the second day she was worse, and a second injection of 750 cc. was given. She continued to grow worse, and died three days later. An autopsy revealed areas of bronchopneumonia in both lungs. Cultures from the blood of the heart cavity were made separately, and in both series a prolific and pure growth of streptococci was found. The author quotes a case of ulcerative endocarditis treated by this method with no beneficial result, and further blood cultures showed no decrease in the number of microorganisms. He says it seems improbable that this treatment has any specific value in septicemia, and that normal saline will dilute the toxins equally well and with less probability of injuring the structures of the blood. [C.A.O.]

**6.—Hematophilia and Amygdalotomy.**—A case of dangerous hemorrhage occurring several hours after the removal of adenoids of the postnasal space and hypertrophied faucial tonsils is reported by F. H. Washburn. A hemorrhagic diathesis is considered the principal factor in the production of hemorrhage in this case. [C.A.O.]

1.—See *American Medicine*, Vol. IV, No. 17, p. 648.

#### 2.—Mechanism of Mental States in Alcoholic Insanity.

—According to W. K. Walker, alcoholic cases are, as a rule, too complex to be grouped under any simple classification. They present symptoms common to other forms of insanity with variations depending upon degree and duration of alcoholic poisoning and susceptibility of individual neural tissue. The modern tendency is to attribute the greater importance to the latter. Of the cases he reports, all had shown marked mental defects, but these seem to have been disregarded by the courts. Clinically they present widely varying pictures, but all show a definite mechanism of development following familiar psychopathologic laws. In cases of gradual mental deterioration produced by alcohol, long before marked mental disorder is noted, there may be manifestations of blunted moral and esthetic sensibilities and change in normal affections and emotions. Later, develop morbid ideas, suspicions, etc., having their origin in some past occurrence or some vague sensory disturbance, attention becoming concentrated upon them. Misinterpreted sensations gain increased importance, and the patient explains everything in the light of accompanying emotions, which are nearly always in the key of fear. The higher reasoning faculties become more and more involved until finally they are not to be reckoned with as inhibitory or restraining forces; the emotional element now in full sway impels to the commission of acts which are the logical outcome of the idea to which the field of consciousness is narrowed. This is the mechanism of even those cases in which purpose and motive have apparently been present. In their last analysis the acts are seen to be actuated by self-preservation, and to be instinctive. It is a reproach to medical science that these should be left to the tender mercies of the law. Recognition of early deviation from a normal mechanism might, in many instances, prevent it from reaching a dangerous development. [H.M.]

**3.—Scope of Vaginal Section.**—H. J. Boldt prefers vaginal operation to abdominal section. He says many who eight years ago opposed vaginal operations are now their most earnest advocates. Meantime his own views have been modified and after a study of the subject, based upon more than 500 vaginal sections, he concludes that its application is much more limited than he formerly supposed. He would employ this method for suppurative salpingitis and ovarian abscess and in all instances of pelvic suppuration in which it is evident that the pus can be reached through the vagina. With the exception of such instances as described he thinks conservative surgery upon the uterine adnexas can best be performed by abdominal celiotomy. Diseased ovaries or small ovarian tumors should be removed by way of the vagina unless the adhesions are too extensive; but abdominal section is generally to be preferred for ectopic gestation and also for myomectomy for certain kinds of tumors. Displacements of the uterus are often indications for colpoceliotomy, but for backward displacements Boldt prefers shortening the round ligaments through an abdominal incision. [W.K.]

**4.—Scope of Vaginal Section.**—According to H. N. Vineberg vaginal section finds its scope in the following conditions: 1. Pelvic abscess. 2. Pyosalpinx and ovarian abscess under certain conditions (a) when the abscess is situated in the Douglas sac and is fairly movable; (b) when the abscess sac is not large and can be readily removed through an anterior vaginal incision; (c) in pyosalpinx and ovarian abscess during the acute stage, if the pus is accessible through a posterior vaginal incision, to tide over the dangerous period; and sometimes this palliative measure may prove curative. 3. Conservative surgery in diseased adnexas. 4. Ovarian cysts. 5. Myomectomy. 6. Ectopic pregnancy (a) in obscure cases to aid in diagnosis; (b) in cases in which it is evident there is no further hemorrhage, and when the already diffused blood has formed a hematocele in the Douglas sac at the base of the broad ligament. [W.K.]

**5.—Mistaken Diagnosis of Cancer of the Stomach.**—M. I. Knapp reports cases in which there were found what is alleged as being the "cardinal" symptoms of cancer, both proving in reality, however, excellent examples of gastritis fungosa. Diagnosis should never be made without a test-meal examination. Chocolate colored vomit does not necessarily mean blood. It may be due to a mold. [H.M.]

**6.—Operative Treatment of Fracture of the Patella.**—R. S. Fowler says operative treatment is contraindicated in those suffering from intercurrent disease, which would make operation dangerous; in longitudinal fractures; as a rule in comminuted fractures, and in transverse fractures in which rupture of the capsule has not occurred—a rare condition. Without operation there will be only fibrous union except in the rare cases in which there is perfect apposition without intervening periosteum. At operation great care is observed to prevent the possibility of infection, no hand or instrument being permitted to enter the joint-cavity. The knife used in cutting the skin is not used for the deeper structures. The seat of fracture is exposed, the torn fringes removed, two holes are drilled through each fragment, the drill emerging in every instance in the fractured surface slightly away from the articular surface. Chromicized catgut is used to approximate the fragments, lateral sutures of the same material being passed through the fibrous structure on either side of the patella. Nine cases are reported. [A.B.C.]

**7.—Physiologic Observations on a Crustacean Heart.**—G. V. N. Dearborn announces as the result of his investigations that there is strong physiologic evidence that the heart of *Daphnia* has nerves connected with it, the stimulation of which inhibits its action and evidence of a similar sort, although negative, that the heart has no augmentor nerves. This heart appears to be eminently automatic and very independent, especially in its rate of beating, of agencies usually modifying or even destructive. Puncture of parts of brain and body, especially just ventral to the heart and in a supposed caudal ganglion, inhibits the heart for a few minutes only. Induced electricity, unless of an intensity which disorganizes the protoplasm, has no effect beyond momentary inhibition. Division of the animal into parts inhibits the heart for a time, or permanently, according to the mode and place of section. Openings of the circulation channels lessens both the force and average size of the beating heart. When a *Daphnia* dries up the heart continues to beat after all the other organs are still. Absorbed beef-serum increases the force of the beat and the pulse-rate, but not beyond the normal for that individual. Alcohol, nicotine, chloral, aconite, chloroform, curare, and digitalis act in general as on other hearts. The embryonic pulse-rate is half that of the adult, which about 240. The advantages of using small, transparent animals, as *Daphnia*, in research is perhaps not adequately appreciated by physiologists. [H.M.]

1. The Increase of the Use of Cocain Among the Laity in Pittsburg. THOMAS G. SIMONTON.
2. The Use of the Electrothermic Angiotribe in Lieu of the Employment of Ligatures in the Open Operation for the Relief of Varicocele. ORVILLE HORWITZ.
3. Additional Notes on Organacidia Gastrica. MARK I. KNAPP.
4. Mouth Infection, Due to Natural Teeth. D. D. SMITH.
5. Psychopathic Epidemics. JOHN B. HUBER.

**1.—The Increase of the Use of Cocain Among the Laity.**—T. G. Simonton details the increased use of cocain among the laity of Pittsburg. Many of the drugstores of Pittsburg make a very large annual profit from the sales of cocain, any one being able to purchase the drug. It is a shocking revelation of the use of the drug by the citizens of the above city, and the comparative ease with which it is procured. The two types of cocain habit are occasional and continuous, social and solitary. The social indulgence is becoming more common. Many of the habitues resort to the use of the hypodermic needle, but the present day method is to "snuff it," so this requires one to be more alert for its detection. Two of the prominent symptoms of cocain poisoning are self-consciousness and elation, and when present they are a great aid in making a

diagnosis. The treatment of the cocain habitue is described. [F.C.H.]

**2.—The Use of the Electrothermic Angiotribe in Operating for Varicocele.**—Orville Horwitz claims the following advantages for the Downes instrument over the simple angiotribe suggested by Freeman, in lieu of the employment of ligatures in the open operation for the relief of varicocele. The substitution of a more scientific instrument, a less crude and less dangerous method than that depending upon violent traumatism so as to produce hemostasis; there is less danger of secondary hemorrhage; the operation is not followed by pain; the use of the electrothermic instrument does not produce orchitis, a condition commonly attending operations in the vicinity of the cord. The electrothermic angiotribe has been employed successfully in place of ligating the cord after castration, as well as for resection of thickened and vascular sacs of large hydroceles. [F.C.H.]

**3.—Organacidia Gastrica.**—Mark I. Knapp details some additional notes on this condition. He believes that we are forced to admit that every pathologicoanatomic change, traumatism excepted, must be preceded by pathologicochemic conditions. Such a pathologicochemic condition is organacidia gastrica. Organacidia gastrica always means either absolute or only relative hypochlorhydria. It may as well show hypoacidity, and that is the fact in very many cases. It is the natural course to begin with hyperacidity and advance to hypoacidity. The prognosis of uncomplicated cases is very favorable. A very frequent complication is organacidia enterica with or without insufficiencia pylori. [F.C.H.]

#### EDITORIAL COMMENT

**The Leukocytosis of Measles and Rötheln.**—Combe, in 1899, described a new sign characteristic of measles in the period of incubation, consisting of a polymorphonuclear hyperleukocytosis without any other morbid symptom. During the last two days of the period of invasion or of the enanthem, and during the entire period of the exanthem, the blood presents a decided hypoleukocytosis, which is due to diminution in the number of polymorphonuclear cells. There is no change in the lymphocytes. The observations of Combe have been repeated by Plantenga.<sup>1</sup> The leukocytes were not stained, but were counted after diluting with the fluid of Prus, consisting of 10 parts each of a 0.1% solution of osmic acid and of a 0.1% solution of chromic acid, and 1 part of glacial acetic acid. Counts were made in 13 cases of measles and in 5 cases of rötheln. The results as regards measles confirm the observations of Combe. The hypoleukocytosis is sometimes accompanied with a marked lymphocytosis, usually attended with violent and persistent diarrhea and general adenopathy. After the exanthem has subsided, the number of leukocytes return to normal unless there are complications. The same modifications of the blood as in measles were found in rötheln, and from this Plantenga concludes that it is identical with measles. The differences presented by these two diseases may, according to the author, be accounted for by differences in the degree of virulence of the causative agent, or by differences in the portal of entry of the organisms. The possibility of diagnosing measles and rubella during the incubative stage by means of blood-examinations affords an important auxiliary for the institution of prophylactic measures.

#### REVIEW OF LITERATURE

**Experiences of an Epidemic of Cerebrospinal Meningitis.**—E. T. Smith<sup>2</sup> bases his article on 36 cases of epidemic cerebrospinal meningitis observed in Dublin during 1900. These cases showed the wildest diversity in duration and severity

<sup>1</sup> Arch. de Méd. des Enfants, March, 1903.

<sup>2</sup> The Practitioner, March, 1903.

and inconstancy of symptoms and signs, even those most frequently present varying remarkably as to their appearance after onset, their degree, and their duration. Hence Smith does not attempt to describe a "typical case," but discusses *seriatim* the most constant and prominent clinical phenomena. The oldest patient was 47, the youngest 2, and the mortality 14, approximately 38%. The time of death in 12 cases whose onset was definitely determined varied between the first and two hundred and forty-sixth days of the disease. Diagnostic stress could not be laid on the situation of the pain in headache, which was present in every case. It was more frequently frontal than occipital. Smith believes that textbook writers have confused pain which is strictly headache and pain in the cervical spine, of which these patients so often complain. Kernig's sign was present without exception. Smith has also found this present in children suffering from severe enteric fever. The following points regarding the sign should be remembered: (1) It is sometimes more marked in one leg than the other; (2) in any nervous disease in which the legs are kept flexed long enough for a degree of contraction to develop there is pain and resistance to extension. This is not Kernig's sign; (3) normally in those who have not practised the feat the required movement is difficult and painful. Treatment was directed mainly to the relief of headache, for which morphin hypodermically was the only efficient agent. Autopsy findings in 13 cases varied. The severest inflammation was most frequently found on the superior surface of the cerebellum. [A.G.E.]

**Xeroform in Pediatrics.**—Xeroform, chemically tribromophenol bismuth, has been extensively used as a wound dressing, and also internally, to a limited extent. It is not only a good astringent, but also a powerful intestinal antiseptic, being split in the intestinal canal into tribromophenol and bismuth oxide. E. Toff<sup>1</sup> has used it for seven years in the treatment of acute and chronic diarrheas in children, with very satisfactory results. It is tasteless and odorless, and the author has never observed toxic symptoms from its use. To the antiseptic and astringent action of the drug is to be added the analgesic effect of the bromin, which makes the administration of opiates unnecessary. It may be used in doses of 0.5 to 1.0 gm. (grs. 7½ to 15) daily, for children under two years, and 2.0 gms. (grs. 30) daily for older children. The author has used it in diarrheas, gastritis, abnormal fermentations, dysentery, and typhoid fever. He has also found it very useful externally, as a dusting powder for wounds, intertrigo, moist eczema, burns, suppurative otitis media, and scrofulous affections of the eye. [B.K.]

**Tannoform in Intertrigo.**—S. E. Ostrowski<sup>2</sup> has employed tannoform in the intertrigo of infants with strikingly favorable results. More than 50 cases were observed, all children under 1 year. The remedy was prescribed either as a dusting powder mixed with an equal part of starch or in 10% ointment-form with vaselin. The affected area was first washed with 2% boric acid and the ointment applied. The effects were prompt and marked, owing to the astringent as well as antiseptic properties of the drug. The most neglected cases responded rapidly to this treatment, which the author pronounces to be invaluable in the intertrigo of infancy. [L.J.]

**The Prognosis in Pneumonia.**—After stating that the mortality from pneumonia exceeds that from any other acute disease, and that the already large deathrate is steadily increasing, J. M. French<sup>3</sup> considers the prognosis as modified by age, sex, constitution, and habits of life, extent and portion of lung involved, complications, severity of the epidemic, pulse, respiration, temperature, and treatment. Many tables from the report of Sears and Larrabee are incorporated in the article. Of individual symptoms, the most reliable is to be placed upon the pulse, the mortality from pneumonia being in direct ratio to the frequency of the pulse. French does not agree with the conclusions of those writers who state that pneumonia is uninfluenced by treatment, or even with the statement that the mortality does not vary materially even under the most diverse methods of treatment. Judging from either statistics or clinical observation, he believes that the most which can reasonably

be said is that no one mode or system of treatment has shown itself so superior to every other as to lead to its general acceptance as the best. [A.G.E.]

**Sanatogen in Pediatrics.**—Sanatogen is a combination of 95% casein with 5% sodium glycerophosphate. It is easily dissolved, and is very readily absorbed. E. Fromm<sup>1</sup> has tried this preparation as an addition to the food in weak and convalescent children, with most favorable results. The doses given varied from a few grains for infants to one or two dessertspoonfuls for older children. It may be dissolved in water, milk, or soup. In almost all the observed cases there occurred an increase in weight and improvement in the character of the stools. In some cases the gain in weight started one or two days after the first administration of sanatogen. [B.K.]

**Electrolysis in Stenosis of the Esophagus.**—J. B. Fel-doritch<sup>2</sup> recommends electrolysis in the treatment of cicatricial esophageal strictures. Without claiming decidedly radical curative powers for the method, it may be safely relied upon to effect rapid and comparatively painless dilation. In three or four sittings, each lasting two or three minutes, the author succeeded in stretching a stricture with a diameter of 3½ mm. to 13 mm., a feat which it would require months to achieve by means of the ordinary dilating measures. Recurrences are apt to take place even after electrolysis, but they come considerably later, and valuable time is thus gained. From a palliative point of view, no other method can compete with electrolysis. The technic is extremely simple, and consists in attaching an esophageal sound to the constant current. A galvanometer is indispensable. With weak currents and short sittings, no harm will result to adjacent organs. [L.J.]

**Differential Diagnosis Between Diphtheric Croup and Morbid Conditions Simulating It.**—A. Delcourt<sup>3</sup> discusses at length the differential diagnosis between diphtheric croup and (1) acute laryngitis that may or may not be associated with pulmonary affections and complicated with spasms of the glottis; (2) laryngitis occurring in measles before the eruption, during the course of the disease, and during convalescence; (3) laryngitis stridulous or false croup; (4) foreign bodies in the respiratory tract; (5) adenoids and hypertrophy of the tonsils; (6) retropharyngeal abscess; (7) polypus of the larynx and other tumors; (8) edema of the glottis; (9) spasm of the glottis or phrenoglottic spasm; (10) pseudomembranous non-diphtheric tracheobronchitis; (11) stridor of the newborn; (12) asthma. [J.H.W.R.]

**Disease Simulating Acute Rheumatism.**—Reference to statistics bearing on the treatment of acute rheumatism with the salicylates elicits the fact that a small proportion of the cases are little, if at all, influenced by their administration; the fever goes on for weeks and weeks, and the pains and sweating remain. C. J. Macalaster,<sup>4</sup> from his own observations, has concluded that these resisting cases are not rheumatic fever, their clinical histories as well as their relation to the salicylates are different, pointing to a totally different toxin. In these conditions the temperature is remittent, the joint pains tend to be symmetric and to spread to new joints without leaving those affected, not flitting about as in acute rheumatism. The temporomaxillary and cervical joints are often affected, and the small joints of the hands and feet and the sternoclavicular articulation are not infrequently attacked as well as the larger joints. [H.M.]

**Tidal Percussion of the Apices of the Lungs.**—E. H. Colbeck<sup>5</sup> insists that the phenomena which may be elicited by so-called "tidal percussion" over the apices of the lungs are commonly and widely misrepresented and misunderstood. He adduces (1) anatomic and physiologic and (2) clinical evidence to show that the limits of supraclavicular resonance do not increase with full inspiration and decrease with expiration, as currently taught. Under the first head it is claimed that the fascial coverings of the apices are not capable of distention, that the movements of the upper part of the thorax and the clavicle diminish the distance of the apex of the lung above

<sup>1</sup> Zentralblatt für Kinderheilkunde, March, 1903.

<sup>5</sup> The Practitioner, March, 1903.

the clavicle during the inspiration, and that the apical portion of the lungs tend to collapse during that period. Under the head of clinical evidence it is stated that inspection of the supraclavicular fossas, in conditions both of health and disease, more especially in thin subjects, not uncommonly reveals sucking in and descent of these spaces during a full inspiration. ### EDITORIAL COMMENT

#### Enterostomy in the Treatment of Intestinal Obstruction, Peritonitis, and Typhoid Perforation.

—The making of an artificial anus for the relief of obstruction or great abdominal distention in cases of peritonitis probably dates back to an early day in surgery. Greig Smith, in his *Abdominal Surgery*, published in 1897, considers this operation indicated in desperate cases of obstruction in which there is imminent risk of death from distention, vomiting, and toxic poisoning. In such cases the first coil of dilated bowel that is met on opening the abdomen is brought to the surface, incised and drained without any regard being paid to the removal of the cause of obstruction. He also advises this procedure in cases of obstruction in which the cause has been removed but in which there is still a great deal of distention, and also in cases in which the cause of obstruction cannot be removed or cannot be found. While enterostomy is frequently employed in such cases by many surgeons, its value is perhaps not sufficiently appreciated. Every operator of experience recognizes the fact that patients suffering from intestinal obstruction are far more ill than their general condition at first seems to indicate. If an extensive operation be undertaken in such cases, the patient almost inevitably succumbs. Enterostomy might, no doubt, well be employed in many of these cases which at first sight do not seem so desperate. If obstruction is caused by adhesions about an appendix abscess or some other intraabdominal focus of infection, it would be impossible to remove it without soiling the general peritoneal cavity. In such cases enterostomy is certainly the method of choice. At the thirty-first German Surgical Congress, Doyen,<sup>1</sup> of Paris, called attention to the treatment of acute general peritonitis with distention by making temporary enterostomy, and Heidenhain presented a paper in which he advocated its use in the treatment of intestinal obstruction. Doyen has found the best results by employing enterostomy both in the ileum and in the upper part of the jejunum in cases of peritonitis, after the usual measures of cleansing the peritoneum have been carried out. Heidenhain, at the same congress, also advocated the use of enterostomy in cases of obstruction accompanied by peritonitis. In many such cases the obstruction is a temporary one caused by the pressure of paralyzed and overdistended loops of intestine on some other loop which is bent upon itself, and this obstruction is relieved spontaneously as soon as the bowel is emptied. An entirely new indication for the employment of enterostomy is suggested by Escher,<sup>2</sup> surgeon to the City Hospital in Trieste, Austria, who advocates its general employment in the treatment of all cases of typhoid perforation. In looking over the statistics of typhoid perforation, he finds 10 cases treated by this method with 40% of recoveries, which is in striking contrast to the 20% to 23% of recoveries which have followed suture of the perforation. He reports four cases which he has treated personally with three recoveries, and believes that it is better to bring the perforated loop of intestine into the abdominal wound, thus making an enterostomy, than to attempt suture

except in the rarest cases. Suture is occasionally justified, Escher believes, very late in the disease; when the patient is in good condition, when the operation is undertaken early, and when there is a slight amount of distention. This method of treatment not only saves time, but drains the intestine and prevents the development of distention and paralytic ileus. There are constantly appearing in the literature so-called new operations, new methods and new apparatus. Many of these discoveries like enterostomy are not new, and simply show that practical men when faced with conditions similar to those which have been previously met by others, naturally fall into the same or similar ways of treating them. In most cases it is not a desire to claim originality for the work which has been previously done by others, but simply that such work has been overlooked. We are not aware that Doyen or Heidenhain claim any originality for their advocacy of more general use of enterostomy, but they do deserve credit for again directing attention to a simple and effectual means of treatment which has much to commend it to those who have frequently to deal with the acute abdominal conditions mentioned. Escher's suggestion as to the routine treatment of typhoid perforation by bringing the perforation into the wound and thus forming an enterostomy is, so far as we know, a new one, this having been done previously only in cases in which suture was difficult or impossible. The results which he finds in a limited number of cases which have been previously treated in this way and in his own four cases encourage a further trial of this method.

### REVIEW OF LITERATURE

**Nephrectomy for Hypernephroma.**—The case reported by Bean<sup>1</sup> is that of a woman of 42, who six months before had noticed a lump in the left side. This gradually increased in size and became tender and painful. The diagnosis of cystic kidney was made and nephrectomy performed. This disclosed a tumor of the kidney measuring 6½ by 5½ inches. Microscopic examination showed the tumor to be a hypernephroma. A case of sarcoma of the kidney in a child is also reported, Bean stating that the abdominal incision for nephrectomy in these cases is preferable to the lumbar incision. The pedicle is ligated after the tumor is removed, first having been clamped with forceps. This allows free access to the parts involved. [A.G.E.]

**Recurrent Appendicitis.**—F. C. Southam<sup>2</sup> bases his remarks upon the results by operation in the treatment of 50 cases of recurrent appendicitis. Of these 39 were males, 11 females. In 5 cases there had been only one distinct attack; in 10 cases there had been two well marked attacks; in the remaining 35 cases there had been three or more attacks. In almost every case the lumen of the appendix was either partially or completely occluded in some part of its course. In 3 cases collections of pus were shut off in the distal portion of the appendix which was dilated into a small cyst. In 6 cases fecal concretions were present. In the remaining cases the contents consisted of mucoid or mucopurulent fluid. In no instance was a foreign body present. In 11 cases a localized suppuration existed outside of the appendix, chiefly associated with perforation of its wall. In 2 cases the patients had previously been operated on for appendical abscess. One case had been operated on a year before, the abscess drained, the appendix not removed. The wound healed spontaneously and there was no trouble until a year subsequent when another abscess formed. In many cases marked lesions were found in the appendix, there having been entire absence of local signs or symptoms during the quiescent period. All the patients recovered. [A.B.C.]

**The Radiographic Diagnosis of Renal Calculi.**—After quoting a few successful cases in which kidneystones were found by the radiographer prior to the operation, Kienboeck<sup>3</sup>

<sup>1</sup> *Zentralblatt für Chirurgie*, 1902, xxix, p. 78 (Beilage).

<sup>2</sup> *Mittheilungen aus den Grenzgebieten der Medizin und Chirurgie*, 1903, xi, 104.

<sup>1</sup> *Northwest Medicine*, January, 1903.

<sup>2</sup> *British Medical Journal*, January 10, 1903.

<sup>3</sup> *Wiener klinische Wochenschrift*, December 11, 1902.

says in his opinion in thousands of cases the stones are not discovered. This is due to inexperience and errors in technic. He describes his own method carefully, laying stress on the use of a partially evacuated tube, which must be lit up intensely. A purgative must have acted the day before, and palpation indicate a fairly empty intestine. A lead diaphragm should be used, and the tube should be brought as near to the abdomen as possible. Exposure is best made with breathing pauses of from 10 to 40 seconds, as the movements of the kidney cause considerable blurring. [E.L.]

**Hystero-Traumatism: Convulsions Cured by Excision of a Cutaneous Scar.**—M. F. Mouisset<sup>1</sup> describes the case of a man of 43, who, 16 years before, had received a blow on the head, this causing a wound of apparently little gravity. As a sequel, however, the man was the subject of convulsive, epileptiform seizures which were preceded by pain and pricking sensations in the scar that resulted from the wound. Medical treatment availed nothing. Excision of the scar was followed by cure. The larger part of Mouisset's article is devoted to a discussion of the causes of cure in these peculiar cases. He concludes that different hypotheses may be invoked in different cases. In some hysterical subjects who desire operation and have great confidence in the surgeon, the cure is really by suggestion. The destruction, or anatomic and physiologic modification, of the epileptogenous zone caused by the scar is the cause of cure in some cases. Surgical anesthesia plays a role in still other instances. [A.G.E.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**The Use of Bossi's or Other Metallic Dilators.**—A. Ostreil<sup>2</sup> reports four cases of eclampsia, in three of which he used Bossi's dilator and in one Frommer's. With the latter the dilation occurs more easily and uniformly, but the points of the instrument are too thick to permit their ingress into the narrow cervix of a primipara unless first enlarged in some other manner. In no case did he detect any laceration from the use of a metallic dilator, but in certain cases in which it was important speedily to end labor the instrument was invaluable. Leopold Meyer states that he agrees fully with Zaugeneister that this instrument should not be used in cases of placenta prævia, since its use might increase the hemorrhage, and in placenta prævia the patient has often lost much blood before the arrival of the physician. The aim is not to hasten delivery, but to hasten the control of the hemorrhage and so gain time to strengthen the patient. In such cases a metreurynter is preferable. But with indications for a speedy delivery he recommends Bossi's instrument. In his experience the fear of hemorrhage from laceration of the os or cervix is unfounded. The greater the resistance and the longer the cervix the more time required for the dilation. He has used Kaiser's instrument also, but it is too short and fills the vaginal passage so completely as to prevent following the dilation by either eye or finger. It is eight-bladed and suitable in construction. Perhaps the advantages of both might be united in one. A. Callmann,<sup>3</sup> however, gives the preference to manual dilation as equally practicable in most cases, and less liable to produce cervical laceration. Then the metallic dilators have this disadvantage, they lighten the purse and make heavy the instrument case. He deems manual dilation worthy of further trial. [w.k.]

**Care of the Perineum During Labor.**—E. V. Davis<sup>3</sup> details the precautions used to prevent laceration of the perineum, and states that in the last 514 cases confined in the obstetric clinic for the benefit of the students of Rush Medical College but 18 cases of laceration occurred. Of these cases 9 were multiparas. In a number of them the labor was directed by students. Ten of the 18 had but one or two stitches, and the most severe required but four. Episiotomy was formerly employed in certain cases, but attention to the measures out-

lined has decreased its necessity so that it was not employed once in the 514 cases in question. All primiparas and most multiparas are placed in the left lateral position when the presenting part reaches the pelvic floor. Chloroform is administered unless contractions are gentle. Direct pressure is applied to the head when it appears at the vulva. Hohl's position of the hand is commended. Pressure is applied to the jaw and lower part of the face by the method of Ritgen. Finally, the head is lifted out with a slight rotary motion. [A.G.E.]

**Reproduction of the Sacrouterine Ligaments for Prolapsus Uteri.**—E. Stanmore Bishop<sup>1</sup> claims that the true ligaments of the uterus which preserve it at its normal level and prevent prolapse are the fundopubic or round ligaments in front and the sacrouterine or retrosacral ligaments behind. Of these the latter are by far the more important. Their relative shortness, the position of their implantation below the main bulk of the uterus, their coordinate action with the vesical attachment in front, all render them more effective in maintaining the uterus in its normal position than the comparatively longer round ligaments which act upon the fundus. To ventrofixation, which he has many times performed, Bishop sees many objections and mentions vaginofixation only to condemn it. He states the anatomic and physiologic objections to these procedures and contends that the true remedy for any severe prolapse is the reproduction of the sacrouterine ligaments, since in those cases in which they are absolutely torn through no amount of rest will reunite them. Torn fibers retract and atrophy from disuse. In the upper extremity of the posterior fornix a sufficiently firm resistant material is available which, while firmly attached to the cervix, yet is of sufficient length between its most superior point and that blended with the latter to permit of normal freedom of movement. It is this which is utilized as the new sacrouterine ligament. Its superior surface is covered with peritoneum. If this is denuded by removal of a short, narrow strip its connective tissue surface is bared for attachment to the parietal peritoneum behind; the best point of attachment is between the rectum on the inner side and the ureter on the outer, its height on the sacrum varying with each case. The technic of the operation is given in detail. Bishop has performed the operation ten times with uniformly good results. It claims to be a rational attempt to attack the problem of prolapsus uteri in a scientific manner. [w.k.]

**Placenta Prævia Without Hemorrhage.**—Dr. Burger<sup>2</sup> says that he, when called to a case of labor, has many times diagnosed a placenta prævia to the astonishment of the midwife, who thought it not possible without hemorrhage. If there is a well distended os uteri and there are no labor pains present, the presenting placenta may cause no hemorrhage. In placenta marginata the hemorrhage first begins during labor. Perhaps it is here that edema and hydramnios occur instead of hemorrhage. Burger describes the technic of delivery in a case of this kind. [w.k.]

**The Ligation of the Hypogastric and Ovarian Arteries on Both Sides in Inoperable Uterine Carcinoma.**—O. Th. Lindenthal<sup>3</sup> gives the history of three cases of inoperable cancer of the uterus in which ligation of the hypogastric and ovarian arteries was employed with a favorable effect upon the hemorrhage. The advance of the cancer was not restricted, but the fetid discharge was improved by a simultaneous curetment. In two cases the general condition was improved by the cessation of hemorrhage, but in the third cachexia was so severe that improvement seemed no longer possible. The writer cites cases of Kronig's in which the hemorrhage ceased after this palliative treatment. After reviewing a number of other cases he concludes that the ligation of the hypogastric and ovarian arteries is to be recommended in those cases in which inoperable cancer has not extended far into the vagina, in which there is little or no cachexia, and the threatening hemorrhages can be controlled in no other way. If in any case the abdomen has been opened to perform a radical operation which is found impracticable, then this palliative procedure should be carried out. [w.k.]

## TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPELMAN

## REVIEW OF LITERATURE

**Solubility of Iodin in Glycerin.**—Catillon<sup>1</sup> calls attention to the fact that iodine is almost as soluble in glycerin as it is in acetone. He has been able to obtain a solution of 1 gram (15 grains) of iodine in 2 grams (30 minims) of glycerin by heating the mixture in a closed vessel at a temperature between 250° and 300° F. This solution has the color and odor of free iodine. It does not give off irritating fumes of hydriodic acid and other substances as does the solution of iodine in acetone. The author believes that the iodine does not undergo any reaction since it separates in crystals by sublimation or in the form of a fine sediment by the addition of water. Glycerin favors the absorption of iodine and the solution is preferred to the tincture of iodine when it is necessary to act on the deeper tissues or when a milder and more prolonged action is desired. [L.F.A.]

**Treatment of Metrorrhagia.**—Lutaud<sup>2</sup> directs that a dessertspoonful of the following solution be given every two hours:

Ergotin . . . . .	2 grams (30 grains)
Alcohol . . . . .	3 cc. (45 minims)
Distilled water . . . . .	135 cc. (4½ ounces)

Vaginal injections of hot water 110° F. may also be used with advantage. Curetment should be practised in metrorrhagia following miscarriage and in those cases in which the loss of blood is due to retained placenta or to polypi. [L.F.A.]

**Pyrogallol Triacetate in the Treatment of Nonparasitic Skin Diseases.**—Clau<sup>3</sup> advises pyrogallol triacetate in a 20% paste for the eczemas seen in scrofulous children. The ointment should be made with vasoline instead of vaselin and the remedy applied with a bandage, to remain in place for three days. A cure follows in the course of a few days. [W.E.R.]

**Eukinase and Pancreatokinase.**—Hallion and Carrion<sup>4</sup> discuss the physiologic properties and the therapeutic applications of these substances. Eukinase is an extract from the duodenal mucous membrane of the pig; it is a yellowish powder, which contains the enterokinase of Pawlaw in a very active form. Eukinase is indicated in various acute and chronic affections of the intestines, either of primary origin or secondary to infectious diseases; in intestinal indigestion it is also of great value. Pancreatokinase is a combination of pancreatin and eukinase, which is not only eupeptic, but also a powerful digestant. In order that these substances may not be acted upon by the gastric juice, they may be given either in gluten capsules or incorporated with a gluten paste which, after desiccation, is formed into granules. [L.F.A.]

**A New Method of Administering Chaulmoogra Oil.**—H. Danlos<sup>5</sup> recommends the administration of chaulmoogra oil by the rectum when it cannot be taken by the stomach. An emulsion is prepared by mixing 12 cc. (3 drams) of the oil with 75 cc. (2½ ounces) of warm milk and thoroughly beating with a fork. This is administered after the patient has evacuated the bowels; he is then directed to remain in bed for two or three hours. [L.F.A.]

**Bromocoll in Pruritus.**—Joseph<sup>6</sup> advises the use of a 10% solution of bromocoll to relieve the itching in pruritus, lichens simplex, etc. [W.E.R.]

**The Preparation of Colloidal Silver.**—Danlos and A. Cothereau<sup>7</sup> give the following method of preparing colloidal silver: 1. 100 grams (3½ ounces) of citric acid is dissolved in distilled water, and ammonia is added until the color of phthalin is obtained; enough water is then added to make 500 cubic centimeters (1 pint). 2. 186 grams (6 ounces) of ammoniacal ferrous sulfate is dissolved in 500 cubic centimeters (1 pint) of distilled water. 3. The two preceding solutions are mixed;

this mixture is still further diluted by the addition of 1½ quarts of distilled water, and into it is gradually poured 100 cubic centimeters (3½ ounces) of a 20% solution of silver nitrate, care being taken to stir constantly while pouring. A reddish-brown precipitate is formed and allowed to settle. The supernatant liquid is poured off and the precipitate placed on a rapid filtering apparatus, washed with a small quantity of water and then dried. These different manipulations must be performed rapidly in order to avoid the action of the air and light as much as possible. The precipitate must be dried in a vacuum over sulfuric acid and protected from the light, or in a drying-stove at a temperature of 122° F. The product thus obtained occurs in small masses, having a metallic reflex and containing 97% of silver with traces of iron and citric acid. It is completely soluble in water, and its solutions will not pass through the membrane of a dialyzer. The metal is precipitated by acids, and the addition of bromine, chlorine or iodine causes the formation of silver bromide, chloride or iodide. [L.F.A.]

**Observations on the Action of Soluble Silver.**—A. T. Dvoretzky<sup>1</sup> reviews the literature and reports his own experience with soluble or colloidal silver introduced into therapeutics in 1897 by Credé. Rubbed into the skin in the form of an ointment colloidal silver is absorbed and carried along by the blood, exerting its influence locally and generally. The remedy may therefore be applied far from the seat of disease and good results be obtained. The effects of colloidal silver, probably due to its germicidal action, are as follow: An almost instantaneous general improvement, fall of temperature, better pulse, and disappearance of subjective septic symptoms. The remedy is highly potent in local inflammatory or infectious processes caused by streptococci or staphylococci, such as phlegmon, erysipelas, furunculosis, glandular swellings, excepting advanced stages with softening and necrosis of tissues. The author had no opportunity of testing soluble silver in general sepsis and puerperal sepsis, but is inclined to expect great results from the remedy in the future. [L.J.]

**Intravenous Injections of Collargol.**—Thiroloux<sup>2</sup> reports a case of pneumonia in an old person, which was successfully aborted by the intravenous injection of colloidal silver or collargol. This substance was used in the strength of 1 to 200, of which 6 cc. (1½ drams) was employed at each injection. This drug has been used by several investigators for the purpose of combating acute infections, but with widely different results. Dabot used it in a case of bronchopneumonia with good results. Widal tried it in the treatment of infectious endocarditis, but no amelioration resulted; in this case the condition had been present for two or three months, which may explain its unfavorable influence. Chauffard employed intravenous injections of 10 cc. (2½ drams), representing 1½ grains of collargol, in a case of staphylococcal septicemia following typhoid fever with no effect. Huchard has obtained no definite results from its use. On the whole, effects of the drug are uncertain. [L.F.A.]

**Abortive Treatment of Furunculosis.**—P. Gallois and Coureux<sup>3</sup> replace tincture of iodine, which is commonly employed in the treatment of furunculosis, by a solution of iodine in acetone, as follows:

Metallic iodine . . . . .	4 grams (1 dram)
Acetone . . . . .	10 grams (2½ drams)

This solution contains about four times as much iodine as can be dissolved in the same quantity of alcohol. Its appearance is nearly identical with that of the tincture of iodine, but it gradually changes in character. At the end of 15 days the solution becomes black and syrupy, and resembles black currant juice. Clermont and Chautard<sup>4</sup> found that a definite chemical compound was formed—monoiodoacetone—with the liberation of hydriodic acid. Monoiodoacetone turns black in the light. In the action of iodine on acetone, diiodoacetone is also formed, the proportion of this increasing with the age of the preparation. In the treatment of furunculosis the action of this solution is much more powerful than tincture of iodine. It is more caustic

<sup>4</sup> Bull. de la Soc. de Chimie, t. xliii, p. 614.

than tincture of iodine, and must be used more cautiously. The absorption of the drug seems to be governed by the degree of congestion of the inflamed tissues. When iodoacetone is applied to an unopened boil which is surmounted by a small pustule the drop of pus is dried up and is later removed as a crust. At the end of 24 hours, if the pustule is still red and inflamed, the application may be renewed. When applied early the furuncle is usually aborted. Slight irritation may result from its use where the skin is thin, as in the axilla. It is recommended that the applications be made by the physician himself. [L.F.A.]

#### FORMULAS, ORIGINAL AND SELECTED.

**Treatment of Eczema.**—The following ointment has given good results in certain cases of eczema:<sup>1</sup>

Camphorated naphthol . . . . . 0.5 gram (7½ grains)  
Zinc oxid . . . . . 5.0 grams (75 grains)  
Vaselin . . . . . 45.0 grams (12 drams)

**To Prevent Vomiting.**—Soupault<sup>2</sup> advises chloroform in the following combination to prevent vomiting:

Chloroform } of each . . . . . 5 cc. (1½ fluidrams)  
Tincture of iodine }

Dose.—Five drops after meals if there is a tendency to nausea.

For severe **gastralgia** he uses:

Cocain hydrochlorate . . . . . 0.05 gm. (½ grain)  
Chloroform water } of each . . . . . 60 cc. (2 fluidounces)  
Distilled water }

Dose.—One tablespoonful every two hours. [W.E.R.]

#### LEGAL MEDICINE

JOHN MARSHALL

J. H. W. RHEIN

#### EDITORIAL COMMENT

##### The Differentiation Between Animal Bones.—

An article of practical importance to all those interested in forensic medicine is the description by Schütze<sup>3</sup> of a method for differentiating between human and animal bones. The method is based upon the principles of the so-called "Wassermann's method." Wassermann was the first to demonstrate that the blood-serum of an animal treated by successive injections of the serum of an alien species gives a specific precipitate when the serum used for the injections is added to it. To give a concrete example: a rabbit is treated with successive injections of the serum of the ox; after a certain interval—the degree of immunity is proportional to the total amount of serum used for the injections—serum is collected from the rabbit, and to it is added a trace of bovine serum; a delicate clouding is seen immediately, and a considerable precipitate collects in the bottom of the test-tube after standing. No other serum except bovine serum will give this reaction with this rabbit's serum. The reaction is therefore, practically speaking, absolutely specific. We say practically speaking, for it has been found that the serum of some of the anthropoid apes will give a precipitate with the serum of an animal immunized against human serum, though even here a quantitative difference is discernible. But such a condition would hardly occur in forensic practice, and there would be absolutely no reaction of the serum of an animal immunized against human serum if it were tested against the serum or blood of any of the common domestic or wild animals. In practical use the reaction is therefore specific. Dried blood and extracts of old stains can be used as well as fresh serum. The method has been successfully employed in practice in differentiating between bloods, in identifying a given blood for forensic purposes, and in determining the biologic relationships of species. It has also been practically applied to distinguish between beef and horse-meat—the serum albumins necessary for the reaction being

extracted from the meat by maceration. Schütze has applied the method to the differentiation between human and animal bones with success. For this purpose the serum of an animal immunized against human serum was taken, and to it was added the fluid resulting from the maceration of the ground and pulverized bones. A specific reaction was obtained—only fluid obtained from the maceration of human bones gave the precipitate. Dried bones gave the reaction, but since the reaction depends upon the extraction by maceration of the serum albumins, it is evident that it can only be obtained from bones which still have enough of the marrow substance adherent to them to permit of obtaining these albumins. The reaction fails if the albumins have been previously coagulated by heat; the method is therefore limited to more or less fresh bone substance, yet the majority of forensic cases would doubtless fall under this heading.

The Röntgen ray has a twofold medicolegal significance, its relation to the offering of skiagraphs as evidence in the courts and its relation to suits in malpractice. The courts have accepted the skiagraph in testimony in a number of cases. Its importance depends, however, upon the care with which it has been prepared and whether it is explained by an expert professional witness. Several malpractice suits have grown out of the use of the Röntgen ray in the diagnosis and treatment of disease. Patients receiving harm as a result of the use of the Röntgen ray have sued the physician employing this measure for malpractice. It would seem wise, in view of these facts, for any one employing this measure to insist upon a written agreement not to bring suit in case of accident occurring from its use. The patient should have the danger of the procedure fully explained to him before undergoing examination or treatment.

#### REVIEW OF LITERATURE

**Medical Laws of Maryland.**<sup>1</sup>—The Legislature of Maryland in 1902 passed an act which provided for two separate examining boards: one representing the Medical and Surgical Faculty of the State of Maryland, and one representing the Maryland State Homeopathic Medical Society. The applicants are examined in anatomy, physiology, medical chemistry, surgery, practice of medicine, materia medica, therapeutics, obstetrics, and pathology. The applicants may show a diploma from a legally incorporated college in the United States or a diploma or license entitling him to practise all the branches of medicine and surgery in some foreign country. If the diploma is from a college in the United States, it must have been conferred by a college requiring a four-years' standard of education, as defined by the American Medical College Association or the Intercollegiate Committee of the American Institute of Homeopathy, provided that these requirements shall not apply to any applicants who shall have practised outside of the State for three years prior to the passage of this act, if he is duly registered or licensed in the place where he so practised; provided further, that two courses of medical lectures, both of which shall be either begun or completed within the same calendar year, shall not satisfy the above requirements; provided also, that in the case of students who at the time of the passage of this act shall be in their second year in a medical college, a three-years' course of study or attendance on three courses of lectures delivered in different years shall satisfy said requirements. Licenses may be granted without examinations to applicants who are licensed practitioners of the District of Columbia or other States where the standard of requirements are as high as those governing the Board of Medical Examiners of Maryland; provided that such States reciprocate the same privilege. Medical students at the end of their second year of study who have completed the studies of anatomy, physiology, medical chemistry, and materia medica, shall, upon application, be examined in these branches by the

<sup>1</sup> Bulletin Général de Thérapeutique, Vol. cxlv, No. 5, 1903, p. 192.

<sup>2</sup> Bulletin Thérap., October 15, 1902.

<sup>3</sup> Deutsche medicinische Wochenschrift, No. 4, 1903, p. 62.

<sup>1</sup> Medicolegal Bulletin, February, 1903.

State Licensing Board, the results to be considered as a part of the final examination. Diplomas presented by graduates of foreign colleges shall be accepted if the course of four years has been required by such foreign college before issuing such diploma.

**New Illinois State Bill to Regulate the Practice of Medicine.**—This was introduced March 3, 1903.<sup>1</sup> The bill retains all the good features of the present law and guarantees representation of all schools. It defines the practice of medicine as follows: "Any one shall be regarded as practising medicine who shall treat or profess to treat, operate on or prescribe for any physical injury to or deformity of another." It provides for the restricted practice of medicine—that is to say, a person may engage in the practice of medicine without using drugs or appliances, performing surgical operations, or attending cases of labor. Midwives must be licensed. Itinerant vendors of drugs, nostrums, and ointments, or those who profess to treat diseases or injuries by any other method, must be licensed.

**Incompetent to Offer Certain Quotations in Giving Expert Evidence.**—The Supreme Court of Alabama, in the murder case of Timothy vs. State,<sup>2</sup> decided that it is competent to offer in evidence quotations from standard medical works relating to wounds and personal physical conditions, but that statements of a work on medical jurisprudence relating to certain experiments made with guns at various distances in order to determine the distance a weapon should be held from a target to leave no powder marks cannot be accepted as evidence, nor can the conclusions of the author from these experiments. Opinions upon such subjects must be given by word-of-mouth and only by experts.

**Judgment Against Charity Patient.**<sup>3</sup>—A physician brought suit for \$20.00 against a patient treated as a charity patient in the Postgraduate School of Chicago in the free clinic, whom he afterward discovered was financially responsible. Judgment was rendered in his favor.

**Diagnosis of Blood Stains, Human and Animal.**—The *Journal de Med. de Paris*<sup>4</sup> reviews in an editorial the recent work of Nobele, who made a number of interesting experiments on animals, with the object of confirming the results of Wassermann and Schütze relating to the differential diagnosis between the blood of man and the blood of animals. The process consisted of injecting animals with human serum; the serum of the inoculated animal acquiring the property of throwing down a precipitate when mixed with human blood. Nobele injected into the peritoneal cavity of a rabbit 10 cc. of ascitic fluid from a woman who had a uterine tumor. After six injections the animal was killed, and it was found that the serum of the blood when mixed with equal parts of human serum gave a flocculent precipitate. A second rabbit was injected subcutaneously six times with 10 cc. of a liquid expressed from a fresh human placenta. The animal was then killed and the serum was found to react upon human serum. When the blood for examination is dry it is dissolved in a physiologic solution of sodium chlorid or a weak solution of caustic soda. He proved that the serum of injected rabbits gave no precipitate with the blood of dogs, horses, oxen, cats, rabbits, pigs and cows. It gave a precipitate when mixed with the serum of milk, the serum of pus, saliva, nasal secretions, coryza and albuminous urine. Putrefied blood reacted equally well. A stain of human blood was made upon linen many days previously, and when diluted in a solution of sodium chlorid gave a characteristic reaction. A piece of linen stained with human blood was washed in water, then dried, so that the stain was distinguished with great difficulty. When placed in a solution of sodium chlorid it was found that the serum of the injected rabbit gave with this solution a feeble precipitate. Linen stained with blood in 1893 was treated in the same fashion, but no reaction was obtained. Rusty scissors which had been stained with blood two months previously were scraped and the debris mixed with a solution of sodium

chlorid, with which solution the characteristic precipitate was obtained. A few drops of blood were placed upon three pieces of glass which were subjected to a temperature of 75°, 100° and 125° respectively. When the blood stain was taken up by a solution of sodium chlorid, the liquid containing the blood subjected to a temperature of 125° was the only one that did not give the reaction. When he gave the ascitic fluid by the mouth the serum of the rabbit so treated did not give the characteristic reaction of human blood. On evaporating in vacuum the reactive serum, he obtained a substance which he preserved in sealed glass tubes protected from the light. He found that after six months serum so preserved retained its activity.

**Power of Board of Education.**—The Supreme Court of Michigan in the case of Mathews vs. Board of Education<sup>1</sup> held that the board of education exceeded its power when it made it essential to admission to school that a child shall be vaccinated. In this State a rule had been enacted by the School District Board in 1894 by which no pupil was permitted to attend school who could not give satisfactory evidence that he or she had been vaccinated, or was in some other way immune to small-pox. The court held inasmuch as it was the duty of a child to attend school, and that the parent is liable to a fine or penalty or imprisonment or both if he neglects to send him, that this practically gives the board of education the authority to compel vaccination, for if the parent does not have his child vaccinated the child can not go to school, and as the parent is compelled to send his child to school he becomes liable to the penalty mentioned above. The court further holds that in spite of this decision the board of education has the power temporarily to close the schools during the prevalence of epidemics of contagious diseases. Only the legislature can change the existing laws so that a child can be lawfully excluded from attending school for the cause relied on.

**Board of Expert Medical Witnesses.**—Johnson,<sup>2</sup> in discussing the question of the medical expert evidence, proposes that the court should appoint a medical board of witnesses, who may be cross-examined just as expert witnesses are cross-examined, as a remedy for the evils arising from the present method of obtaining expert testimony.

**Damages for Loss of Eyesight.**—The Appellate Court of Indiana,<sup>3</sup> in the case of Van Camp Hardware Company vs. O'Brien, allowed \$25,000 damages in the case of a girl 9 years of age who lost the sight of her left eye by accident. **Damages for Broken Leg.**—The Supreme Court of New York, in the case of the American Sugar Refining Company vs. Wieszynski,<sup>4</sup> believes that \$1,000 is the proper amount of damages received for the breaking of a leg.

**Injuries Sustained by Röntgen Ray Examination.**—The Supreme Court in the case of MacDonald vs. Shields, Jernigan and O'Conner,<sup>5</sup> dismissed the case without letting it go to the jury. A suit of \$50,000 was brought for injuries sustained through an examination by the Röntgen ray, and as a result the patient's hair fell out and she became bald. The court held that the evidence went to prove that she had consented to the examination, and that there was no case against the defendants.

**Liability of Druggist in Dispensing Poisons.**—In the case of Gibson vs. Torbert<sup>6</sup> the Supreme Court of Iowa is of opinion that if a person of mature age, apparently in possession of his faculties, represents to a druggist by implication that he knows the properties and uses of the drug for which he asks, and that he a proper person to receive the same, such a transaction may be made without special inquiry or instructions, and that the seller thereof is not liable for damages or injuries to the purchaser that may result from any improper use of such drug, when there has been nothing suspicious about the transaction by which the seller might judge that the person was an improper person to receive the drug. To say that a man is illiterate does not mean that he cannot be trusted with dangerous substances.

<sup>4</sup> June 8, 1902.

**Legal Value of a Woman's Life.**—The Supreme Judicial Court of Maine,<sup>1</sup> in the case of Oakes vs. the Maine Central Railroad Company, decided that \$3,500 was an excessive amount to pay for the life of a woman aged 35, whose husband was in poor health; who was a good milliner; a prudent, industrious woman; an affectionate mother, and who possessed a fair education. The court held that in determining the amount of pecuniary injury resulting from the death of the woman it was proper to show the expectancy of life; the probability of her surviving her husband; the burden of supporting her child; the time that might reasonably expire before the child could assist in the support of himself and mother; the possibility that the mother might become dependent on the child for support; the loss of proper moral training. The court decided that a new trial must be granted if all over \$2,500 was not remitted. The Supreme Court of New Jersey, in the case of Rafferty vs. the Erie Railroad Company, held that \$5,000 was an excessive amount to pay for the death of a woman 45 years old who had kept house for three brothers and a sister, all of whom were single. The court held that the damages were limited by statute to the pecuniary loss sustained by the nearest relatives. Unless the damages were placed at \$2,500 the verdict would not stand.

**Contamination of Wet-nurse.**—In the Court of Lyons<sup>2</sup> an opinion was rendered in favor of a wet-nurse who had been contaminated by a child suffering from hereditary syphilis.

**Examination of Blood Stains.**—The Supreme Court of Idaho,<sup>3</sup> in the murder case of State vs. Rice, held that it is not necessary to call an expert witness to prove the existence of blood, but only when there is a doubt as to whether the blood comes from man or from some lower animal.

**Malpractice.**—Falconbridge, Chief Justice of the King's Bench,<sup>4</sup> gave an important opinion upon the subject of malpractice. A woman who had injured her foot called in a surgeon who, with the assistance of a second surgeon, set the foot, after which they were discharged by the patient. The woman, more than a year afterward, brought suit against the physicians for malpractice, claiming that improper treatment of the foot had resulted in deformity and permanent lameness. It was claimed by the defendants that the foot had been properly set, and that the deformity that subsequently developed was the result of negligence on the part of the plaintiff. Furthermore, that the proceedings were begun more than a year after the date of their last visit. It was claimed by the plaintiff that the astragalus was dislocated, that there had been no fracture of the fibula, and hence an incorrect diagnosis had been made. Skiagraphs were offered in evidence. The court decided in favor of the defendants, and stated the opinion that there is "no implied warranty on the part of a physician or surgeon that he will effect a cure."

**Obligation of Insured in Medical Examinations.**—The Court of Appeals of New York<sup>5</sup> held that the obligation of the insured is only to submit to the examination of a medical examiner and to answer the questions asked by him. If the examiner omits important points in his record of answers given to him, the responsibility falls upon the insurance company, and in the event that the company claims a forfeiture on the ground that the answers were false, the beneficiary may show the answers as actually given. Although the insured may agree that the physician is his agent, the examiner is really the agent of the company.

**Magnetic Healer.**—The Indiana Supreme Court,<sup>6</sup> in the case raised by a magnetic healer, held that healing of the character employed by the magnetic healer was merely a magnetic phenomenon and could not be considered the practice of medicine. This decision has important bearing upon proceedings against "professors" without licenses or Christian Scientists.

**Expert Testimony and Hypothesis.**—The Court of Appeals of Maryland<sup>7</sup> held that when expert testimony depends

wholly upon hypothesis inaccurate conclusions are likely to follow. Two experts of recognized ability often come to opinions diametrically opposite when a hypothetical case is propounded, and the court emphasized the importance of exerting unusual care in dealing with this sort of evidence.

**Professional Secrets.**—The Comité consultatif de l'Assistance Publique<sup>1</sup> decided that facts that may be acquired during professional care of a patient must be considered as professional secrets, and that it is improper to inform the authorities of evidence of crime thus discovered.

**Practice of Medicine Defined.**—Beates, in a recent monograph, asks the question, "How should the practice of medicine be legally defined?" The technical legal interpretation of this question, he states, may be as follows: "To practise medicine is to treat disease and accidents by means of drugs or medicines, and if the treatment of these is conducted without drugs or medicines, one so doing is not practising medicine." The following definitions, he believes, meet all the objections of which he has knowledge: *To Practise Medicine.*—"For any one, except those carrying out the directions of the attending physician, to engage, directly or indirectly, habitually or occasionally, gratuitously, or for pecuniary or other compensation, in the care, management or treatment, by any means whatsoever, either material or immaterial, for the relief or cure of any or all diseases, accidents, or disabilities to which human or animal life is exposed, threatened, or afflicted." *Practitioner of Medicine.*—"Any one, except those carrying out the directions of the attending physician, who engages directly or indirectly, habitually or occasionally, gratuitously, etc., as above." *The Practice of Medicine.*—"The engaging by any one, except those carrying out the directions of the attending physician, directly or indirectly, habitually or occasionally, gratuitously, etc., as above."

**Registration of Pharmacists.**—The Kentucky statutes<sup>2</sup> make it a misdemeanor for any one except a registered pharmacist to sell or compound drugs. It also provides that it shall not interfere with the business of a licensed practising physician or prevent his supplying his patients with drugs, or compounding his own prescriptions. The Court of Appeals of Kentucky in the case of Commonwealth vs. Hovious says that this statute does not give the physician the privilege of selling drugs indiscriminately or to compound and sell drugs indiscriminately to any who may call for them, but that he has the privilege of giving any drugs to or compounding any drugs for parties applying to him for treatment.

**Malpractice Defined.**<sup>3</sup>—This article defines malpractice in its various phases. It is divided into two general classes—civil and criminal malpractice. A physician when he takes charge of a patient contracts that he has the requisite skill to properly perform the duties of his profession. The reasonable and ordinary skill and knowledge which is required of a physician by law is that possessed by physicians practising in the neighborhood in the same line of work. A physician contracts that he will use a reasonable degree of skill and knowledge, due care and diligence in treating his patients, and that he will continue in attendance as long as his services are needed; that he cannot retire from the case except after due notice and allowing sufficient time to elapse for the patient to engage another physician. On the other hand, a patient may discharge a physician without notice. The physician must give clear and explicit instructions; he must follow recognized methods of practice; he must be familiar with the advances made in medicine and he must employ the latest methods, though the law holds him responsible if untoward results follow the use of untried remedies. As to the employment of the Röntgen ray in therapeutic medicine no court of last resort has passed upon the question of the propriety of using it in medical treatment. The physician must employ the best judgment, though this does not imply that it shall be infallible. If the patient fails to follow his advice the physician shall not be held responsible for unfortunate results. The fact that a physician's services are gratuitous does not render him exempt from responsibility. Medical experts are held responsible according to the opportunity for possessing

and using skill and care. A patient contracts to pay when accepting the services of a physician, and this is independent of the results of the treatment. When a certain amount has been agreed upon the amount may be increased when upon further examination the physician discovers that the treatment will be more extended and more difficult and explains this to the patient, though no mention as to increased fee be made. The law recognizes this contract between physician and patient when made on Sunday. Medical ethics offset the implied promise to pay when medical services are rendered to a medical man. Refusal on the part of the patient to follow instructions laid down by the physician will prevent a recovery for damages.

**Licenses and Examining Boards.**—Beates read before the National Confederation of the State Medical Examining and Licensing Boards at Saratoga Springs, N. Y., June 9, 1902, a paper entitled "How May the Topics in Examination for Licensing be Best Arranged by Examining Boards?" This question is of great importance because these examining boards, by controlling licenses that are granted, indirectly establish a standard of medical education. He emphasizes the fact that on account of the indiscriminate way in which medical colleges have issued diplomas many illiterate men have been given the privilege of practising medicine. The examinations for licensure vary in the different States, and the memory character of the State examinations and the varying requirements set up are a source of great injustice to competent practitioners who, licensed in one State, desire to practise in another. The State board should so arrange the topics in examinations as to establish a uniformity of standard which compel medical colleges to so modify their courses that their graduates may readily pass the State examinations, which shall be of such a character as to demonstrate that the successful candidate is qualified to practise medicine. The relation of general education to medical education must be carefully considered. Previous education on the part of the candidate for advanced standing should only receive due consideration when it has included the branches that are required in that course of the medical curriculum that it is desired to replace. Topics in the examinations held by examining boards should be so arranged that medical colleges shall be compelled to teach them. Colleges granting a degree should have the same curriculum; the State examinations should be the same in type and extent; matriculation examinations should be of the same standard; uniform standard in both general and medical requirement for uniform license-right will result in the best arrangement for the topics for licenses by examining boards.

**Morphinomania.**—An action was brought against a physician by a nurse<sup>1</sup> for negligence resulting in the development of morphinomania. She claimed that the physician negligently administered or negligently gave her opportunities of administering to herself various narcotics to such an extent that she lost her reason and very nearly lost her life. An attempt was thus made to fix the responsibility upon the physician for developing the morphin habit, which had been acquired as a result of his treatment. The drug had been prescribed for the relief of spasmodic asthma, which had resisted treatment by other remedies. The jury rendered a verdict for the defendant.

Judge Stowe entered judgment for the defendants in the case of Addy vs. Trustees of the Western Pennsylvania Medical College.<sup>2</sup> Addy brought proceedings against the trustees of this college to compel them to award to him a degree of doctor of medicine. The court, however, says that the trustees have a right to refuse to approve the recommendation of the faculty that a degree of doctor of medicine be granted, excepting in violation of the principles of right and justice. The law does not give the faculty the privilege of authorizing the issuing of diplomas, unless the trustees agree to it, and it is not necessary to examine into the reasons that the trustees may have for not granting the diploma.

**Liability of Railroad Company in Caring for a Case of Smallpox.**—The Supreme Court of Texas, in the case of the Missouri, Kansas and Texas Railway Company of Texas vs. Wood,<sup>3</sup>

decided that the railroad company was liable for the damages caused by the escape from quarantine of a patient suffering from smallpox while under the care of a surgeon employed by the company. When the company undertook to take charge of the patient to protect the public from infection by coming in contact with such a patient it assumed the responsibility of using ordinary care to avoid transmission of the disease, and when by the negligence of one of its employes the patient escaped and communicated it to others the company was liable for the damages caused thereby.

**Verdict for a Physician.**—Dr. George D. Head,<sup>1</sup> of Minneapolis, sued the American Bridge Company for a bill of \$66.00 for services rendered to eight employes who were injured in the construction of a steel elevator. The bookkeeper of the company sent the patients to Head. The company requested him to send the bill to the Travelers' Insurance Company, which paid half the bill, claiming that it was only liable for first aid, and informed the doctor that he must collect the other half of the bill from the American Bridge Company, or from the men who were injured. The latter company held that its agent had only the authority to employ the doctor for first aid only, but it was shown in the testimony that Dr. Head did not know of this restriction until long after the services were rendered. The case was decided by the Municipal Court and later by the Supreme Court in favor of Head. The Supreme Court gave the following opinion: "If a physician is summoned to attend an injured person by another having authority from his principal to hire the first aid services, and nothing is said about his authority being limited, and the physician is unaware of such limit, the agent binds the principal to pay not only for the first aid, or initial service, but for the subsequent service as well."

**Malpractice Suit for Röntgen Ray Burn.**<sup>2</sup>—In the case of Shelly vs. Dr. G. W. Spohn, of Indiana, the La Grange Circuit Court decided in favor of the defendant. Dr. Spohn had treated Shelly for a cancerous growth on the under part of his tongue with the Röntgen ray. The patient was told of the possibility of a burn, and consented to the treatment. After daily treatment for two weeks a slight dermatitis developed on the patient's face, after which the treatment was discontinued. After receiving a few treatments for the dermatitis, the patient left the city to obtain treatment for his burns elsewhere. He brought action against Dr. Spohn for malpractice, claiming \$10,000 damages for injuries to his face and left hand, which, he claimed, was permanently crippled as a result of his burns. He alleged that the doctor directed him to hold the lower jaw down with the left hand during the treatment. It was proved in the trial that the only real injury was to the hand of the plaintiff, and it was shown by experts that this was due to infection of a wound in the hand by poisonous saliva, which came in contact with the hand at certain times when the patient persisted in wiping saliva from his mouth against the advice of the doctor.

**Exception to Physician's Fee.**—In the case of St. Louis Southwestern Railway Company of Texas vs. Stone-Cypher,<sup>3</sup> the latter made a claim of \$100, the expense incurred in physician's fees and treatment for injuries sustained by the company's negligence. Exception was taken on the ground that the dates and places of the alleged services were not stated, but the Court of Civil Appeals of Texas overruled the objection, maintaining that the claim was for the amount he was compelled to pay for the company's negligence, and that it was unnecessary to be more explicit about the claim. If the doctor had been suing for the amount of his bill, then the case would be different, and an itemized account would be necessary.

**Life Insurance in Case of Suicide.**—An action was brought against the Knights Templar and Masons' Life Insurance Indemnity Company by Rosa B. Jorman<sup>4</sup> to recover \$5,000 upon a life insurance policy issued upon the life of John P. Jorman, her husband, who had committed suicide. The case was first brought into the Circuit Court of Grundy County, Missouri,

<sup>1</sup> Northwestern Lancet, January 15, 1903, p. 33.

<sup>2</sup> Medicolegal Bulletin, January, 1903.

<sup>3</sup> Journal of the American Medical Association, September 14, 1901.

<sup>4</sup> Baltimore Underwriter, November 5, 1902, and Public Ledger, December 8, 1902.

<sup>1</sup> British Medical Journal, March 8, 1902, p. 605.

<sup>2</sup> Medicolegal Bulletin, December, 1902.

<sup>3</sup> Journal of the American Medical Association, March 15, 1902.

and later into the Circuit Court of the United States for the Western District of that State. The policy contained a suicide clause by which the holder of such policy was not entitled to indemnity in case of suicide, "whether voluntary or involuntary, sane or insane." The Missouri law of 1879, however, provides that suicide shall not be used as a defense against settlement of a life insurance policy. Judgment was rendered in favor of the plaintiff by the Circuit Court and was affirmed by the Circuit Court of Appeals, and later by the United States Supreme Court.

**Privilege of Increasing Fee.**—A Supreme Court jury of New York decided in the case of *Asch vs. Goldsmith* that when a physician attending a patient in a summer resort moves to the city he has the privilege of increasing his fee for the subsequent visits out of town. The patient claimed that the fee for the out-of-town visits should be the same as charged when the doctor was staying at the summer resort.<sup>1</sup>

**Malpractice in Vaccination.**—Action was brought by Bridget Nugent against Dr. Harvey M. Righter before Judge McCarthy, in the Common Pleas Court No. 3, of Philadelphia, to recover for the death of her child of six years who had been vaccinated by Dr. Righter. It was claimed by the plaintiff that impure virus had been used and that the method had been careless, and as a result of this that impetigo contagiosa developed, in consequence of which the child died. It was also alleged that proper skill and diligence was not exercised in the treatment of this disease. The testimony of a number of reputable physicians went to show that Dr. Righter had used more than ordinary care in vaccinating the child; that the impetigo which developed nearly a month after the vaccination and after the wound had healed could not possibly have been introduced at the time of vaccination, and further that Dr. Righter had not only recognized the impetigo but had administered the proper treatment for it. It was shown in the testimony that the plaintiff's home was in a bad hygienic condition. On the contrary, several witnesses testified to the cleanliness of the plaintiff's home. The jury returned a verdict in favor of the plaintiff, awarding her \$1,000 damages. The case has been appealed and the Philadelphia County Medical Society has voted funds for the defense.

**The Legal Aspect of the Premature Infant.**<sup>2</sup>—A case was tried before the Tribunal de la Seine in which the plaintiff endeavored to recover the dowry paid on his daughter's marriage, claiming that she had died without issue to inherit from her. His daughter died in giving birth to a child 6½ months old, who lived in an incubator 25 days. The question to be decided was whether the child was viable. According to the French law if a child was viable he could inherit from his mother, one-half going to the child's father, the other half returning to the mother's father; or if the child was not viable, the maternal grandfather could claim the return of the dowry. The court appointed a jury of experts to consider the evidence as to the following points: (1) That the child was born after a gestation of 6½ months; (2) that it weighed at the time of birth 1 kilo. 200 grams (2.4 pounds), and continued to gain in weight afterward; (3) that the nails were not fully formed. If these asserted facts can be proved by the plaintiff he will probably win the case.

**Osteopath Fined.**—An osteopath was fined \$100 for practicing medicine illegally by Judge Heisley,<sup>3</sup> of the Monmouth County Court, New Jersey, who maintained that healing by the application of the hands was a remedy just as the administration of drugs.

**Legal Privileges of Board of Health.**—The Supreme Court of Massachusetts,<sup>4</sup> in the case of *Stone vs. Heath*, holds that a board of health can not be restrained from entering on premises for the purpose of abating a nuisance if the owner has neglected to abate the same after being so ordered; nor can it be restrained from instituting proceedings against the owner on account of negligence in obeying the order. But if subsequently it is discovered that there was no nuisance, then the board of health acts at its peril. In proceedings against the

parties to recover the expenses for abating a nuisance, the question whether there was a nuisance, or if such existed whether it was maintained by the said parties, may be litigated by such parties. This question may be also litigated in proceedings to recover the loss or damage to property caused by the abating of the nuisance, and may also be litigated by parties against whom proceedings are instituted for the neglect or failure on their part to obey the orders of the board of health directing them to abate the nuisance.

**A Verdict of \$100,000 Damages.**—A suit was brought against the New York Central and Hudson Railway Co. for \$250,000 damages by the widow of a man who had lost his life in the Park Avenue tunnel accident in New York City.<sup>1</sup> The widow claimed that her husband was making \$35,000 per year. She was awarded a verdict of \$100,000 with interest, together with an allowance of \$2,000 for counsel's fees.

**Microscopic Appearance of Human Hair.**—Lunson<sup>2</sup> claims that human and animal hair may be readily distinguished by the microscope from all other substances. Human hair may be distinguished from animal hair, and even the species of animal discovered. It is also possible to determine the locality from which the hair comes. The root of hair that is plucked out is irregular, has an undulating surface and excrescences of different form and thickness; the root of hair that has fallen out has a rounded extremity and a smooth surface. He uses a polarization apparatus to determine between gray or blond hair. He found that a chlorin solution completely decolorized black hair, and states that arsenic can be discovered in the hair of those suffering from arsenic poisoning.

**On the Resistance of the Colloidal Substance of the Thyroid to Putrefactive Processes.**—M. U. Masini<sup>3</sup> presents a contribution to the knowledge of the course of putrefaction in the various tissues, first investigated by Tamassia from a medicolegal standpoint, with a view to the decisive establishment of the date of death. He finds that the thyroid is an organ which putrefies very quickly, dissolving completely in the course of from 12 to 14 days in a moist atmosphere and at a temperature of 10° C. The colloidal substance of the thyroid, however, resists the putrefactive processes which destroy the fibrous tissues and enables the organ to be identified after all the other elements have disappeared. Certain alterations which have been described by authors as the results of morbid processes are found to be the result of cadaveric changes, and thus exclude all pathogenic influence. This paper is accompanied by a bibliography of papers on cadaveric alterations. [C.S.D.]

**The Detection of Simulation in Hysteria and After Accidental Injuries.**—Malingers suing for damages after accidents and hysteric individuals simulating symptoms and diseases are easily exposed, according to Hoesslin.<sup>4</sup> If along with other probable symptoms of hysteria the diameter of the visual field does not increase when the point of fixation is removed to a greater distance the diagnosis of hysteria is assured. If no symptoms of hysteria exist with it the individual is probably a malingerer. He speaks of this field as a "tubular visual field." The diagnosis of malingery is made certain if paradoxical contraction of antagonistic muscles exist. The patient is asked to perform a certain motion and this movement is slightly resisted. The resistance is suddenly released. In individuals either perfectly well or suffering with an organic paresis, the released member will jump in the direction of attempted exertion. Malingers to prove injury will, instead of attempting to perform motion asked of them, contract the muscles opposing this movement, and the limb will stay in the same position. Hoesslin has found this phenomenon in 37 individuals during the course of one year and further investigations have proved them simulators. In all cases where the absence of paradoxical contractions was noted, even though the patient was known to be hysteric, the injuries proved to be founded on an organic basis. [E.L.]

**Changes in the Medical Corps of the U. S. Army for the week ended March 28, 1903:**

**MAUS**, Lieutenant-Colonel LOUIS M., deputy surgeon-general, is granted leave for one month from about April 1, with permission to apply for an extension of one month.

**KILBOURNE**, Lieutenant-Colonel HENRY S., deputy surgeon-general, in addition to his other duties will assume charge of the medical supply depot, San Francisco, Cal., during the absence of Lieutenant-Colonel Louis M. Maus, deputy surgeon-general.

**LOCKHILL**, First Lieutenant EDWARD P., assistant surgeon, is relieved from further duty at the United States General Hospital, Presidio, and will report to the commanding officer of the Presidio for duty at that post.

**HOLMES**, THOMAS G., contract surgeon, is assigned to duty as examiner of recruits at Detroit, Mich., in addition to his duties at Fort Wayne.

**MILLS**, FREDERICK H., contract surgeon, will proceed to his home, Buffalo, N. Y., for annulment of contract.

**ASHFORD**, Captain BAILEY K., assistant surgeon, is relieved from duty at Ponce, P. R., and will report at San Juan, P. R., for temporary duty at that post.

**WILLIAMS**, First Lieutenant ALLIE W., assistant surgeon, is relieved from duty at Mayaguez, P. R., and will report at Cayey, P. R., for duty, to relieve First Lieutenant Willard F. Truby, assistant surgeon. Lieutenant Truby will proceed to New York City and report by letter to the adjutant-general of the army for further orders.

**SORBER**, ORD M., contract dental surgeon, is relieved from temporary duty at Fort Clark and will proceed to Camp Eagle Pass, Tex., for temporary duty, upon completion of which he will return to his station, Fort Sam Houston.

**BUFORD**, OLIVER H., contract surgeon, is granted leave for two months.

**KIERSTED**, First Lieutenant HENRY S., assistant surgeon, is granted leave for ten days, beginning March 27.

**YOST**, First Lieutenant JOHN D., assistant surgeon, is assigned to duty in the office of the attending surgeon and medical superintendent, army transport service, with station in San Francisco, Cal.

**BUSHNEIL**, Major GEORGE E., surgeon, is granted leave for ten days.

**STEPHENSON**, Major WILLIAM, surgeon, is relieved from duty at Monterey, Cal., and will proceed to the Presidio, to relieve Lieutenant-Colonel Henry S. Kilbourne, deputy surgeon-general. Lieutenant-Colonel Kilbourne will report to the commanding general, department of California, for duty as chief surgeon of that department.

A board of officers to consist of Majors Louis A. La Garde, Henry P. Birmingham, James D. Glennan, surgeons, is appointed to meet at the Army Medical Museum Building, Washington, D. C., April 1, 1904, for the examination of officers of the medical department for promotion.

The following named officers will report to Major Louis A. La Garde, surgeon, president of the examining board, at the Army Medical Museum Building, Washington, D. C., for examination for promotion: Captains Geo. M. Wells, Henry C. Fisher, Henry A. Shaw, Charles F. Kleifer, assistant surgeons.

**SMITH**, HARRY T., hospital steward, medical supply depot, Washington, D. C., upon expiration of furlough authorized March 21, will proceed to Manila, P. I.

**GORGAS**, Colonel WM. C., assistant surgeon-general, is granted leave for three months from about April 1.

The board of medical officers appointed to meet in Washington, D. C., for the examination of candidates for admission to the medical corps of the army is dissolved.

A board of medical officers to consist of Colonel Calvin DeWitt, assistant surgeon-general, Major Louis A. La Garde, surgeon, Major Henry P. Birmingham, surgeon, Major Jas. D. Glennan, surgeon, Captain Carl R. Darnall, assistant surgeon, is appointed to meet at the Army Medical Museum Building, in Washington, D. C., April 15, for the examination of candidates for admission to the medical corps of the army.

**WHEELER**, LEWIS H., contract surgeon, is granted leave for one month from about April 13.

**OVERTON**, Captain WINFIELD S., is granted leave for one month from about April 5.

**CROSS**, WILLIAM A., hospital steward, is relieved from further duty with the company of instruction No. 2, hospital corps, Fort McDowell, and will report at Fort McDowell for duty at the post hospital.

**GRISWOLD**, W. CHURCH, contract surgeon, is authorized to proceed to Manila and report to the president of board of medical officers for examination for appointment as assistant surgeon.

**Changes in the Medical Corps of the U. S. Navy for the week ended March 28, 1903:**

**GROVE**, W. B., passed assistant surgeon, detached from treatment at Naval Hospital, New York, and ordered to duty at Naval Dispensary, Washington, D. C.—March 23.

**PLUMMER**, R. W., passed assistant surgeon, detached from Navy Yard, New York, and granted sick leave for three months—March 25.

**MURPHY**, J. F., assistant surgeon, detached from the Glacier and ordered to the Monocacy—March 25.

**Changes in the Public Health and Marine-Hospital Service for the week ended March 26, 1903:**

**STONER**, G. W., surgeon, to proceed to Washington, D. C., for special temporary duty—March 20, 1903.

**GODFREY**, JOHN, surgeon, department letter of November 22, 1902, granting Surgeon Godfrey extension of leave for three months, amended so that said extension shall be for two months and twenty-five days from December 13—March 18, 1903.

**MEAD**, F. W., surgeon, granted leave of absence for five days from April 13—March 25, 1903.

**SMITH**, A. C., passed assistant surgeon, granted leave of absence for fifteen days from April 8—March 25, 1903.

**ROBINSON**, D. E., assistant surgeon, granted leave of absence for two months and fifteen days from April 1—March 17, 1903.

**SCHERESCHESKY**, J. W., assistant surgeon, granted leave of absence for one day—March 23, 1903.

**GIBSON**, R. H., pharmacist, department letter of March 18, 1903, granting leave of absence to Pharmacist R. H. Gibson, amended so that leave shall be for eight days from March 9—March 20, 1903.

**STIER**, CARL, pharmacist, granted leave of absence for one day, March 24, 1903, under paragraph 210 of the regulations.

## Promotion.

**FOSTER**, M. H., assistant surgeon, commissioned as passed assistant surgeon, to rank as such from March 11, 1903.

VOL. V, No. 15.

APRIL 11, 1903.

\$5.00 YEARLY.

**Public Health and Cleanliness.**—Her child was ill and the mother had sought the aid of a nearby hospital. A physical examination was necessary, but the mysteries of the child's garments were incomprehensible to the physician. To his request that the mother undress the child came the answer, "Aber, mein Gott, I have sewed it in for de winter." Thrift, not cleanliness, was uppermost in that mother's mind. We little guess what a large influence the so-called "filth-diseases" have on the public health, nor the amount of illness directly or indirectly caused by lack of personal cleanliness. Could the community be kept clean, the physician would be saved many a bad half hour and the deathrate would be lowered. Could the necessity for such notices as "Patients must be clean or they cannot be treated" be eliminated from the dispensary there would result a material saving to our hospitals.

Were it possible to enforce personal cleanliness in the community the bath would in very many cases supersede the need for the medicine bottle. It is at all events the duty of every city to provide the opportunity for cleanliness to its people. From an economic standpoint it pays to keep the citizen well. One of the best illustrations of this truth known to us is the revolution being made in the health, personal appearance, and cleanliness of children by means of the employment of thirty-one trained nurses employed by the New York Board of Health to visit the public schools of the city. Trachoma, pediculosis, filthiness, etc., are disappearing among the school children, and secondary education of the parents in these matters is not a small part of this noble reform.

**Quack Consumption-Cure Companies.**—With the professional crusade against pulmonary tuberculosis there have arisen a number of fraudulent "cures" which should receive the attention of city and State governments. Medical societies should institute suits and "clean the rascals out" wherever it is legally possible to prosecute them, for hardly any crime is more heinous than to defraud the ignorant poor as these scoundrels are doing. There is said to be at least a dozen of these large "absolute consumption-cure" concerns in New York City. Every trick of the quack scamp is skillfully carried out to deceive the unwary, and as money is easily got by him it is freely spent to fleece the unfortunates. The worst feature of many of

these companies is a skilful use of the names of eminent physicians and scientists in such a way that it becomes difficult to trap the rogues and the cheap newspapers become *particeps criminis* by publishing their shameless advertisements. We have previously published an account of the exposure of one advertiser who deliberately adopts and trades upon the name of a great authority upon tuberculosis. The New York Charity Organization Society through a committee is seeking to restrict the operations of these nefarious firms and should receive the help of the profession and of all good citizens. So far this committee is able only to advise. It has printed for general circulation resolutions it recently adopted, declaring that there is no special medicine for pulmonary tuberculosis known; that the so-called cures and specifics, and special methods of treatment widely advertised in the daily papers, are in the opinion of the committee without special value. These "cures," the committee proceeds, "do not at all justify the extravagant claim made for them, and serve chiefly to enrich the promoters at the expense of the poor and frequently ignorant or credulous consumptives." No cure, it is the committee's opinion, can be expected from any kind of medicine or method except the regularly accepted treatment, which relies mainly upon pure air and nourishing food. Physicians may aid by disseminating the circular and by asking the newspapers they take to warn their readers against the wretches.

**Compulsory Education of Defectives.**—In the *Bulletin of Iowa Institutions* Mr. Henry W. Rothert, Superintendent of the Iowa School for the Deaf, makes a wise plea that the law as to compulsory education of the normal child should be extended so as include the defective. It is just as incumbent upon the State to educate the deaf and dumb child, even more so we should say, as the hearing and speaking child. At present the Iowa law makes the education of defective children permissive. Mr. Rothert would change the "is entitled to receive the physical and mental training and care of this institution at the expense of the State" so that it shall read "must receive, etc." The Oregon law, which should serve as a model, reads as follows:

Whereas, the State has provided an institution for the free instruction of all resident deaf-mute children of lawful school age, every parent, guardian or person having control of any

child or children afflicted with deafness shall be required, under the penalties hereinafter specified, to send such child or children to said institution for a period of not less than six (6) months of each year between the ages of 8 and 16 years, unless children be taught in a private school, etc., etc.

The same logic would also extend the provision to the blind, the weak-minded, young criminals, etc. As a measure of prevention of dependency if not for humanitarian reasons the suggestion is excellent.

**The Prison Physician.**—The *Bulletin of Iowa Institutions* always contains something to interest and instruct. The article in the latest issue by Dr. Druet, the physician to the Anamosa Penitentiary, is illustrative. One would suppose that practice among convicts would be very different from that among patients of the outside world, but Dr. Druet finds it much the same, "or even more so," one might add. An instance of difference shows that honor is not absent, even in prisons. The doctor may have to hunt up his patients and "force them to come in," for some men will not report at sick call, although really ill, because they are ashamed of the make-believes. The man that never pays his bill is the most difficult man for the physician to please, and it is so in prison practice says Dr. Druet, meaning that these patients shirk work and their duties to the State while demanding much of the physician and other officers. Owing to the perfect control of the patients, the treatment of inebriates and narcomaniacs is very successful—a hint to the Keeleyites! There is a pathetic side to the fact that there are convicts who, unable to pay for the services of a physician outside, have committed crimes in order to be sentenced to the penitentiary where they could secure good medical treatment gratis. This sounds strange to the physician of our crowded city dispensaries. Dr. Druet says:

One will feign sickness to avoid work; another will say that he only wants a little treatment for some slight ailment when he is a very sick man. The one is passed without treatment or excuse from work; the other, against his protest, is passed to the hospital for treatment. We have here the chronic medicine taker the same as in our private practice. They are hypochondriacal, and imagine that they have all kinds of ailments, and are not content unless they are constantly taking some kind of medicine. This class must be treated according to the peculiarities of each case. Others are refused treatment and the reason for nontreatment explained to them. Their pleadings for medicine are limited only by their terms of sentence.

We had not supposed that the patent medicine syndicates would follow their victims beyond prison walls, but—

Again we have the chronic patent medicine taker. He has dosed himself all of his life, and cannot, or will not understand why the State will not furnish him with everything that he imagines he wants.

We hesitate to offend our surgical confreres, but we are compelled to quote again:

We are frequently asked by the inmates to perform surgical operations that are not required. Some patients have a morbid desire for a surgical operation, and especially when it can be had without expense. When this class comes in contact with a prison physician who rushes into surgery at every opportunity, we have our surgical ward unnecessarily full, and we also have results that are an injury to the patient and a discredit to the surgeon.

And lastly, the prison physician must as well as we feel "the marble-hearted fiend, ingratitude."

We have cases where a man comes to us with a diseased body, the result of a life of dissipation and crime. If he becomes an inmate of the prison hospital, and after months of careful treatment by the prison physician and unremitting care by the hospital steward, with his every want supplied in the liberal manner made possible by the generous supplies furnished by the Board of Control of State Institutions, should this man answer the last summons we find that some discharged convict or some friend of the deceased, after being refused space by a score of respectable editors, finds some irresponsible member of the press, ever eager for a sensational article, who comes out in large head lines and heralds to the world "Another Scandal in Connection with Our State Institutions," in which "ignorance," "cruelty," and "neglect" are charged.

**The Proposed Leper Colony in the Philippines.**—From the report of the Secretary of the Interior to the Philippine Commission we learn that there are three leper hospitals in the Philippines, situated at Manila, Palestina, and Cebu, respectively. During the past year a beginning has been made toward taking a leper census of the islands. This census is already quite complete for many of the provinces, and its results lead to the conclusion that the estimate of those persons who have heretofore expressed the belief that there were 30,000 lepers in these islands is wide of the mark. It is believed that the total number will not exceed 10,000, and it may fall considerably below this figure.

The desirability of establishing a colony where persons in the early stages of leprosy can have their homes, cultivate the soil, and in general lead a free, out-of-door life, instead of being practically imprisoned and compelled to pass their days in company with fellow-unfortunates in the last stages of this horrible disease, has long been appreciated by both military and civil authorities. Efforts were made by the military government to find an island suitable for the establishment of a leper colony, and a military board reported favorably on the island of Cagayan de Joló after somewhat cursorily examining it. As satisfactory information was not given concerning the supply of drinking water on this island, and as the accuracy of the board's report that there were but two or three hundred inhabitants had been seriously questioned, a committee, consisting of the Commissioner of Public Health, the Sanitary Engineer, and the Secretary of the Interior, was appointed to reexamine the island, and if it did not prove satisfactory to search for a more suitable one. This committee reported adversely on the island of Cagayan de Joló, on account of the entire lack of a favorably situated supply of drinking water, the absence of any port, and the presence in the island of some 3,000 Moros, whose removal would have been both difficult and expensive, and recommended the island of Culion, in the Calamianes group, on account of its healthful climate, rich soil, extensive cattle ranges, abundant water supply, good harbors, and small population. The present inhabitants are so few and have so little property that their removal, if deemed necessary, can be effected with little difficulty and at small expense.

An appropriation of \$50,000 was included in Act No. 389 for the purpose of erecting a warehouse on Halsey

Bay, building a road to the proposed site of the colony, and erecting superintendent's house, hospital, and 100 separate dwellings for lepers, the hospital and dwellings to be of bamboo and nipa palm, which the island of Culion produces in abundance. Unfortunately the cholera epidemic prevented the prosecution of this work, and the appropriation lapsed at the end of the fiscal year. A new appropriation was made in October, and it is hoped that the colony may be established and the inmates of the San Lazaro, Palestina, and Cebu lazarettos transferred to it during the coming dry season.

**The Nurse Corps of the Army.**—A brief account by Dr. McGee of the nurse corps of the army as it exists now has recently been published in the *Journal of the Association of Military Surgeons of the United States*. A previous article described the conditions attending the appointment of trained women nurses for army duty, which began in May, 1898, and culminated in September, when about 1,200 were employed. Between then and the present time they have served in the United States, Cuba, Porto Rico, Hawaii, Japan, the Philippines, and even in the Chinese campaign. The number is now fixed at 100 on active duty, with a small body of "reserves" who have seen active service and are ready to answer future calls. Trained nurses are permanently stationed at the army hospital at San Francisco, at the one for tuberculosis at Ft. Bayard, New Mexico, and at the largest hospitals in the Philippines. They are temporarily sent to any post where they may be needed. They serve under a section of the army reorganization law, framed in 1900, which provided that the medical department should consist of specified medical officers, of the enlisted men of the hospital corps, and of "the nurse corps (female)." A superintendent is stationed in the surgeon-general's office, and a chief nurse is at each of the hospitals where nurses are serving. Recent regulations provide for an examination in nursing, cooking, and allied subjects before promotion from the grade of nurse to that of chief nurse. Women are employed with marked success as teachers of nursing and cooking, in the two schools maintained to give brief preliminary instruction to the hospital corps recruits. Dr. McGee urges that in future the nurse corps be more largely utilized in giving systematic ward training to fit the hospital corps men for their duties in the smaller hospitals, where they have no trained supervision. She also recommends the gradual formation of a large corps of reserves who have received some postgraduate military training.

**The Physician and the Murdered Baby.**—An interesting discussion is going on in the columns of our contemporary, the *Medical World*, as to the duty of the medical attendant who is sure that the parents have murdered the child he has helped to bring into the world. The conditions of the problem are that the physician could not legally prove the fact of murder, but he has no doubt of the fact in his own mind. The letters of physicians published show that the occurrence is far more common than one would at first be inclined to believe. One of these asks as to the birth-certificate and

the death-certificate. But the editor rightly answers that in many States such returns are not required by law, and this fact operates to make the physician postpone any inquiry. But where there is a law to encourage the indignant obstetrician, the correspondents are unanimous that compliance with the law should be demanded, whatever be the shame of the parents and the cost to the doctor. If he violates the law he also becomes a criminal. Where no law exists he should strive to secure one by all the means in his power. In our issue of the twenty-eighth we published an account of the methods in vogue in Chicago of caring for mothers and their illegitimate children, and in our own news columns today we notice the existence of institutions in Philadelphia and Washington with a similar purpose in view. The physician in such cases, by tact and good-will, can usually succeed in preventing murder and suffering through an appeal to the better nature, and by pointing out the means of avoiding crime.

**The American Red Cross in Need of Reorganization.**—The newspapers have contained a good deal of late concerning the difficulties and mismanagement of the Red Cross Society. There have long been more than whispers of scandals in connection with the direction of the Society's business affairs. The Spanish-American war is still fresh in memory. Only angels, said a cynic, can be trusted with the spending of much money furnished by other people and no accounting demanded. The contest in the Society seems to be caused by a desire to retire Miss Barton, and to "thoroughly reorganize the Society and provide for a careful and business administration of its finances." Several private individuals offered to provide the means to pension the permanent president, but she would not be so disposed of. Then Bishop Potter, Mr. Ogden, and other prominent men appealed to the minority in the cause of reorganization. The decision reached is that the appeal must be taken for settlement to the annual international meeting of the general organization at Geneva. The appellants are certainly correct in saying that without reorganization, etc., the confidence of the American public will fail.

**"Optometry" in Pennsylvania.**—A bill "to define and regulate the practice of optometry in Pennsylvania" is before the Legislature. It should have been entitled "An act to enable opticians to practise medicine and to humbug the public as to diseases of the eye." Good opticians will have nothing to do with it and do not want their business "defined or regulated" in any such ways; they do not wish to "examine eyes free." Physicians, of course, are wholly opposed to permitting men ignorant of medicine to treat ocular diseases or to encouraging the dangerous delusion that measuring the eye optometrically or "ophthalmotricianly" has much to do with the treatment of ametropia, heterophoria, or other pathologic conditions of the organ of vision. These facts will of course encourage a certain class of legislators to help the opticians and ophthalmotricians, but they will also encourage sensible men to oppose all such debasement of the practice of medicine.

Of "Chiro" and "Chiropractics."—A kind correspondent sends us the circulars of a new sect of healers which has arisen, or is said to have arisen, in California, although the faculty, consisting of one man, says he was born near Toronto, and there "listened to his mother's sweet lull-a-by." The discoverer has found out even the nerve of smallpox and of pneumonia and can cure cataract "without surgery." The funniest part of the circular is a list of all the outrageous words that could be gleaned from the oldest medical dictionaries concerning bone-diseases, all misspelled or so used as to show that the bone-collector has no idea even of their meaning. We gather that the osteopaths must look to their laurels and incomes, and we suppose our legislative halls may soon be invaded by committees of Chiropractics demanding that the outrage of medical legislation against this greatest of all discoveries shall cease. We cannot say in what way Chiro differs from Osteopathy, because to learn Chiro (or *chico*, as it is sometimes spelled) "takes four months of close application" and we have given the subject but five minutes. It seems to be a more morbid teratologic product of that sect if it is capable of inbreeding. *Chropractic* (another spelling!) is defined as "common sense," and is said to "simplify the treatment of the most painful and prostrating forms of disease by adjusting the displaced bones which are the cause." The relation of Chiropractic to Osteopathy and of this to the bone-setters, and of these to something else, and of this to medicine, reminds one of the old saw:

Great fleas have little fleas upon their backs to bite 'em,  
And little fleas have lesser fleas, and so *ad infinitum*.  
And the great fleas themselves, in turn, have greater fleas to go on,

While these again have greater still, and greater still, and so on.

Of course De Morgan meant no pun or disrespect by using the word *still*. The father of Chiropractic is himself a poet also and asks his audience (60 patients a day):

Why take drugs strange  
To cure disease?  
Why not adjust the frame  
And put at ease  
The feeling nerves  
Which run the human mills,  
When Chiropractic serves  
To cure all ills?

The invariable fee for teaching Chiro in four months (entitling the student to all future discoveries) is \$500. Even medics, as we are called, may learn the science and art in four months.

**Consumption of Alcoholic Beverages 50 Years Ago as Compared With the Present Time.**—Figures given in the Statistical Abstract of the United States for 1902 enable us to make interesting comparisons of the consumption of liquors at the present time as compared with 1850, when the first report was compiled. At that time the average per capita consumption of wines and liquors was 4.08 gallons as compared with 19.48 gallons at the present. Distilled spirits—whisky and brandy—were then consumed to the extent of 2.23 gallons as against 1.36 gallons in 1902, and the malt liquors were then consumed to the extent of 1.58 gallons as against 17.49 at the present time. In 1850 the per capita consumption of wines was .27 of a gallon, while in 1902 it was .63. The importation of wines in the United States has materially decreased in the past 10 years, there being a falling off in value from \$10,205,353 in 1893 to \$8,921,138. The importation of champagnes shows a corresponding decrease. Illinois takes the lead as the whisky-making State of the Union, surpassing Kentucky, the figures being for the last year, Illinois, 39,142,876 gallons of distilled spirits; and for Kentucky, which ranks second, 26,018,166 gallons. New York State leads in the manufacture of beer.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**Navy Needs Young Surgeons.**—Vacancies for young surgeons in the United States Navy still remain unfilled at the present time, there still being 27 such vacancies unoccupied. It is stated that Surgeon-General Rixey in various addresses and visits throughout the country is calling the attention of young medical men to the opportunities for valuable service in the United States Navy. Applicants must be between 21 and 30 years of age, physically sound, have a good high school education, and be master of their profession to a degree that will insure a successful career in civil life.

**Doctors Should be Cheerful and Optimistic.**—The *Cosmopolitan* says the longevity of the medical man is materially less than that of workers of other professions. Only those with a sound physique, other things being equal, can win in a struggle for success. The sick look with confidence to the well. They demand the hearty dogmatism that comes from the overflowing of animal spirits. They enjoy the cheerful optimism that comes from a good digestion. They lean upon the doctor in their weakness, and yield willing obedience to his kindly influence. Much of the power possessed for good may be outside of pills or potions, correct theories or sound deductions.

**To Fumigate at Sea.**—Plans have been presented by the general manager of the Mexican-American Steamship Company to the Surgeon-General of the Public Health and Marine-Hospital Service which provide for the establishment of a floating fumigating plant, the time required for fumigating vessels while in transit being deducted from the five days they are required to remain in quarantine before being allowed to come up to the city of New Orleans. The adoption of the scheme would, it is asserted, greatly facilitate the intercourse between New Orleans and Central and South American ports. This is of particular consequence just now since the Chinese Commercial Company has adopted a short route to New Orleans by steamers sailing to Manzanillo instead of to San Francisco as heretofore.—[*New York Medical Journal*.]

**Habitual Criminals.**—It is asserted that the Iowa Legislature has passed a law under which a person twice convicted for crime in any city or borough of the United States shall be deemed a habitual criminal and sentenced to 25 years. A bill was also recently introduced into the Mississippi Legislature providing for life sentences for habitual criminals on a third conviction for felony. The two previous convictions may have taken place anywhere within the limits of the United States. This law provides that such life prisoners may have the benefit of parole under such rules and regulations as the board of parole may impose. Superintendent Collins, of New York State, has made a recommendation in the same direction, claiming that the great majority of the professional criminals in the State criminal institutions have served three previous terms for felony, and that for these there is no hope for reform. On the other hand, the Ohio Legislature last year repealed its habitual criminal law.

**An Engineer's Idea of Typhoid Fever Prophylaxis.**—Can a plant lay eggs? "The typhoid bug," according to an editorial in the *Engineering News*, does, and a water meter's mechanism would squash it, and thus prevent propagation of the dread disease. According to the editorial in question, fault is found with the assumption on the part of some that the water meter affords a breeding place for typhoid germs. A reporter of the *Union Advertiser* is said to have visited the office of the Commissioner of Public Works and examined a couple of meters that the point might be settled. He is reported as having said: "It was possible to see at once that there was no chance for fever to generate in the meters." This accords with the editorial previously alluded to, which further says: "Those whose knowledge of the habits of the 'typhoid bug' make them fear that it will pause to lay its eggs while passing through the water meters should remember the like probabilities that the 'bug' would be crushed in the water meter's mechanism and squashed into innocuous desuetude."

**A Department of Health?**—The following appeared in a recent issue of the *Louisville Courier-Journal*:

The appointment of Dr. J. N. McCormack, secretary of the State Board of Health, as national organizer of the American Medical Association is considered an evidence of the strength of that organization, which has grown with wonderful rapidity since the inauguration of the movement for a better and a more solid association of the physicians of the United States, begun two years ago under the presidency of Dr. Charles A. L. Reed, of Cincinnati. Dr. McCormack will go to Texas next month to organize a State association and county associations in that State, and will follow up this work in other western States. It is the purpose of the association to form a strong organization of all the legalized practising physicians of the country, which will have influence enough to secure needed sanitary legislation in the States and in Congress. An ultimate purpose is to have Congress establish a department of health, the secretary of which will be a Cabinet officer, instead of having the national health department under the charge of a bureau of the Treasury Department, the Marine Hospital Service.

It may be a little early after the creation of the Department of Commerce and Labor to enter upon a movement for the

creation of still another department of the government, but as health is a great proposition we may expect this movement to attract attention and find some friends.—[*Washington Star.*]

#### EASTERN STATES.

**New Hospital for Greenwich, Connecticut.**—At a mass meeting held at the instance of the Greenwich Medical Society March 27, it was announced that the sum of \$30,000 had already been subscribed of the \$100,000 necessary to construct a new hospital. It is confidently believed by those having the project in charge that the \$100,000 will be raised without difficulty.

**Hospital for Infectious Diseases in Baltimore.**—The tract of land of 143 acres adjoining Bay View which has been acquired by the municipality of Baltimore is to be utilized for the erection of detached buildings for the care of tuberculous patients and a detention home for neglected colored children, and later it has been decided to erect a hospital for the treatment of infectious diseases, of which Baltimore is said to be sadly in need.

**Manhattan Eye and Ear Hospital to be Built Anew.**—It has been announced that the Manhattan Eye and Ear Hospital has chosen a new site, and will erect new and commodious buildings to cost not less than \$200,000. The present site on Park avenue and Forty-first street will be abandoned, and a less valuable location will be chosen for the new structure. The hospital now has an endowment of \$171,000, and an additional sum of \$200,000 is needed. One of the directors has offered \$50,000 of this sum provided the other \$150,000 shall be raised by January 1, 1904. The great increase in eye and ear diseases, particularly the latter, in New York within the past year has caused such an overcrowding of the Manhattan Eye and Ear Hospital as practically to force the abandonment of the old institution and erection of more commodious quarters.

**Sargent's Strength Test.**—Dr. Dudley Allen Sargent, director of the Hemenway Gymnasium at Harvard, has devised a system of a universal test of strength and endurance of the human body which is likely to cause a revolution in the present plans of physical exercises. It is said that the author will issue an illustrated pamphlet bearing upon his new method. That the method probably possesses merit is evidenced by the fact that it was considered authoritative in the appointment of men in the various fields of athletics at Harvard during the past season. Generally speaking, the unit of measurement is obtained by multiplying a man's weight by his height in inches, thus showing the distance which his muscles lift a given number of pounds, and dividing the result by 12, so as to reduce it to foot-pounds. It is specified that the series of exercises, of which there are six, so devised that every muscle in the body shall be brought into play, shall occupy 30 minutes in every case. It is evident, then, that the number of times a person can perform the exercises in the half-hour indicates at once his speed, endurance and strength. Each exercise is allotted a certain percent in a fixed scale to equalize the natural differences between the various muscles of the body, and by means of a simple chart it is possible to keep a record of the improvement and development from week to week or month to month.

#### NEW YORK.

**New Nurses' Home for Presbyterian Hospital.**—Plans have been filed for a six-story building for nurses of the New York City Presbyterian Hospital. It is estimated that the cost will be about \$300,000.

**Registration of Nurses.**—A second bill which provides for the registration of nurses in New York has been introduced into the New York Legislature. This provides that nurses may register and practise in the State merely by making affidavit to be filed by the Secretary giving the history of their training and experience. As this bill raises no standard of experience and efficiency it is strongly opposed by the representatives of the Nurses' Association and by the leading training schools.

**Camp for the Treatment of Tuberculosis.**—Dr. Lederle, of the New York Health Department, has sent a letter to Mayor Low, urging the appropriation of \$35,000 for the establishment of a sanatorium for the treatment of tuberculosis on the tent and ducker plan. It is proposed to erect this camp on a tract of 20 acres in Orange county, which has been offered to the city for two years, rent free. Dr. Lederle states that with the \$35,000 he could provide a camp for 60 patients from May 1 to December 31 next. During the year 1902, 8,883 persons died in New York City from lung diseases, and in 1901, 8,135.

**Baby Convalescents.**—The fact that many babies after being discharged from the New York Babies' Hospital as cured or improved have been returned again at a later date for treatment through not receiving the proper care in their homes has led to the appointment of a visiting physician whose duty it is to follow up the serious cases. This physician goes to the home

and instructs the mother in the proper care to be given the infant, giving directions as to the preparation of food, bathing the child, ventilation and sanitation of the home, especially of sleeping-rooms, and if it is necessary he prescribes for the child.

**Gift to Long Island College Hospital.**—Through the generosity of J. Rogers Maxwell Long Island College Hospital is to have a new building. The donor has offered to build at his own expense the two central sections of the proposed structures as a memorial to his brother, Henry W. Maxwell, who before his death was a member of the board of the Long Island College Hospital and engaged in a plan for its reconstruction. A new wing will probably be constructed by the friends of Dr. Alexander J. C. Skene, and an appeal to the public will be made for the construction of an additional wing. George, Royal, and Charles Peabody have offered to equip an operating amphitheater which will seat 250 students. The whole structure will cost in the neighborhood of \$1,000,000 and when erected will be one of the best equipped hospitals in the country.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**University of Pennsylvania to Have Hospital Improvements.**—An appropriation of \$175,000 has been made by the Pennsylvania Legislature for the purpose of making various additions to the hospital of the University of Pennsylvania. An x-ray plant and a sterilization building will be constructed.

**Allegheny General Hospital.**—The Board of Directors of the Allegheny General Hospital has awarded the contract for the new building of that institution. It is to occupy the site of the old building on Stockton avenue. It will be six stories high in front, a three-story building in the rear. It is asserted that the foundations are now in place, and that the award of the contract assure the completion of the new structure by June 1, 1904.

**Pure Food Legislation.**—A bill which has recently become operative in New Jersey provides that no person shall distribute or sell, or offer to distribute or sell, or have in his possession with intent to distribute or sell, any milk which has been produced by cows that have not been daily supplied with pure and wholesome water; and no person shall wash or attempt to cleanse any can or utensil used for handling or transporting milk in water which he shall have reason to believe is polluted, contaminated or impure. A penalty of \$50 is imposed for each violation.

**State Board of Barbers.**—A bill creating a State Board of Barbers in Pennsylvania has passed the Pennsylvania Legislature and is now ready for the signature of the Governor. It creates a State board of two master and three journeymen barbers who shall formulate sanitary rules and regulations for the government of barbers. Every barber at present engaged in his occupation in first, second, and third class cities, and in boroughs of 10,000 population must pay a license fee of \$1 to the secretary of the board. Barbers throughout the State are almost unanimous in the opinion that the bill is commendable. It is believed that it will tend to drive out of business the cheap barber and his usually inexperienced workmen. Every shop must have up-to-date sanitary appliances.

#### SOUTHERN STATES.

**North Carolina Nurses' Bill.**—A bill which has passed the North Carolina Legislature requires that before a nurse can practise her vocation she must have had special training for at least two years, or must have a statement signed by three reputable physicians that she has actually engaged in nursing for a period of two years and in their opinion is qualified for such work. After January, 1904, a State board of examiners of nurses is provided for, said board to consist of five members composed of two physicians and three registered nurses to be elected by the Medical Society of the State of North Carolina and the North Carolina State Nurses' Association. The duty of the board shall consist in holding examinations at least once a year of all applicants who have pursued the necessary course and have the proper credentials as to moral character, etc. The board is provided with power to revoke any license which has been granted to a nurse in the State upon sufficient cause. An anomalous section of the bill reads as follows: "Nothing in this act shall in any manner whatever curtail or abridge the right and privilege of any person to pursue the vocation of a nurse whether trained or untrained, registered or unregistered."

#### WESTERN STATES.

**Plea for the Establishment of an Institution for Epileptics.**—The Indiana State Board of Charities in its annual report makes a plea for the establishment of a separate institution for epileptics. The statement is made that there are now in the State hospitals for the insane 402 epileptics; in the school for feeble-minded youth, 265; and in the county poor

asylums 293, making a grand total of 960. Of these 485 are insane, 410 feeble-minded, and 65 who have no marked mental deficiency.

**Street Car Colds.**—At a recent meeting of the St. Louis Medical Society resolutions were adopted declaring that as many colds and diseases of the respiratory tract are caused by prolonged riding in badly ventilated, draughty, and crowded cars, street car officials should be requested to take measures for obtaining a more uniform and equable temperature in their cars, and better protection against draughts. Cars making long runs with a temperature under 60° are condemned as dangerous and a menace to health.

**Mentally Weak Pupils to be Segregated.**—The Board of Education in Chicago is contemplating segregating mentally deficient pupils from those of the normal standard. A striking illustration of the deficiency of the present system emanated from the fact that a citizen was compelled to remove his deaf and dumb child from a school for the deaf because of her mental deficiency. Since there is no provision in the city for the instruction of such deficient children the board is seriously considering the above proposition.

**Charities in Cincinnati.**—A recent investigation of the contributions and public charities in Cincinnati showed that 24 institutions today receive about \$13,000 less from private subscriptions than 10 institutions received in 1870 that were doing the same kind of work. During this period the population in Cincinnati has increased about 50%. An examination of the church expenditure shows that the giving has not been diverted in that direction, for the total amount spent by churches had increased but 39%, while the increase in population had exceeded it by 11%.

**Contagious Disease Hospital for Children.**—It has been announced to the League of Cook county, says the Bulletin of the Health Department of Chicago, that two subscriptions, amounting to \$175,000, have been pledged for the support of the Children's Hospital Society of Chicago. It is believed that the sentiment raised by the "Thanksgiving story of the friendless cats and dogs" feasting while a grief-stricken father was vainly seeking a hospital for his 2-year-old daughter, who died in his arms from diphtheria, as told in the Bulletin of Health for November 29, is responsible in a large measure for the generous contributions which have been received to provide a children's hospital for contagious diseases in Chicago.

**Placing-out of Dependent Children.**—A bill which has been passed by the South Dakota Legislature prohibits the placing-out of dependent children from other States unless adequate supervision of the child's welfare is provided for. The society desiring to place a child must file a bond for \$2,000 with the county treasurer, "conditioned that such child has no contagious or incurable disease, has no deformity, is not of feeble mind or vicious character, and that such association or society will promptly receive and remove from the State such child if it becomes a public charge within a period of five years. Violation of this act on the part of the society or the persons receiving the child will be deemed a misdemeanor."

**Peculiar Method of Interment.**—The Michigan Bulletin of Vital Statistics for February, 1903, is authority for the following: One of the latest difficulties in the way of registration brought to the attention of this department is found in the complaint filed by the registrar of an upper peninsular township. He writes: "Quite a colony of Finlanders have immigrated to our land, and they seldom have a physician. When there is a death the corpse is put into a grave and left uncovered (save a few loose boards thrown over the top of the grave) for as long as two or three weeks, until some minister immigrates from the copper country." The registrar was uncertain as to whether the original deposition of the body in the ground or its final covering with earth attended with religious ceremonies was to be considered as the "interment." The department instructed him that the placing of the body in the ground, although the covering was not complete, was to be considered "interment" under the law and that a permit must be obtained in advance. The department also called the attention of the State Board of Health to the possible sanitary consequences resulting from such imperfect burial.

**Legal Restrictions of the Marriage of Defectives.**—The House of Representatives of the Kansas Legislature has passed the following bill:

Section 1. No woman under the age of 45 years, or man of any age, except he marry a woman over the age of 45 years, either of whom is epileptic, imbecile, feeble-minded, or afflicted with insanity, shall hereafter intermarry or marry any other person within this State. It is also hereby made unlawful for any person to marry any such feeble-minded, imbecile, or epileptic person or any one afflicted with insanity, or any person who has ever been so afflicted. Children born after a parent was insane shall not marry except under the above named conditions.

Sec. 2. No officer authorized by law to issue marriage licenses in this State shall hereafter issue such a license to any persons either of whom is afflicted with any of the diseases mentioned in Section 1 of

this act, knowing them to be so afflicted, unless the female party to such marriage is over the age of 45 years.

Sec. 3. No clergyman or officer authorized by law to solemnize marriages within this State shall hereafter perform a marriage ceremony, uniting persons in matrimony, either of whom is afflicted with epilepsy, imbecility, feeble-mindedness, or insanity, knowing them to be so afflicted, unless the female party to such marriage is over the age of 45 years.

Sec. 4. Any person violating any of the provisions of this act shall on conviction thereof be punished by a fine of not more than \$1,000 or by imprisonment in the State's prison for not more than three years, or by both such fine and imprisonment.

**Notifiable and Nonnotifiable Diseases.**—The Bulletin of the Health Department of Chicago for March 28 contains an interesting comparison of the deaths in London and Chicago from notifiable and nonnotifiable diseases. Seven specified causes of death from the contagious or infective diseases are included in the London table: Smallpox, scarlet fever, diphtheria, typhoid fever, the diarrheal diseases, measles and whoopingcough. Under the law all cases of the first four diseases must be notified or reported forthwith to the medical officer of health, and ample hospital provision is made for their isolation and treatment. The diarrheal diseases, measles and whoopingcough are not required to be reported or removed to hospital. Excluding smallpox from the comparison, the tables show the following remarkable results in the deaths from the notifiable and from the nonnotifiable diseases:

NOTIFIABLE DISEASES.

	London		Chicago	
	Total deaths.	Rate per 100,000.	Total deaths.	Rate per 100,000.
Scarlet fever.....	563	12.3	445	24.4
Diphtheria.....	1,181	25.7	596	32.7
Typhoid fever.....	590	12.9	801	41.0

The average mortality, in proportion to population, of these three diseases in Chicago—where there is no special hospital provision for their reception and treatment—is almost exactly double their average mortality in London, where every case must be reported, and where adequate hospital facilities are provided—the figures being 16.9 in London and 33.3 in Chicago in each 100,000 of population. On the other hand the mortality from the three nonnotifiable or optionally notifiable diseases is lower in Chicago than in London.

NONNOTIFIABLE DISEASES.

	London		Chicago	
	Total deaths.	Rate per 100,000.	Total deaths.	Rate per 100,000.
Measles.....	2,361	51.5	123	6.7
Whoopingcough.....	1,880	41.0	266	14.6
Diarrheal.....	2,504	54.7	713	39.1

The average mortality of this group is 49 per 100,000 in London and only 20 in Chicago, or nearly 2½ times greater in the former city. There is no adequate provision in Chicago for any of the contagious and infectious diseases save smallpox and the smallpox record since the isolation hospital was opened is more than satisfactory. There were but 5 deaths from the disease in Chicago last year, while there were 1,314 in London. In proportion to population these figures give 23.7 for London and 0.27 for Chicago in every 100,000.

CANADA.

**Hygienic Institute for Western University, London, Ont.**—The *Canadian Journal of Medicine and Surgery* for April asserts that a deputation recently waited on the Ontario Cabinet at Toronto, presenting a request that an institute of hygiene be established in London in connection with the Western University. The government has replied that they cannot at present accede to their application. The object of the university is to have the government build and maintain an institute equipped with laboratories for the purpose of providing scientific facilities for the prevention and treatment of infectious and epidemic diseases. The petitioners assert that something is due the western section of the province in view of the assistance granted Toronto and Queen's Universities; they will prosecute their application at a future date.

**Growth of Hospitals in Ontario.**—In 1881 there were 11 hospitals in Ontario; in 1890 there were 21, and in 1901 there were 53. During the last year several new hospitals have been built. The cost per patient daily in 1881 was 55 cents. In 1890 it had risen to 71 cents, while in 1902 it had risen to 90 cents. Nearly every good-sized town has now a hospital, and several small cities have more than one hospital. In 1881 there was one general hospital in Toronto, whereas at present there are 4, and a number of special and private hospitals. The cost has increased from 55 cents a day in 1881 to 90 cents in 1902, or an increase of 64%. Thus while the cost has greatly increased, the grant made by the government for the aid of charity cases has steadily declined. It is now only one-half of what it was some years ago. The total amount paid out last year by the hospitals in Ontario for the maintenance of these hospitals was about \$700,000. Of this sum the Ontario Government contributed \$110,000. The remainder came from municipal grants, the payment of pay-patients and donations.—[*Canada Lancet*.]

## FOREIGN NEWS AND NOTES

## GENERAL.

**Increase in Cancer.**—A paper by Dr. C. Templeton, of Dundee, Scotland, gives a review of the history of cancer as represented in that city in the last 25 years. The author states that the deathrate from cancer has doubled in that locality. The increase is found to be greatest after 45. Though both sexes have suffered from the increase, it is more marked in the male, the actual mortality, however, is higher among women. Males die most frequently from cancer of the internal organs, while in them cancer of the mouth and upper digestive system is also much more frequent. Smoking and worry, often given as theoretic causes of cancer, are eliminated by the author.

**Ophthalmia in Egypt.**—According to the *Lancet*, a meeting was held recently in Cairo, Egypt, to discuss the disposal of Sir Edward Cassell's gift of \$200,000 for the relief of ophthalmia in that country. It was proposed to create an "Ambulatory Dispensary," which would consist of a tent in charge of an inspector and officer, appointed for a term of three years. By the adoption of such an "ambulatory dispensary," they would be enabled to travel around the provinces and give special attention to diseases of the eye without putting the patients to the inconvenience of traveling any distance to receive treatment. The idea is to have the inspector work for two months in the province and then one month in Cairo. This plan, however, is only tentative and will in all probability not be accepted, as it has many objectionable features, among which is the inability to perform properly in a tent operations upon the eye.

## GREAT BRITAIN.

**Medical Women in England.**—It is asserted that medicine as a profession for women is constantly growing in extent and popularity in London, and that medical women now holding degrees in Great Britain number more than 500.

## OBITUARIES.

**James A. Stenart**, of Baltimore, Md., March 27, aged 75. He was graduated from the University of Maryland School of Medicine in 1850. From 1850 until 1851 he was physician of the Baltimore Dispensary, and from 1851 to 1861 was assistant physician at the Maryland Hospital for the Insane. He was appointed president of the Board of Health in 1873, and his prompt action in stamping out yellow fever by deporting whole colonies of patients and those who had been exposed to infection from the city to Anne Arundel county, about twenty years ago, was commented upon by the American Public Health Association as a remarkable feat of sanitary protection. In 1889 he retired from the Health Department, and in 1894 became secretary of the Maryland State Board of Health. He was also physician to the Maryland School for the Blind, surgeon of the First Maryland Regiment, a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, the American Public Health Association, and was local inspector of the National Board of Health.

**John Wallace Collins**, near Pueblo, Col., March 20, aged 67. He was graduated from the University of Louisiana, New Orleans, in 1860. He was professor of gynecology and abdominal surgery in the Denver Medical College from 1886 to 1895 and emeritus professor since 1895. He was at one time president of the Colorado State Medical Society and was also physician and chief surgeon at the Colorado State penitentiary at Canon City.

**Russell P. Fay**, of Yonkers, N. Y., March 31, aged 39. He was graduated from the New York Homeopathic Medical College and Hospital in 1887. He organized the Yonkers Homeopathic and Maternity Hospital and was a member of its governing staff. He was also a member of the American Institute of Homeopathy and of the New York Homeopathic Society.

**Thomas Foster**, of San Francisco, Cal., April 1, aged 85. He was one of the oldest newspaper men in the country, having been connected in an editorial capacity with the Philadelphia *Public Ledger* and the *Daily Minnesotan*. He was government physician and surgeon for the Indians in Minnesota up to 1873.

**William Henry Crosse**, principal medical officer of the Royal Niger Company, died in London, Eng., February 24, aged 45. He was a recognized authority on blackwater or hemoglobinuric fever, and gave several valuable contributions on this disease to the pathological and epidemiological societies.

**Frederick L. Marcotte**, of Concordia, Kan., died at Leavenworth, Kan., March 18. He was graduated from the Chicago Medical College in 1877. He was formerly surgeon of the Missouri Pacific and Burlington and Missouri River Railways.

**Goronwy Owen**, of Mobile, Ala., March 30, aged 69. He was graduated from the University of Pennsylvania, Philadelphia, in 1857, and was professor of obstetrics and diseases of women and children in the Alabama Medical College.

**Charles B. Ferrell**, in Columbus, Ohio, March 23, aged 63. He was graduated from the Bellevue Hospital Medical College, New York, in 1873 and was a member of the Franklin County Medical Society.

**John H. Woods**, at Thomas, Okla., March 23, aged 101. He was the first probate judge of Douglas county, Kansas, and had been actively engaged in the practice of his profession for seventy-five years.

**William Eastman**, in Mineral Point, Wis., March 15, aged 70. He was graduated from the Rush Medical College, Chicago, in 1871 and was a member of the American Medical Association.

**T. G. Godshall**, at Edge Hill, Pa., April 4, aged 43. He was graduated from the Hahnemann Medical College, Philadelphia, in 1888 and was a member of the Tri-County Medical Society.

**James Shackelford**, in Maysville, Ky., March 25. He was graduated from the Jefferson Medical College, Philadelphia, in 1861 and at one time served as State Senator.

**Andrew Halliday**, in Halifax, N. S., March 10, aged 37. He was associate professor of pathology in the Halifax Medical College and bacteriologist for Nova Scotia.

**Nathaniel Oliver Cornwall**, of Portland, Conn., March 31, aged 87. He was graduated from the New York College of Physicians and Surgeons in 1846.

**Harry A. Noyes**, of Pittsfield, Mass., died at Asheville, N. C., March 24. He was graduated from the Hahnemann Medical College, Chicago, in 1891.

**William A. Howell**, in Jarvis, Ont., March 23, aged 66. He was graduated from the University of the Victoria College, Cobourg, Ont., in 1860.

**Hans M. Martin**, of Newark, Ill., died in Aurora, Ill., March 17, aged 34. He was graduated from the Rush Medical College, Chicago, in 1897.

**Cyrus E. Baker**, in Claremont, N. H., March 23, aged 67. He was graduated from the College of Physicians and Surgeons, New York, in 1862.

**James C. Burlington**, in Attica, Ind., March 15, aged 65. He was graduated from the Indiana Eclectic Medical College, Indianapolis, in 1886.

**Charles W. Dulin**, in Nevada, Mo., March 23, aged 30. He was graduated from the College of Physicians and Surgeons, Chicago, in 1895.

**August Negendank**, of Wilmington, Del., April 2, aged 80. He was graduated from the Philadelphia College of Medicine and Surgery in 1854.

**John Steifel**, in Bucyrus, Ohio, March 14, aged 78. He was graduated from the Homeopathic Medical College of Missouri, St. Louis, in 1887.

**John M. Douds**, in Beaver Falls, Pa., March 17, aged 60. He was graduated from the Homeopathic Hospital College, Cleveland, in 1881.

**Charles W. Roberts**, in Scranton, Pa., March 20, aged 55. He was graduated from the Hahnemann Medical College, Philadelphia, in 1889.

**Ross C. Kirkpatrick**, in Los Angeles, Cal., March 13, aged 60. He was graduated from the Starling Medical College, Columbus, in 1870.

**Reinhard H. Weber**, of Philadelphia, March 29, aged 59. He was graduated from the Jefferson Medical College, Philadelphia, in 1865.

**Augustus C. E. Hertel**, in San Jose, Cal., March 14. He was graduated from the Cooper Medical College, San Francisco, in 1859.

**John H. Fisher**, in Augusta, Mich., March 23, aged 69. He was graduated from the Eclectic Medical Institute, Cincinnati, in 1852.

**T. T. Oliver**, of Chicago, Ill., April 1, aged 73. He was graduated from the medical department of Victoria College, Toronto, in 1853.

**Charles Howell**, in Ann Arbor, Mich., March 20, aged 73. He was graduated from the University of Michigan, Ann Arbor, in 1861.

**Albert R. Erksine**, in Huntsville, Ala., March 24. He was graduated from the University of Pennsylvania, Philadelphia, in 1851.

**Clayton T. Hall**, of Mason, Ohio, March 11, aged 36. He was graduated from the Medical College of Ohio, Cincinnati, in 1889.

**Charles F. Parker**, in Boston, Mass., March 24. He was graduated from the University of Vermont, Burlington, in 1883.

**Rosecoe M. Parsons**, in Traer, Iowa, March 21, aged 55. He was graduated from the Chicago Homeopathic College in 1882.

**Harvey L. James**, in Shelby, N. Y., March 14, aged 46. He was graduated from the University of Buffalo, N. Y., in 1881.

**Oscar Steur**, at Washington, D. C., April 4. He was medical examiner of the American Museum of Natural History.

**J. P. Shacklett**, in Ekron, Ky., March 22. He was graduated from the Louisville Medical College in 1880.

**Walter H. Vincent**, in Orwell, Vt., March 6. He was graduated from the New York University in 1884.

**John Miller**, in Buffalo, N. Y., March 18, aged 79.

**Joseph S. Ames**, of Holden, Mass., April 1.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

THE POSSIBILITIES OF CLEAN OBSTETRIC WORK IN THE SLUMS.<sup>1</sup>

BY

W. D. WARD, M.D.,  
of Rochester, N. Y.

Ex-resident of Presbyterian Hospital of Philadelphia; Physician in Charge of Obstetric Department of the Old Philadelphia Dispensary, October, 1901, to March, 1902.

The maternal mortality in childbirth in the General Hospital of Vienna in 1846 was 11½%. In 1889, less than fifty years later, Dr. Price, in his annual report to the managers of the Preston Retreat, Philadelphia, mentioned a series of 540 deliveries without a death. Such results have been made possible, it is now well known, by antiseptics or asepsis.

The antiseptics of obstetric work as usually described in the textbooks is so complex and elaborate that it is rarely fully carried out by the ordinary practitioner in all his cases, and as a result there is still room for improvement in his records. This elaborate procedure can be greatly simplified and rendered easily attainable for all without destroying its efficiency if the motto "he doeth all things well" is remembered and practised. For antiseptics substitute cleanliness, and for chemical solutions, soap, water and a scrubbing-brush, and obstetric technic becomes very simple and easy enough for every one to practise, and to practise always. It is not enough to rinse the hands with a little soap and water, but a good-sized hand-brush is necessary, and with it the accoucheur must go over every part of his hands systematically. Don't miss cracks and crevices, but scrub them all, 15 minutes at a time; scrub well, scrub constantly. Use plenty of soap and hot water and change the water frequently. Germs are apt to collect beneath the nails, and unless the latter are kept very short and scrubbed often, they will always be found there. In this way by the use of soap, water, and a scrubbing-brush the doctor's hands can be rendered quite sterile without the use of any irritating chemicals or rubber gloves. If any one doubts this fact, and happens to be about a hospital, let him get the bacteriologist to take a culture from his hands after they have been so scrubbed and see what growth he will get.

After the hands are once clean, keep them so. You may scrub for an hour, but then, if you wipe your hands on a dirty towel that some helping friend hands you, your asepsis will be destroyed. Dirt must be avoided at all times. The day has passed when the doctor after tying and blanketing his horse could enter the house and make a vaginal examination of a woman in labor without even asking for water. If puerperal sepsis follows, such a doctor has only himself to blame, and, though he may appease his conscience and save the woman by an early cleaning out of the uterus, still he might far better have avoided the trouble entirely, for by far the most common cause of sepsis is a dirty physician's finger.

It is unquestionably an advantage to have the lying-in room as clean as possible, but, if you are called to a little back alley, and after groping your way up a pair of stairs that daylight never reaches, find a negress who indulges in a bath only once a month or semiannually, even there good results are possible if the doctor himself does his work well. But here, as in all his work, he needs the greatest patience and care, and above all a conscience. Though the case is one for which he will not get a cent, he cannot say to himself, "I am in a great hurry; I must get on to that next patient of mine; I haven't time to wait for nature to take its course; I will just put on the forceps and save the woman much suffering," but he must remember that the chances of sepsis are greatly increased by the use of forceps, especially in surroundings such as I have drawn. Unless there is a distinct indication for their use, they

should be avoided, and in the end the patient will have much more comfort and much less danger and suffering.

To repeat, the most important rule in obstetric work is cleanliness—in the first place of the physician's hands, in the second place of the woman. Ordinarily, even in "slum" work, a vaginal douche before and after labor is not necessary, but, if the patient has a recent vaginal discharge, particularly if yellow in color and profuse in quantity, not only should a bichlorid douche be given, but the vagina should be thoroughly scrubbed, for the discharge is probably gonorrhoeal in nature and there is great risk of sepsis to the mother and of an ophthalmia for the child.

A woman in the "slums" seldom has a place where she can get into a tub and take a full bath, but she can take a sponge-bath in a basin, and she can scrub the pubes and perineum thoroughly with soap and water, and this should be insisted upon. Another small detail that should never be forgotten is the enema just as labor is commencing. If, when the doctor reaches his patient, he finds that an enema has not been given, he should make it an invariable rule to see that it is given without delay, and if there is no one at hand to give it, or if the woman has no syringe, the physician should give it himself with his own syringe. This is of great importance in order to keep the woman clean, for with few exceptions, if the enema is omitted, the bowels will move as the head comes down onto the perineum, and the birth-tract will be infected with feces.

The use of a Kelly pad in labor is rather unusual, but it will be found very convenient, and helps materially to keep both the patient and the bed clean. If the left lateral position is used, the pad is placed under the left buttock, the woman lying very near to the edge of the bed, or, if the dorsal position is preferred, the procedure recommended by one of our western doctors is very useful. It consists simply in placing the patient across the bed as for a forceps application with the buttocks projecting beyond the edge and the legs of the patient resting one on each of the physician's knees. The Kelly pad is then placed under the buttocks, and it will be found that both the patient and physician are quite comfortable, and can remain in this position two or three hours if necessary, and the woman's perineum is kept clean.

After cleanliness has been procured for both doctor and patient, the next essential to good obstetrics is an accurate diagnosis of the position and presentation of the fetus. In the vast majority of cases, labor would proceed to a normal and successful termination if left entirely to itself, but occasionally there is an abnormality in the position or in the course of labor which demands the physician's interference, and sometimes this must be immediate. If an arm comes down by the head and the doctor mistakes it for a leg—a mistake not so hard to make—and makes traction upon it, he not only fails to help the woman, but he greatly increases her difficulties, for he brings the shoulder down into the pelvis and produces an impossible position, and the harder he pulls the more firm he makes the impaction, which later must be relieved and version performed before the woman can be delivered. Such a case illustrates the need of an accurate diagnosis, for then the doctor is master of the situation, he knows just what is going on, and if anything unusual happens he knows immediately what it is and how to handle it.

To discuss the different means of diagnosis is beyond the scope of this paper, but in all of them experience is a very important, if not the most important factor. When a medical student reads the description of the fetal heart sounds, he imagines he has only to put his stethoscope or his ear to the abdomen of a pregnant woman in order to hear something as distinct as the ticking of a watch. In a few cases this is a true picture and the heart sounds can be heard without difficulty, but in most cases it is not true, and the first time one listens for them probably nothing is heard. I have heard a young physician, in charge of one of the largest obstetric and gynecologic clinics in Philadelphia for over a year, say that he heard the fetal heart sounds in what turned out to be a fibroid, and I can well remember a case in which, though I had already done considerable obstetric work, I said that I heard the fetal heart sounds, but when the baby was delivered a few minutes later, it was macerated and had evidently been dead for some days,

<sup>1</sup> Presented to the Rochester Pathological Society, November 20, 1902.

The opposite mistake is even easier to make, and many a living healthy baby is delivered when the doctor fails to find the heart sounds. As the ear must be trained, so must the finger, and the student who examines his first patient usually has trouble in finding the os; and I am sure that it is a considerable time before he can differentiate between the large and small fontanelles.

I mention these facts simply to illustrate my point that experience is very important in obstetrics, as in almost everything else. In most medical schools the student, at best, has an opportunity to take care of but two or three patients, and he needs further practical experience in this branch before he begins the practice of his profession. The wise student, either during or after his medical course, will take advantage of the opportunity to do further obstetric work in the different dispensary courses. If he works for one, two, or three weeks in this way, he will find the experience obtained of more value to him than most of his courses in the medical school.

Obstetric cases are so common that few are reported except from the large maternities where thousands are delivered within a single year; but in order to give some proof of the value of the preceding remarks, I should like to report 120 cases, over 100 of which were delivered in the "slums" of Philadelphia. Some of these patients were in the poorest possible surroundings; none of them had a regular trained nurse, and many of them had absolutely no attendant except some inquisitive friend who was glad "to see how things went," but was afraid even to wash the baby. I shall not go into details of these cases, of some of which I have not the full statistics. The earliest were delivered while I was an undergraduate, and most of them I had never seen until called to the labor, so they had practically no care during pregnancy.

Of the first 35 cases I have the record of only the names, addresses, dates of delivery and results. The mothers all recovered, and none suffered from sepsis. I lost two babies, both stillborn, and one was born 40 minutes before I reached the house. In both cases, after practising artificial respiration for from half an hour to an hour, I succeeded in getting the child to breathe, but both died within two or three days of pneumonia.

Of the remaining 85 cases my records are more complete. There were 43 cases of the L. O. A. position, 17 of the R. O. P., 12 of the R. O. A., 5 of breech presentation, 1 of arm presentation, and in 8 cases the position was unknown, as the children were born before I arrived. This makes a total of 86 cases instead of 85, but the discrepancy is due to the fact that one was a case of twins. The percentage of the R. O. A. cases is exceptionally high, and I believe that some of them were probably wrongly diagnosed, as I see that many of them were among the earlier cases.

In these 85 cases there was one maternal death, three fetal deaths, and two premature and macerated fetuses were delivered. One of the three children I lost was one of the twins; it was stillborn and I could not revive it. I think the cause was pressure from the prolonged labor, for the mother was a primipara, and finally forceps had to be used. In the second case the child was born two hours before I reached the house; it had never breathed, and efforts to revive it were unavailing. The third infant died from pneumonia on the fifth day. The premature and macerated fetuses were syphilitic.

One of the fetal deaths just mentioned, and the two in the first part of my series, could probably have been prevented by more prompt attendance on the patient. This is one of the most difficult problems in "slum" work—how to avoid these delays. Many women don't send for the doctor until the last moment, and unless he can go at once, he is too late. Moreover, cases of labor, like most medical cases, seem to run in groups, so that some day the calls come thick and fast. I have been obliged to look after five deliveries in a single day, and other days there were few or none. If there are enough men on the course to avoid a rush on busy days, they will sit around doing nothing most of the time. An occasional fetal death, then, due to delay, seems unavoidable.

I lost one mother, a primipara. The labor was normal, but immediately after the birth she complained of a severe pain in the left side at the junction of the sixth rib and anterior axil-

lary line. Upon listening to the heart, which was beating violently from the efforts of labor, I discovered a loud mitral murmur which I had not previously detected. No other signs were then present. On the next day the pain was as severe as ever and signs of beginning consolidation in the lung at the point mentioned were found. The third day the signs of consolidation were more definite and the patient was sent to the Pennsylvania Hospital, as the care she had at home was very poor. She died there three days later, her symptoms being like those of pneumonia in which the heart finally gives out. The temperature, however, was never above 102°, and from the way in which the trouble began and from the heart lesion I believe that it was not an ordinary pneumonia, but a large hemorrhagic infarct of the lung caused by an embolus from the diseased heart. No autopsy was permitted.

One other case was complicated by organic heart disease, but the trouble was detected beforehand, and, as soon as labor began, the patient was anesthetized and delivered rapidly by forceps after manual dilation of the cervix. She did nicely.

As other complications occurring in this series of cases I would mention four cases of sepsis, two of postpartum hemorrhage and one of eclampsia. In three of the four septic cases I found that the woman had a profuse yellow leukorrhoea for a week or ten days before delivery. It was probably gonorrhoeal in nature, and in one case surely so, for the baby developed a typical gonorrhoeal ophthalmia. In none of these cases was the leukorrhoea discovered before the birth of the child and no preparatory vaginal douches were given. This seems to me to furnish a very plausible cause for the sepsis which developed later. In the fourth case, a primipara, there was a bad laceration of the perineum, which was sewed up immediately, but which did not heal by first intention, and I believe that the sepsis was due to absorption from those raw surfaces, for the uterus never at any time seemed involved. None of these cases of sepsis was severe, all responded well when the source of infection was thoroughly cleared away.

I cleaned out the uteruses with my finger, the whole hand or half-hand being introduced into the vagina, and then gave an intrauterine bichlorid douche. After this in each case the symptoms promptly ameliorated and nothing more was needed. I should like to mention the fact, however, that in some of these cases the patient had one or more chills within two or three hours after the cleansing, the first chill sometimes severe, the others milder and milder until they stopped. They did not return the next day. I think that these chills were caused by the sudden and more rapid absorption of septic material from the uterus, for after scraping away the diseased tissue, many new lymph spaces are opened, so that the first effect is a further poisoning of the system heralded by a chill. This further poisoning is temporary, however, and permanent relief soon follows. Another possible explanation is that the chills were wholly nervous in origin, for I did not use an anesthetic in any of these cases, so there was more or less nervous shock.

I prefer the use of my finger to a curet because it is simpler, with it a more exact idea of the conditions of the inside of the uterus can be obtained, it does not frighten the patient with the thought of an operation, and an anesthetic can be dispensed with. However, if in any particular case the results were not satisfactory, I should not hesitate to use the curet, and use it early. The source of sepsis must be got rid of in one way or another.

In the whole 120 cases the forceps were applied only ten times, the most common indication being uterine inertia.

To summarize: The mortality for the mother was 1 death in 120 cases, about  $\frac{1}{120}$  of 1%; the mortality for the child, 5 deaths out of 121 children, about 4%, but several of those, as has been explained, were due to the absence of the physician when the child was born. That there is nothing remarkable in this record I fully realize, and I publish it simply to show the results obtained in the "slums" by the use of the precepts of the earlier part of this paper. It does show, however, that by very simple methods even in very unfavorable surroundings a presentable record can be obtained.

NOTE.—The obstetric cases reported do not include all those occurring in the dispensary while I was in charge, but only those attended personally by me.

## BLOOD SPREADS AS A ROUTINE MEASURE.

BY

RAYMOND WALLACE, M.D.,

of Chattanooga, Tenn.

A method of routine examination which I have used with considerable success may perhaps be condemned as somewhat superficial and more or less inaccurate, but to a trained observer and in private practice it has some marked advantages. The method in brief is as follows:

Make blood spreads in each case just as you would take the pulse or the temperature. To insure accuracy, several points must be borne in mind. The cover-glasses should be absolutely clean—preferably washed with soap and water, followed by a solution of acetic acid and alcohol. These may be wrapped and carried in filter paper, ready for use. Some experience should have been had in making good spreads, so that the observer becomes accustomed to a spread of an approximately equal concentration of corpuscles. These spreads may be taken to the office and at once stained in a solution of Wright's malarial stain, the fixation occurring synchronously with the staining, through the methyl alcohol contained in the stain. The spread may then be immediately mounted in balsam and examined.

With a little experience, various blood changes—a poikilocytosis, endoglobular degeneration, normoblasts, megaloblasts, an eosinophilia, the malarial parasite, a marked decrease in the number of red cells, a leukocytosis of any considerable degree, or a leukemia may at once be recognized, and thus point to the necessity of a more thorough blood examination with a numerical or differential count.

This method, combined with the use of the Tallquist hemoglobin chart at the bedside, makes a very satisfactory routine measure, and I am convinced that not only are obscure cases often cleared up, perhaps with considerable surprise, but that this method faithfully carried out will, in the long run, yield more valuable results than the occasional blood count and examination which is generally made only in extreme cases.

## COMPRESSION OF THE AORTA IN POSTPARTUM HEMORRHAGE.

BY

L. D. SHEETS, M.D.,

of Bloomfield, N. J.

In *American Medicine* of March 7, Leo Jacobi, M.D., has recorded a case of postpartum hemorrhage, which reminds me of a case of my own which occurred in 1856, while practising in Indiana.

I was called to attend Mrs. G. in her second confinement. I was told that she had a very serious time in her first labor, the child was still-born after she had been in labor nearly four days.

This labor progressed well, but in from 15 to 20 minutes after delivery a very profuse hemorrhage occurred with the placenta undelivered. Remembering that Prof. G. S. Bedford advised large doses of tr. opii in such cases I immediately resorted to it in teaspoonful doses.

I now introduced my hand to remove the placenta, which I found after considerable difficulty, forcing my way through an hourglass contraction at the fundus of the uterus. Nearly the entire placenta was adherent and my efforts to detach it caused the patient so much pain that upon the urgent importunities of herself and husband I withdrew my hand.

Hemorrhage continued and patient seemed sinking. I therefore sent for a consultant to confirm the necessity of removal of the placenta. Patient was now almost pulseless, skin was cold and covered with a cold, clammy sweat, she declared she was dying. Having no other stimulant I gave her laudanum and camphor.

It then occurred to me to exert pressure over the abdominal aorta (although I did not remember ever hearing of its being done) with the hope of saving her until a consultant arrived. The hemorrhage ceased immediately, the perspiration soon dried up, and the patient seemed to rally somewhat, but she complained bitterly of cramps in the lower extremities.

Word having been received that the doctor for whom I sent was not at home I urged the patient to let me make another attempt to remove the placenta. Having received consent I again introduced my hand and persevered against all entreaties to desist, until the placenta was detached and removed. The hourglass contraction continued, almost paralyzing my hand.

Constant pressure was maintained on the aorta during the detaching and removal of the placenta.

I then pressed the uterus well down in the pelvis, that hemorrhage might not be renewed, and began to administer brandy, which was given every 15 minutes for 30 hours, when reaction commenced. All this time she had to remain on her back, the least effort to turn her to either side would induce syncope. The brandy was gradually withdrawn. After reaction was fully established, as the patient was very constipated, a laxative was ordered. In those days it was the regular routine to give a cathartic on the third day. Some little fever followed the reaction, but soon passed off. Quinin was then ordered for a few days. Attendance ceased in about a week and patient made a good recovery.

As you may have observed this case occurred many years ago; also in a country practice, which will account for the meagerness of the remedies at hand. And in regard to the short attendance I would say that in those days an obstetric case some distance in the country was not visited the second time unless something unusual occurred. In another bad case I checked the hemorrhage immediately by the introduction of tolerably large pieces of ice. This was a primipara to whom I had given chloroform; and I blamed the chloroform for preventing contraction of the uterus.

## REPORT OF A CASE OF ECTOPIC PREGNANCY OF LONG DURATION.

BY

E. E. EVANS, M.D.,

of Lawrence, Kan.

L. B. R. was born in New York, September 6, 1828. Her family history is good. Measles in childhood left a cough, which persisted through life. Menstruation began at about 14 years. At 16 the contraction of a "cold" during a menstrual period brought on dysmenorrhea, from which she afterward suffered. Her periods were regular. She attained a stature slightly above the average. She was married at 23. She first became pregnant 13 years after marriage (in March, 1865). The

Lithopedion. On the left is seen the trunk and head, and on the right the uterus and appendages.

usual signs of pregnancy were present, and quickening occurred about the fifth month. Except for the continuation of the monthly periods, gestation was considered normal. Labor began about the expected time (December, 1865), and continued about 36 hours, when there was a complete abeyance. About a week later vigorous fetal movements were noted, which suddenly disappeared and never returned.

Abdominal enlargement persisted for 12 or 15 years, then began to diminish, but never entirely disappeared.

Upon her death (in October, 1898, almost 33 years after the futile labor noted) I removed the lithopedion here illustrated. It occupied the right tube, which was not ruptured, and lay in the right iliac fossa.

That portion next to the uterus (in illustration) represents the head. It is of bony hardness, but without structure or section. The other portion represents the trunk, a heterogeneous mass, no vestige of the limbs remaining. The whole fetus is 7 x 4 x 3 inches, and weighs four pounds.

CONGENITAL ABSENCE OF THE CLAVICLES, WITH PHOTOGRAMS AND RADIOGRAMS: CLEIDOCRANIAL DYSOSTOSIS.

BY

HARRY M. SHERMAN, A.M., M.D.,  
of San Francisco, Cal.

The present paper is not in the shape it was when presented to the Association in Philadelphia in June; another case has been added, and some recent literature bearing directly on the subject has been quoted. But as the paper was never anything more than a description the changes are only in the direction of additions and amplifications. At the meeting of the Association I presented the following description of Case I:

The child was a boy of 3; he was normal mentally but had marked evidences of rachitis, without having, however, in his long bones curvatures which required surgical intervention. An obvious lesion was a delayed ossification of the bones of the skull, both fontanelles and the frontal suture being widely open. There was no hydrocephalus, but the frontal bones were very prominent, the right the more so. He had, on the left side, only a rudimentary clavicle on palpation, and only the sternal half of the bone on the right side. The radiogram fails to show either of these as visible bones (Fig. 1). He had deformed scapulas, the spinous processes seeming to be too high on the body, and not as prominent as they should be, but the acromion processes were present and properly located. The supraspinati and infraspinati muscles seemed to be atrophied or absent, and so did the posterior halves of the deltoid muscles, but there must have been some muscular tissue in all of these locations, for the function of the shoulders was practically perfect, and the boy could put either hand on his head or behind his back or hold his arms out sideways horizontally

Fig. 1.

from his body. It was possible to pull the shoulders forward with very little force and to touch them together under the chin (Fig. 2). The act caused no pain or discomfort, and the shoulders returned spontaneously to their usual position as soon as they were released. The lack of the clavicles seemed to be no detriment to the child, and in fact their absence had not been known, and was discovered by me during an examination for other conditions.

A second case is now added to the above. The child is a girl of 7, whom I first saw two years ago, suffering from well-marked rachitis. She readily recovered from this, but became somewhat heavy and slow and at times when she was tired she limped. I examined her several times to discover the cause of the limp and in the course of one examination found the scapulas higher than normal and very prominent, especially in their upper parts. There seemed to be much the same fault to be found with the bone as in the previous case and the supraspinati and infraspinati muscles seemed to be atrophied, even though all motions appeared normal. I sent the child to Dr. L. Newmark for a neurologic examination and he reported that no lesion of the nervous or muscular systems was present and noted the absence of the clavicles. Further examination failed to show even rudimentary clavicles and none appeared in a radiogram (Fig. 3). In addition to the absence of the clavicles the sternum is much depressed. The fontanelles and sutures in the skull have closed, but there are well-marked depressions along the suture lines, including the frontal suture, and the head is large with prominent frontal and parietal eminences. The bridge of the nose is not sunken in, but the line of the bridge is quite concave. Mentally the child is normal. In this case, as in the other, the shoulders can be made to touch each other under the chin easily and painlessly, but not by the voluntary effort of the child (Fig. 4). When they are released from this position they return spontaneously to their usual

Fig. 2.

one and their unusual mobility does not seem to interfere with the use of the arms (Fig. 5).

In *La Tribune Medicale*, July 23, 1902, is reported a lecture by M. Pierre Marie, on "La Dyostose Cleidocranienne," and it describes four cases which are similar to my two.

1. A woman with a large head, prominent frontal and parietal bones, grooves along the suture lines and open fontanelles. She had also a high arch to her palate and evidence that the palatal processes of the bones had not fully united, though there was no cleft-palate. Her teeth were irregular.

She had sternal fragments only of the clavicles.

2. A child, daughter of the woman just mentioned, who was

like her mother in all particulars except that she had no clavicles at all, and she had had a persistence of the first dentition, the teeth being at the same time good.

The amplitude of movement of the shoulders in these two cases was the same as in those I have described, and while in my children no disability had developed

because of the lack of the clavicle, in the woman reported disability had developed and she could not hold her

Marie points out the evident hereditary character of these odd malformations, but says it has never been

Fig. 3.

arms out straight before her, nor lift nor carry her babies easily.

3. A man with a very large head and the usual prominent bones and grooves and open fontanelles. He had a narrow and cleft-palate, and bad and irregular teeth. Of the clavicles he had fragments at each end of the bones.

known to run more than two generations, and that therefore there must be a tendency for a return to the normal type. He notes that all his patients showed signs of rachitis in addition to the malformation, and emphasizes the fact that they may develop syringomyelia and hydrocephalus.

I have asked the two family physicians of my two chance cases to look up the hereditary element, and Dr. J. T. Jones, at Grass Valley, Cal., reports that both father and mother of my boy case are properly and well formed and have clavicles. Dr. Geo. H. Aiken, of Fresno, Cal., reports of the father of the girl patient: "I find the chest full, broad and very well developed. There is no absence of the clavicles, but evidence of fractures of both with overlapping and imperfect union. The fracture of the left clavicle occurred when he was 2 years old. The head is large and square, with the top decidedly flattened. I find no special depression along the whole length of the sagittal suture, but quite a marked depression at and just posterior to the anterior fontanelle. I believe he was rachitic in early life." The mother of the child I have myself examined and she is normal.

Unless, then, there is some hereditary force possible in my girl case, the father having a large head with a depression at the anterior fontanelle site, my cases must be chance occurrences of this particular type of imperfect and aberrant development.

**The Open Door.**—A bill introduced in the Minnesota Legislature March 4 allows the State Board of Medical Examiners to grant licenses, without any examination, to physicians already licensed in some other State which has a standard equal to that of Minnesota. Each applicant for a license must pay a fee of \$10, which the board may retain, regardless of the results of examination. It is made the duty of every county attorney to prosecute cases of practice without license whenever requested so to do by the board of examiners or any five of its members.—[*Journal American Medical Association.*]

Fig. 4.

Fig. 5.

4. A boy, son of the man just mentioned, who was like his father in all essential particulars.

—The man, No. 3, had developed syringomyelia, and, although he formerly had been a skilled artisan, he was then wholly incapacitated for any work.

DEGENERATION OF THE ERYTHROCYTE.<sup>1</sup>

BY

JOHN C. DACOSTA, JR., M.D.,  
of Philadelphia.

Demonstrator of Clinical Medicine, Jefferson Medical College; Hematologist to the German Hospital, etc.

Hematology is a topic which has been so thoroughly investigated that it has become familiar, not only to the laboratory student, but also to every alert clinician. From the latter's viewpoint, however, it may not be unprofitable to consider erythrocytic degeneration and with this aim in view I purpose to approach the topic, endeavoring in the following inquiry to submerge special technicalities and to minimize the discussion of mooted and theoretic points, in the hope of applying practically our present knowledge to medical diagnosis and prognosis. The various degenerative changes affecting the erythrocyte are not to be regarded as definitely characteristic of themselves, but rather as links in the chain of clinical evidence afforded by a complete blood report, which, to be of any real value, must in turn be correlated with the general semeiology of the patient in question. It may not be out of place to remark that the province of hematology is not primarily to furnish absolute criteria of disease, but on the contrary, to develop data which may prove essential either to corroborate or to complete the phenomena otherwise elicited. Interpreted thus, the blood report is of great utility in every day routine medical and surgical practice, but hematology divorced from familiar bedside signs of disease in many cases leads to erroneous conclusions and to false diagnostic inferences. To neglect well-established clinical evidence in our enthusiasm for apparently incontrovertible laboratory findings not only narrows one's diagnostic perception, but brings into disrepute such findings among those who, perchance, have failed to correlate them intelligently.

For the purpose of description, the various degenerative changes to which the erythrocyte is subject may be classified under the following headings:

- I. Alterations in viscosity.
- II. Simple decoloration.
- III. Total necrosis and disintegration.
- IV. Deformities of shape and size.
- V. Atypical staining reaction.
- VI. Megaloblastic forms.
- VII. Granular basophilia.

It is to be understood that no hard and fast line of demarcation can be drawn between these groups, since the several changes here included are more frequently encountered in combination than singly. These changes, it will be noted, are such as can be studied by simple microscopic examination of the fresh blood and of the stained film, and their recognition involves the application of familiar and simple technical methods, easily acquired and available for practical every day work. Of these methods it seems inadvisable to speak here in detail. I shall omit the discussion of the isotonicity and the agglutination of the erythrocytes, as well as their behavior under the influences of thermal, mechanic, and electric agents—all questions of experimental rather than of clinical interest.

I. *Alterations in Viscosity.*—When a drop of blood, collected upon the surface of a glass slide, is allowed to remain exposed to the air, the slippery, greasy feeling of the freshly-shed blood is soon replaced, as coagulation progresses, by a sensation of stickiness or viscosity, readily appreciable by the finger. In normal blood the erythrocytes, by virtue of their adhesiveness, tend to adhere face to face, and under the microscope are seen to cling together like a stack of coins. When this inherent property of adhesion is increased (*hyperviscosity*) they lose their normal tendency to form rouleaux, and accumu-

late in large, irregular masses in which the distinctive histologic attributes of the cells are masked or lost. The individual erythrocytes detached from such a mass may show every imaginable type of distortion, losing their typical biconcavity and disc-like form, and being converted into elongated, misshapen bodies which bear not the slightest resemblance to the original cells. When this property of adhesion is greatly enfeebled or lost (*hypoviscosity*), the erythrocytes form neither rouleaux nor irregular masses, but float free in the plasma as isolated cellular entities. The viscosity of the whole blood is apparently influenced to a large extent by the cellular elements, chiefly by the erythrocytes, although the viscosity of the serum must also be regarded as a determining factor of more or less importance.

Hirsch and Beck, who recently published a minute study of blood viscosity, have determined that the "viscosity value," as they term it, of human blood is about five times that of distilled water, *i. e.*, the viscosity of blood having a specific gravity ranging between 1,045 and 1,055 is expressed by the figure 5.1, in comparison with that of water, which equals 1, the temperature of both fluids being the same, 38° C. Although no close relationship can be distinguished between the degree of viscosity and the specific gravity of the blood, these experimenters have apparently proved that the lower the density of the blood the less marked its adhesiveness. The latter is exaggerated in individuals living upon a largely nitrogenous diet; and is greatly modified by starvation. Weir Mitchell has observed that hyperviscosity develops when blood is subjected to the direct action of snake venom, while Stengel has noted a similar condition resulting from contaminating fresh blood with the serum of patients suffering from chlorosis, pernicious anemia, and leukemia. Anyone who has done much blood work is familiar with the marked fluidity of the fresh specimen in the high-grade anemias, and with the diminished viscosity of the erythrocytes and their disinclination to form rouleaux under such circumstances.

II. *Simple Decoloration.*—Under the microscope the normal erythrocyte appears of uniform color and density, save for a somewhat paler area corresponding to its central biconcavity, whence the tint insensibly blends with a relatively darker zone paralleling the periphery of the corpuscle. This evenness of color depends upon the homogeneous distribution of the hemoglobin throughout the cell stroma, for, in the light of our present knowledge, we must accept Rollet's view, that the red corpuscle consists of a spongy network or stroma in which the hemoglobin is embedded, possibly in combination with a nucleoprotein of the cell. We must decline to adopt, for obvious reasons, Schäfer's theory, that the erythrocyte is a vesicular mass, the essential parts of which are an external enveloping membrane and an internal fluid content.

Simple loss of hemoglobin, and consequently decoloration of the erythrocytes, is a familiar change in blood deteriorations of a moderate grade, notably in those forms of secondary anemia and of chlorosis which involve neither conspicuous hemoglobin and cellular deficiencies, nor deformity and nucleation of the erythrocytes. The decoloration may be quite uniform throughout the cell, beginning as a symmetric enlargement of the normally lighter area, and spreading progressively toward the periphery. A cell thus affected sooner or later loses its normal biconcavity, and, in the extreme instance, is converted into a practically colorless shell or phantom, which would be invisible were it not for its faintly colored marginal zone, where a small amount of hemoglobin tends to persist, in spite of its dissociation from the rest of the stroma. "Hayem's achromacytes" and "Ponfick's shadow corpuscles" are suggestive terms by which these extreme examples of cellular pallor are designated. Or, instead of this uniform decoloration, the cell may exhibit patches of pallor of unequal intensity, in case the degeneration

<sup>1</sup> Read, by invitation, at the Ninety-seventh Annual Meeting of the Medical Society of the State of New York, Albany, January 27, 1903.

involves several portions of the stroma simultaneously, causing more rapid and greater hemoglobin loss in certain areas than in others. Still other corpuscles show an irregular enlargement of their hyaline centers, with the ultimate production of various irregular figures, as well as of streaky, pale areas overlying parts of the stroma from which the hemoglobin has been removed. In whatever form these hemoglobin-free areas develop, they always exhibit in the dried and fixed blood film a selective affinity for basic stains, such as methylene-blue and

thionin, by which they are colored with abnormal intensity.

This phenomenon of simple decoloration has been exhaustively studied by the Italian school, especially by Maragliano and Castellino, who interpret it as a form of endoglobular degeneration, and by Celli and Marchiafava, who

*Decoloration and Necrosis of the Erythrocytes.* Cells showing various phases of stroma degeneration, ranging from simple loss of hemoglobin to total necrosis and fragmentation. (Fresh blood film from a case of high-grade chlorosis.)

independently have investigated the process in connection with malarial infections. It has been described also by Hayem under the caption "état cribiform," and by Klebs as a "pseudonucleation." The so-called vacuolation of the erythrocytes in the fresh blood film which has been exposed to external influences, furnishes an excellent illustration of this type of cell degeneration excited artificially.

**III. Total Necrosis and Disintegration.**—A general structural change, with ultimate breaking up of the erythrocyte, represents, in pathologic blood, an extreme grade of degeneration, far more crippling in its effects than the process of simple decoloration. These two changes not infrequently coexist in the same corpuscle, or they may progress independently of each other. Cell necrosis of this type is first betrayed by the development of numerous small, elevated, teat-like processes in the stroma, and sometimes by a corrugation or ridging of the flat surface of the cell. The whole corpuscle then appears to become actively ameboid, and this motility, plus its structural weakening and loss of resiliency, tends sooner or later to convert it into a misshapen body, or poikilocyte. From the periphery of a corpuscle thus affected small bits of the stroma may be seen to extrude, break off, and float away in the plasma. These miniature vesicular masses may or may not be deeply colored, according to the amount of hemoglobin which they contain; as a rule, they show a decided affinity for basic stains, although the erythrocyte from which they are derived may not exhibit this tendency.

Decoloration and general necrosis of the erythrocytes may be studied in the fresh film of both normal and pathologic blood. In normal blood they result purely from prolonged exposure of the cells to the air, the hemoglobin dissociation beginning within from one-half to one hour, and the cell destruction within from three to four hours, after the preparation of the slide. In pathologic blood the changes are regarded as an evidence of an increased toxicity of the plasma, but to this principal factor should also be added another essential cause—the lowered resistance of the erythrocytes in consequence of which they become especially susceptible to injury even by a normal plasma, as well as by exposure to extraneous influences. In disease, therefore, these changes develop with much greater rapidity than in normal blood—in fact, they are often demonstrable

immediately after the blood has been withdrawn from the body. Simple decoloration is regarded as a more favorable sign than total necrosis and fragmentation, and is generally symptomatic of more moderate grades of anemia than those in which the latter changes prevail.

**IV. Deformities of Size and Shape.**—In all anemic states it is common to find, in association with normal erythrocytes, cells more or less increased or decreased in diameter, as well as others whose shape is variously distorted, often so strikingly that they bear but a slight resemblance to the typical discs of normal blood.

Well defined increase in the size of an erythrocyte, without notable alteration in its contour, stamps it as a megalocyte or macrocyte. The diameter of such a cell usually ranges between 12 and 15 micromillimeters, but in the extreme instance it may equal or exceed 20 micromillimeters. Its stroma generally, but not invariably, is pale, owing to a relative deficiency of hemoglobin, and it shows more or less tendency to react toward a basic dye, in the stained film. There are at least two tangible views regarding the origin of the megalocyte: the first interprets the change as an actual gigantism of the cell, which is bred in the bone marrow from a correspondingly large nucleated antecedent; the second regards it as a hydropic enlargement of the cell, which by imbibition of fluid from the surrounding plasma, swells, loses its distinctive double concavity, and becomes pale, as its hemoglobin is relatively diminished in proportion to the extent of this cellular dropsy.

The microcyte illustrates the decrease in the size of the erythrocyte under pathologic circumstances, the cell thus deformed consisting of a small vesicular body, from three to five micromillimeters in diameter, and, as a rule, having its stroma colored more deeply than normal. Extremely small cells, not more than three micromillimeters in diameter, of high refraction, regularly spheric shape, and very dark color, have been dubbed "Eichhorst's corpuscles." They were once regarded, in the dark ages of hematology, as characteristic of primary pernicious anemia, but are now known to carry no such clinical import. Microcytes may enter the blood stream as such, their dwarfism being directly related to a defect in hemogenesis. In other instances, and these are many, they may be simple products of corpuscular budding and fragmentation, doubtless stimulated by increased plasma toxicity plus a lowered resistance on the part of the cells; in consequence of these factors the erythrocyte extrudes portions of its stroma, which circulate for a time in the blood as miniature cells containing hemoglobin, and tend to assume their ancestors' biconcavity and disc-like contour. In this connection it does not seem unreasonable to presume that the bodies known as Müller's "hemoconien" or "blood dust" may represent this phase of microcytosis.

Any erythrocyte, regardless of its size, is known as a poikilocyte when its shape distinctly deviates from normal. Such cells present an infinite variety of deformities, ranging from those showing merely a slight ovoid tendency to those distorted into the most bizarre figures imaginable. These irregularities have been likened to various objects, such as a gourd, a canoe, an oval disc, a

*Deformities of Size and Shape.* Illustrating various grades of cell deformity associated with severe anemia. The large nucleated erythrocyte is a typical megaloblast. (Triple-stained specimen from a case of pernicious anemia.)

sausage, a beak, a spindle, and a horseshoe. Minute rod-shaped forms, the so-called "pseudobacilli" of Hayem, are interesting on account of their rapid oscillations in the plasma and their superficial resemblance to large, unstained bacilli. It is probable that poikilocytosis can generally be attributed to an increased toxicity of the plasma whereby the erythrocytes which, it is to be presumed, are abnormally sensitive, readily succumb to its destructive influences and alter structurally. It is also possible that poikilocytes may arise in consequence of a defect in hemogenesis, whereby ill-shaped, as well as normal, erythrocytes enter the circulation from the marrow.

Deformities of size and shape usually are marked in relation to the severity of the anemic process which they reflect. In some cases the changes are moderate, and tend to affect the great majority of the cells; in others, on the contrary, it is apparent that but relatively few corpuscles are affected, but in these the distortion is prone to become most striking. The three varieties of deformity above noted are practically always associated, but in certain cases it is possible to distinguish a prevalence of one or the other type. Thus, in anemias characterized by marked cellular loss, notably in pernicious anemia, a general tendency toward megalocytosis is practically a constant feature of the blood report, while in those in which the poverty in erythrocytes is relatively less decided, as in chlorosis, a general tendency toward microcytosis is the rule. This statement is, of course, very general and subject to exceptions in the individual case. It is a familiar clinical observation that an anemia characterized by oversized erythrocytes is more serious and less amenable to treatment than one in which undersized corpuscles prevail.

**V. Atypical Staining Reaction.**—In the stained specimen the normal erythrocyte invariably shows a strong elective affinity for a single, acid dye, by which it is colored in a characteristic manner. For example, if a solution is used which contains both an acid and a basic dye (*i. e.*, eosin and methylene-blue, or eosin and hematoxylin), the erythrocyte is stained the tint of the acid element, eosin; while with the triacid mixture, which is so formulated that an acid, basic, and neutral principle may be selected by the different histologic elements subjected to its action, the erythrocyte is always stained the color of the acid Orange G. component of the reagent. Thus, under conditions of health the red corpuscle remains consistently *monochromatophilic*, whether the technic of preparing the film involves simple, single, or double, or more elaborate panoptic, staining methods. Under certain pathologic conditions, however, some of the erythrocytes lose their affinity for a single, acid dye, and, with mixtures of both acid and basic dyes, exhibit a definite affinity for the latter, and are therefore said to be *polychromatophilic*. Thus, in eosin and methylene-blue preparations such corpuscles are tinged violet, or purple, or grayish-red, instead of the pure rose color of eosin; while with the triple stain various shades of purple, or reddish-brown, or yellow and pink flecked with deep crimson, replace the rich orange tint of the normally stained cell. Cells thus disfigured are likely to be unevenly stained, and to show contrasting light and dark areas, the latter usually being most conspicuous toward the periphery of the corpuscle, or, if the latter be nucleated, along the perinuclear zone of the stroma. As already pointed out, the areas of pallor in a cell undergoing simple loss of hemoglobin are especially prone to show this basic tendency, but it does not necessarily follow that polychromatophilia is striking in relation to the diminution in the individual cell's hemoglobin content.

It is in the megalocyte and in its marrow antecedent, the megaloblast, that polychromatophilia is most prone to develop and to become most striking; but the change is by no means confined to cells of this variety, since it may also affect, though with much less frequency and usually less conspicuously, the various other types of degenerate erythrocytes.

The exact manner by which polychromatophilia arises is still a mooted point in hematology. Ehrlich, who first described the condition, under the term "anemic degeneration," regards it as an evidence of corpuscular decay, involving a coagulation necrosis of the cell, whereby the discoplasm loses its property of combining with acid, protoplasmic dyes and displays an avidity for basic, nuclear stains. On the contrary, Gabritschewski, Askanazy, Schaumann, and others believe that the change betrays, not old age, but youth of the cells, whose development has been suddenly aborted at a point short of their full, normal maturity. Dissection of these opposing views and their attempted reconciliation is hardly germane to this discussion, interesting as these different opinions may be as pathologic problems. It is important, then, simply to bear in mind the facts that no normal erythrocyte ever shows polychromatophilia, and that cells which exhibit this alteration are functionally imperfect, owing either to a simple deficiency in their hemoglobin content, to morbid structural changes readily detected under the microscope, or, perhaps, to subtler inherent defects attributable to faults of development. Thus, the polychromatophilic cell may be quite normal save for its hemoglobin poverty; it may be old, deformed, and necrotic; and it may be so young that its nucleus still persists. In any event, the fact remains that every cell in a stained specimen prepared with perfect technic, which shows this deviation from the normal reaction to the anilin dyes, must be considered degenerate, in so far as this term implies crippled function.

Polychromatophilia may be encountered in any of the high-grade anemias, regardless of their type, but in pernicious anemia and in leukemia this change constitutes a feature of the blood report which is to be regarded as almost constant. In chlorosis, notwithstanding the unusual hemoglobin poverty which is rather characteristic of this disease, I have seldom noted atypical staining of the erythrocytes, unless the cellular decrease was also extreme. In general terms it may be stated that polychromatophilia is a sign of extreme blood impoverishment, but by its presence alone no prediction is warranted as to the ultimate outcome of the anemia of which it is symptomatic.

**VI. Megaloblastic Forms.**—The detection of nucleated erythrocytes conforming to the megaloblastic type constitutes one of the most valuable and distinctive clues afforded by hematology. In health cells of this class are absolutely foreign to the blood stream, as well as to the bone marrow, in postuterine life, and hence their presence in the stained film is conclusive proof of a severe, though not necessarily a fatal, anemia.

The megaloblast, it will be remembered, is the immediate antecedent of the megalocyte, into which it is evolved by the absorption of its nucleus (Pappenheim and Israel; Neumann and Kölliker). It is a natural inference, therefore, to presume that these two forms of cells are associated, and, clinically, this is generally found to be the case; at least, it is true that megaloblasts never exist without megalocytes, although the latter may be found alone, in case they owe their origin to simple dropsical swelling rather than to nuclear loss. Megaloblasts are found in the circulating blood only in conditions involving more or less reversion of the bone marrow to the fetal type, owing to which this tissue manufactures not only large numbers of defective giant megalocytes, but also throws into the blood stream some of their nucleated precursors of embryonal type. The presence of megaloblasts must be regarded as a sign of striking degeneration of the hematopoietic organs, involving imperfect hemogenesis of embryonal character, and hence the significance of this variety of erythroblasts is diametrically opposed to that of the normoblasts. The latter, though associated with severe anemic states, are the expression of an active and overstimulated, but normal, adult type of blood manufacture,

and reflect a regenerative, conservative process; they invade the blood stream when the marrow, in consequence of demands made upon it for new erythrocytes to replace those destroyed by an anemic state, furnishes not only a quota of normal cells, but also allows the escape of an occasional immature nucleated form, or normoblast. It cannot be too forcibly emphasized that

*Megaloblastic Forms.* Common types of megaloblasts, showing variations in size and shape, and peculiarities of the nuclear structure. (Triple-stained specimen from a case of pernicious anemia.)

periphery of the cell body. The stroma of the megaloblast frequently appears swollen, enlarged, and marked here and there by depressed and elevated areas and perhaps by distinct flaws and cracks which fail to take the stain; generally, it has a more or less regular contour, although it may be conspicuously deformed and distorted; and it is commonly polychromatophilic, exhibiting combinations of color in endless variety. With the triple stain the body of the cell is usually tinted a dull tan color, with deeper shadings of burnt-sienna about the nucleus and near the periphery; or a diffuse crimson tinge may predominate, as if the stain contained an excess of fuchsin. Other cells are likely to be streaked and blotched with yellow and deep brown patches, and still others stain a diffuse purple, often blending into a light pink tone in certain areas. The nucleus, which occupies the greater part of the cell body, is composed of such a delicate and scanty chromatin network that it shows but a slight affinity for basic dyes, in consequence of which it stains pale sea-green or greenish-blue with the triple mixture. This prevailing green tint is frequently stippled with delicate dots of vivid crimson or deep purple, which produce a pseudogranular effect by their contrast with the lighter undertone. In some cells the nuclear structure is coarsely mottled here and there by irregular areas of deep blue or purple. Many other equally striking tinctorial reactions to the anilin dyes are also to be found in other nuclei of this type. The nucleus of the megaloblast is generally differentiated sharply from the cell body by a distinct hyaline, unstained margin, which encircles it and is thrown into bold relief by the nuclear and stroma stain on either side.

Megaloblasts occur in the circulating blood only in the severer types of anemia which are characterized by hemogenesis approximating with greater or less fidelity that of the fetus. An occasional megaloblast may be encountered in various chronic anemias of striking intensity, but in such conditions they are invariably outnumbered by the normoblasts with which they are associated. But in only three conditions, namely, pernicious anemia, infection from *Bothriocephalus latus*, and nitrobenzol poisoning, have megaloblasts been found to be the predominating form of erythroblast. In 37 consecutive cases of pernicious anemia I have found, by

the megaloblast and the normoblast each represents a radically different type of corpuscle, the origin and clinical significance of which are entirely dissimilar.

The typical megaloblast is an unusually large round or ovoid cell, measuring from about 10 to 20 micromillimeters in diameter, and provided with a relatively large-sized nucleus, which is, as a rule, situated toward the

differential counts of the erythrocytes, that the megaloblasts outnumbered the normoblasts in all but five. The average proportion of the former to the latter was somewhat more than two to one, and in seven cases only megaloblasts occurred. In contrast to this I may cite the blood findings in 26 cases of leukemia (15 of the splenomedullary, and 11 of the lymphatic type, respectively). In this disease the megaloblasts invariably were outnumbered by the normoblasts, which in six of the cases were the only type of nucleated erythrocyte detected, and the proportion of normoblasts to megaloblasts in these 26 cases averaged about four to one. Comparing the numerical estimates of both types of erythroblasts in these two forms of primary anemia, it was determined that the average estimate in pernicious anemia was 220, the highest 924, and the lowest 3, cells per cubic millimeter of blood; while in leukemia the average was 5,800, the highest 12,913, and the lowest 748, to the cubic millimeter. These figures illustrate the striking abundance of erythroblasts in leukemia, and also show that in this disease the compensatory hemogenesis does not counterfeit the embryonal type so closely as it does in pernicious anemia. From a rather close study of the question, I am convinced that megaloblasts are the prevailing form of nucleated red cells in every genuine case of pernicious anemia during its active stages. In the exceptional case their absence may be explained by the examiner's carelessness, or perhaps by the fact that the marrow has become so wrecked by the specific toxins of the disease that it is no longer capable of turning out even these makeshifts of corpuscles. It is also true that during the periods of remission, the megaloblastic phase of the blood picture, as well as its other characteristics, temporarily disappears. The presence of megaloblasts in leukemia betrays the existence of fetal marrow changes, and their association here with such an amazing profusion of normoblasts indicates, furthermore, that active blood regeneration accompanies this degenerative lesion.

The megaloblastic blood picture of bothriocephalus anemia, described by Askanazy, may be explained by assuming that in this infection certain unknown poisons, elaborated by the parasite, are absorbed by the human host, in whom they provoke fetal marrow changes. After expulsion of the worm the megaloblasts rapidly disappear from the blood, and are replaced by normoblasts, which in turn disappear, as the patient's blood becomes normal and health is restored. In nitrobenzol poisoning Ehrlich and Lindenthal have observed a similar predominance of megaloblasts, and in this condition it is also to be assumed that a similar degeneration of the marrow must have been excited by the intoxication.

VII. *Granular Basophilia.*—In many of the anemias the film stained with methylene-blue, thionin, or hematoxylin, shows a peculiar basic granular condition of the stroma of some of the erythrocytes, to which the terms granular basophilia and granular, punctate, or basic degeneration are applicable. In the specimen stained, for example, with eosin and methylene-blue these granules appear as a fine or coarse blue stippling, or, rarely, as blue linear markings, or as a combination of these three phases. These basic areas are either distributed quite uniformly through the stroma or are grouped in a more or less compact mass toward the margin of the cell body, against the rose tint of which their intense blue color shows conspicuously. Normally shaped, distorted, nucleated, and nonnucleated corpuscles may be in this manner basically stippled, and it is not uncommon to find that such cells also bear evidences of polychromatophilia.

The exact nature of these granules has provoked a great diversity of opinion among different investigators, whose differences may be narrowed down to these two prevailing views: first, that they are the product of nuclear fragmentation; and, second, that they represent a true stroma degeneration. Among those who urge the

acceptance of the first view may be mentioned the names of Askanazy, Litten, Lazarus, and Engel; while Grawitz, Hamel, Moritz, and Stengel are among those who have advanced clear arguments that the process is essentially protoplasmic. In order to get at the truth of this debated topic, it is necessary to refer briefly to the chief phases of these opposed theories and to the facts by which they are substantiated.

First, to inquire if the granules are nuclear debris or products of fragmentation, occurring as the result of a nuclear absorption by which the erythroblast ultimately becomes a nonnucleated erythrocyte or normocyte. To

*Granular Basophilia.* Erythrocytes showing various degrees of basophilia, with fine, coarse, spherical, ovoid, and spiculate granules. Note the basophilic normoblast. (Eosinate of methylene-blue specimen from a case of lead poisoning.)

support this belief, it is reasonable to presume that some of the cells should exhibit changes which may be interpreted as transitional stages between the typical erythroblast and the nonnucleated granular erythrocyte. But, from the evidence thus far presented, it cannot be said that such forms have been conclusively demonstrated, although both Litten and Ewing appear convinced that they exist. The former has minutely described them, both in the circulating blood and in the bone marrow of a single case of pernicious anemia; while the latter states that in this same disease he has observed the transitional stages and fine subdivision of megaloblastic nuclei. These, however, are isolated annotations, and lack corroboration by the many other investigators who have studied the question. Personally, it has never been my good fortune to discover such intermediate forms of cells, although both in pernicious anemia and leukemia, in which erythroblasts and granular erythrocytes commonly coexist, I have tried to distinguish the progressive pallor and fragmentation of the nucleus with coincident multiplication of the granules, such as Litten describes, and thus to become convinced of the truth of this tempting hypothesis. Askanazy, Simon, Stengel, White, and Pepper have offered most positive evidence against the nuclear origin of the granules by demonstrating in granular erythroblasts signs of active karyomitosis—a finding that seems conclusive, since it is hard to believe that a nucleus can simultaneously divide, by mitosis, and fragment, by rhexis. The last three investigators also found precisely similar types of nucleated and granular cells in the bone marrow and blood, whereas, according to the theory of nuclear fragmentation, the marrow naturally should contain numerous examples of transitional forms, for in this tissue the transition of erythroblasts to erythrocytes occurs normally. In lead poisoning, pernicious anemia, and lymphatic leukemia Cabot has observed granule cells in association with other erythrocytes containing curious ring-shaped bodies, obviously relics of megaloblastic nuclei; but apparently these two types of cell defects were independent.

The fact that these granules are not stained by

methyl-green is also of some importance, for this nuclear dye is the very element of the triacid stain which picks out the nuclear structure of the erythroblasts, and should also color the granules, did they really represent nuclear remains.

Although not found in the blood of the human embryo, granular basophilia of the erythroblasts has been noted in the blood of embryonic mice (Engel, Pappenheim) and cats (Schmauch), as well as in the erythrocytes of fullgrown rabbits (Ehrlich), guinea-pigs (Löwenthal), and squirrels (Simon). The occurrence of basophilia in the embryos of some of the lower animals has been exploited as a proof that the granules are of nuclear origin, but this deduction is by no means warranted from the evidence at hand.

To support the second view, that granular basophilia betrays a form of stroma degeneration, presumably specific, it is necessary only to refer to the clinical and experimental work of Grawitz and his assistant, Hamel, and to the careful investigations recently completed by Stengel and his associates. Four years ago Grawitz declared that basophilia of the erythrocytes was a specific degenerative change, and that the exciting cause was possibly some form of blood poison which acted deleteriously on the circulating cells. His chief conclusions may be briefly summarized as follow: (a) Granular basophilia may be demonstrated in peripheral blood which shows absolutely no other signs of degeneration. (b) Transitional stages between typical erythroblasts and granular erythrocytes exist neither in the circulating blood nor in the bone marrow. (c) Erythroblasts with typically intact nuclei may show striking basophilia of the cell body. (d) Experimentally, granular basophilia of the circulating erythrocytes can be promptly excited in animals by the administration of various toxic substances, as well as by subjecting them continuously to high degrees of heat. After the animal's recovery from either of these harmful influences, the granules disappear from the blood.

Stengel and his pupils have, step by step, confirmed on the whole these data, and, in addition, have recorded the very important observation already referred to, namely, that basophilic granules are not incompatible with nuclear mitosis in the very cells whose stroma they occupy. These workers also lay stress upon the absence of transitional forms of cells in leukemic blood, in which erythroblasts showing various signs of nuclear degeneration (such as atrophy, pyknosis, karyolysis, and karyorrhexis) are not uncommonly demonstrable. They were, however, unable to determine the exact seat of origin of the degeneration, whether it resided in the peripheral blood, in the portal circulation, or in the bone marrow.

Whatever be its mode of production, the fact remains that granular basophilia of the erythrocytes is a change never found in the blood of the normal individual. It is rational to regard it as a stigma of cellular degeneration, and its detection is sufficient grounds for directing the clinical inquiry toward a search for an adequate underlying factor of some anemic condition. For convenience's sake, granular basophilia may be discussed under two headings: experimental and clinical.

*Experimental basophilia*, as Hamel first proved, can be excited in animals by the administration of small doses of lead acetate, either by the mouth or by subcutaneous and intraperitoneal injection. The minimum amount of the metal requisite to cause this change has been found to be .03 gram, although most experimenters have employed larger amounts, ranging as high as 1 gram. Later experiments, notably those by Moritz, Behrendt, Bourret, and Stengel, have fully confirmed the truth of this observation. It appears that under the effect of lead the erythrocytes become faintly basic within so short a period as 24 hours after the initial dose, and that the granules become strikingly developed by the end of three days, if the dosage is continued

(White and Pepper). When this treatment is discontinued the granules disappear after the lapse of a variable length of time, which varies according to the amount of the lead salt administered, the gravity of the toxemia, and the susceptibility of the animal.

Grawitz succeeded in producing granular basophilia in white mice kept exposed continuously to a temperature ranging between 37° C. and 43° C., the change first becoming evident after eight days, and, as the animals later became accustomed to their new environment, quite disappearing in course of time. In these experiments it was observed that the development of the basophilia was associated with a distinct dilution of the blood, and with an obvious decline in the animal's health, and that as the granules disappeared, the blood again became normal and the animals apparently thrived, some of them remaining alive and well for months, in spite of their confinement and exposure to excessive heat. The results of these experiments have a certain clinical bearing, in that they tend to show that possibly some of the tropical anemias may be due, at least in part, simply to the effects of sustained high temperature, which in the newcomer to the tropics is prone first to excite an anemia, which later may disappear, as the individual becomes better adapted to the new surroundings and mode of life.

Grawitz has also succeeded in exciting at will distinct granular basophilia by the administration of various proprietary preparations of hemoglobin devised as substitutes for the different iron preparations in the treatment of anemia. The exhibition of such drugs in ordinary dosage was promptly followed by a basophilia, which was aggravated by increasing the dose, and which soon disappeared after the medicament was discontinued. These results were observed both in anemic and in healthy individuals, but the basophilia developed much more rapidly and more strikingly in the former. From these observations, it appears that the presence of blood in the gastrointestinal canal is attended by the elaboration of certain unknown toxic substances, possibly evolved by the action of the intestinal bacteria of decomposition upon the hemoglobin preparation ingested, and that the absorption of these noxious principles acts deleteriously on the blood cells of the individual. This action Grawitz terms "plasmotropic," or one whereby the poisons in some manner influence the bone marrow, the liver, and the spleen so that they provoke increased destruction of the erythrocytes. In direct contrast to this form of blood destruction stands the process known as a "plasmolytic" action, or one by which the cells are destroyed in the blood stream, with the consequent super-vention of hemoglobinemia.

Among the noxious substances by the administration of which it is possible to excite granular basophilia are tin chlorid (Löwenthal), copper (Sabrazes, Léger, Bourret), pyrocin, atropin (Strauss), methylene-blue and tolylendiamin (Bloch), and phenylhydrazin (Kaminer and Rohnstein).

*Clinically*, granular basophilia is encountered in a variety of anemic conditions, chief among which are lead poisoning, pernicious anemia, leukemia, malarial fever, intestinal helminthiasis, sepsis, and malignant disease. In addition to these conditions, many of the secondary anemias, resulting from other factors, also are associated with this change.

*Lead poisoning*, be it symptomless or frankly developed, is the one condition in which granular basophilia is constantly found. In fact, it is possible to demonstrate this sign in lead workers and painters who show absolutely no other manifestations, either subjective or objective, of saturnism. In such cases the erythrocytes are studded with these granules long before other blood changes supervene, and before the patient's gums become discolored, his wrists powerless, his bowels constipated, and his headache and abdominal colic annoying. Moritz first demonstrated this fact in a series of six cases, and

later Hamel obtained similar results in 25. White and Pepper examined 21 lead workers, none of whom had symptoms, and found the granules in every case, about one-half of which also showed moderate corpuscular anomalies, chiefly defects of size and shape, and a few, atypical staining and normoblastic nucleation of the cells. Simon found granules in 20 lead workers, but two of whom had active symptoms.

The fact that pallor, without decrease in the number of erythrocytes and loss of hemoglobin, is a familiar objective symptom in many lead workers, formerly was regarded as a proof that this class of artisans was only apparently anemic, the source of the deception being referred to a general vasomotor constriction thought to be due to the effect of the metal. The presence of basophilia in such instances, however, dissipates this error, for it shows that, although perhaps there is no notable deficiency in the number of erythrocytes and their hemoglobin content, the cells are, in reality, distinctly degenerate. As the systemic effects of the lead toxemia disappear under treatment, the granules also disappear, usually in from four to six weeks after proper elimination has been instituted. While the presence of granular basophilia can in no sense be interpreted as a conclusive sign of plumbism, it is of symptomatic value in doubtful cases. As a negative piece of evidence, too, it is of utility, for the absence of basophilia in an individual whose symptoms suggest saturnism is a fairly reliable indication that this intoxication is counterfeited by some other lesion, such, for example, as a gastric neurosis or an appendiceal colic.

In *pernicious anemia* basophilia of the erythrocytes is practically a constant blood change in every well defined case. It has been uniformly present in the last six consecutive cases of Biermer's disease which I have had occasion to examine with this purpose in view. But, although this disease illustrates primary anemia in its most intense form, it cannot be said that the abundance of the granules corresponds definitely to the degree of the blood impoverishment; it can, however, be positively asserted that they become less numerous, and may even disappear, during the periods of temporary improvement in the blood and in the patient's general health, only to reappear as the inevitable relapses occur. Under these circumstances the behavior of the granules corresponds to that of the nucleated, deformed, and atypically colored erythrocytes, and, with them, it constitutes a rational means of determining the progress of the disease.

In both forms of *leukemia* the granules are also found with great constancy, but they do not seem to be so numerous as one would be led to expect, judging from the other striking blood changes which accompany this type of anemia. From a limited number of cases at my disposal, I have been unable to determine whether or not any relation exists in leukemia between the abundance of the granules, the height of the leukocyte count, and the behavior, quantitatively and qualitatively, of the erythrocytes. In the late, anemic stage of *Hodgkin's disease* the granules appear in the majority of instances, but they are not to be detected early during its course, when the blood shows little or no deviation from normal.

The *malarial fevers* involve erythrocytic basophilia in the great majority of cases, especially in those in which the cachexia is marked and the anemia of high grade. In our service at the Jefferson Hospital, where many cases of tertian fever and an occasional estivoautumnal infection are treated, we have come to consider basic granulation almost as familiar a blood finding as the presence of the parasites themselves.

Corpuscles containing small parasites may also show the granules, and the latter may be found in the uninfected erythrocytes. Plehn, who was the first to call attention to the presence of these granules in malarial fever, assumed that they resulted from the disintegration

of the corpuscles by the parasites, but in addition to this direct action of the latter upon their cellular hosts, the change must also develop in consequence of the deleterious effects of the circulating malarial toxins.

Certain *intestinal parasites* are capable of causing not only profound diminution in the number and hemoglobin value of the erythrocytes, but also striking defects in their stroma. Both Schaumann and Jawein have described these combined changes in the severe anemia secondary to *Bothriocephalus latus* infection, while Grawitz's studies tend to show that basophilic granules are a prominent feature of the blood picture in the anemia of ankylostomiasis or uncinariasis. Their occurrence in this form of helminthiasis he attributes to an auto-intoxication due to the absorption of a toxic substance developing within the patient's intestine in the blood there collected by the constant capillary oozing provoked by the hookworm. In this instance another illustration of a so-called plasmotropic action of an absorbed toxin is also afforded. According to this theory (which as yet lacks substantiation) the toxic material presumably elaborated by the parasite appears to be of distinctly secondary importance as a factor of the blood changes in this infection.

In *septic conditions*, whatever their origin, the erythrocytes are prone to show basophilia, but with great inconstancy, according to the reports at present available. It is possible that this change develops in direct relation to the deleterious effect, in the individual case, of the septic poisons which are known to produce in grave infections the rapid onset of an anemia of the most intense degree, as well as a marked leukocytosis. Similarly, in *carcinoma* the presence of basophilia is thought to depend upon the toxic effect of the products absorbed from the growth. In this disease it appears that the change occurs only in those cases in which the neoplasm is situated so as to allow free absorption—for example, granular basophilia has been found in gastric and intestinal growths, but not in uterine cancer, even in advanced stages. But in cancer of the stomach and intestines, if they are associated with hemorrhage, another determining factor is naturally suggested, namely, the effect upon the circulating erythrocytes of the noxious substances absorbed at the seat of the bleeding. In this connection it may also be noted that the ingestion of blood, as in the case of tuberculosis with pulmonary hemorrhage, may account for the presence of basophilic erythrocytes; and that liver cirrhosis, peptic ulcer, and other lesions associated with hemorrhage into the gastrointestinal tract, must also be regarded as factors of this pathologic finding.

In *chlorosis*, granular basophilia is extremely inconstant, and the determining factor of the change in this disease remains obscure. Judging from my rather limited acquaintance with this phase of basophilia, I must agree with the general opinion that the erythrocytes in chlorosis but rarely show this degeneration, in spite of their striking hemoglobin deficiency, as well as of the structural alterations which they sometimes exhibit. Stengel, on the contrary, found that the granule cells were abundant in 11 of the 18 chlorotics whom he examined, although only in a single instance were the granules themselves numerous; in all of the 11, polychromatophilia was also demonstrable, but it stood in no definite parallelism to the degree of coexisting basophilia. May it not be that the latter, when it does develop in chlorosis, may be traced to the effects of intestinal auto-intoxication?

*Tuberculosis* does not appear to produce basophilia but if a septic infection be engrafted upon a tuberculous process, the change is prone to supervene. Among the many conditions in which basophilia does not tend to occur are diabetes mellitus, syphilis, influenza, and measles.

In conclusion, an analysis of the foregoing remarks, stripped for clinical application, appears to justify these deductions:

1. The viscosity of the erythrocytes is influenced by cellular and plasma alterations, the nature of which is obscure. The viscosity is exaggerated by the direct influence of various toxic agencies, and is diminished in many anemic states. This phase of cellular pathology is interesting from an experimental point of view, rather than as a finding of clinical application.

2. Simple decoloration illustrates the earliest retrograde change affecting the erythrocytes, and its intensity generally corresponds to the severity of the anemic process by which it is excited. The change may exist alone, as in the milder forms of anemia, or it may be combined with graver necrotic degeneration of the cells, in anemias of greater severity.

3. Deformities of shape and size are common to all pathologic blood, the degree to which such changes develop being related to the intensity of the blood impoverishment. Megalocytosis is a more serious sign than microcytosis.

4. Atypical staining of the erythrocytes betrays an impairment of function, and, as a rule, is found most commonly in corpuscles whose hemoglobin content is subnormal. It is most striking in anemias of the primary type.

5. The prevalence of megaloblasts indicate a fetal reversion of the bone marrow, and stamps the blood changes as pernicious, except in the anemias symptomatic of *Bothriocephalus latus* infection and of nitrobenzol poisoning. The presence of megaloblasts indicate a severe anemia, but not necessarily one of fatal outcome.

6. Granular basophilia, whatever may be its exact origin, should be interpreted as a sign of degeneration. It is a constant blood finding in but a single condition—lead poisoning—but is associated with many diseases involving a variable degree of blood deterioration. The experimental basophilia excited by the administration of preparations of hemoglobin warrants a doubt as to the wisdom of using such medicaments as substitutes for iron in the treatment of anemia.

**Condition of Adult Blind.**—A bill has been introduced into the Pennsylvania Legislature which authorizes the appointment of a commission of three persons by the Governor to investigate into the condition of the adult blind, and to consider the question of establishing State industrial training schools or other institutions for them.

## AN OPERATION FOR CICATRICIAL CONTRACTURES OF THE UPPER EXTREMITIES.

BY

A. H. TRAVER, M.D.,  
of Albany, N. Y.

Instructor of Anatomy and Surgery, Albany Medical College; Attending Surgeon to Child's Hospital; Assistant Surgeon, Albany Hospital.

It would be a tiresome task for one to review all the numerous operations that have been performed for the purpose of curing cicatricial contractures, so I will proceed at once to the description of my case:

CASE.—L. W., a male, aged 7.

*History.*—As the patient is an orphan it is impossible to obtain a very complete history. A friend states that when the patient was 4 years old, while pouring oil on the fire he sustained a severe burn of the right arm. This was followed by

about beneath the skin. The arm was practically useless. There was slight motion at the elbow, but none in the wrist. The patient was unable to feed himself or even touch his face except with the back of his wrist. If he tried to raise any weight it caused severe pain in the wrist.

I began treatment of the patient feeling that the arm was of no use in its present condition and hoping that something might be done to place him in a condition to earn a livelihood.

*Treatment.*—First operation was performed February 8, 1902. A band of the cicatricial tissue 10 cm. wide surrounding the elbow was dissected away, leaving a small strip of fairly normal skin 2 cm. wide along the inner surface of the arm. This permitted the arm to be placed in nearly complete extension—complete extension, however, being prevented by the contracted biceps muscle. It was thought advisable not to interfere with this muscle, as the slight flexion would be of little hindrance to him in performing his work in after years. I then raised from the side of the chest a flap of skin 12 cm. broad by 20 cm. long, the ends of this flap being left intact to keep up the circulation. The skin on either side of the chest from which the flap had been raised was dissected up and by means of tension sutures brought together as much as possible, thus closing about one-half of the

Fig. 1.—(1) a, ulcerated surface; b, scars of previous operation. (2) a, area to be denuded; b, flap to be raised. (3) a, area denuded. (4) a, arm beneath skin of chest.

drawing up of the arm. Nothing is known of the treatment carried out at the time of the injury. In October, 1900, he was operated upon by another surgeon. This operation consisted in making transverse incisions .5 cm. apart through the cicatrix involving the elbow, and the application of an anterior straight splint. No attempt was made to straighten the wrist. The splint was worn about 10 weeks, but after its removal the arm became flexed again to practically the same position as before the operation. The patient came under my care at the Child's Hospital in February, 1902.

*Examination.*—Patient was poorly nourished, very anemic and exceedingly nervous. The elbow was flexed to an angle

gap. The arm was then drawn through beneath this flap, thus covering the surface on the arm from which the cicatrix had been dissected away. A strip of gauze was drawn through beneath the arm to prevent its growing fast to the chest. Dressings were applied and arm and chest put up in plaster-of-paris. Operation was followed with but slight fever and patient complained of but little pain. Dressings were left undisturbed for 18 days, at which time the flap had become firmly adherent to the arm.

The second operation was performed February 26, 1902. The ends of the flap were severed from chest, brought about the arm, and sutured in place, thus completely covering the denuded area on the arm. In bringing the flap about the arm we found we had a small piece of skin in excess of that required, so this was utilized as skin grafts on the chest. Sterile dressings were applied.

The third operation was performed May 1, 1902. A band of cicatricial tissue 7 cm. wide surrounding the wrist was dissected away, leaving a strip 2 cm. wide over the extensor surface. The tendons of the flexor carpi ulnaris and radialis were so tense that it was necessary to lengthen them 2 cm. Even now, after removal of cicatrix and lengthening of the tendons, the wrist cannot be fully straightened owing to the deformed condition of the carpal bones. A flap of skin 10 cm. wide was raised from the right thigh and the hand

slipped beneath. This flap was sutured to the wrist. Sterile dressings and plaster-of-paris were applied. This dressing was left on for 14 days.

The fourth operation was now performed. The flap was severed from the thigh and brought about the wrist in the same manner as at the elbow. Skin grafts were removed from the opposite thigh and applied to the surface from which the flap had been taken.

On June 11, 1902, the patient went to the Orphan Asylum. The elbow, wrist, and chest were healed. There was still a

Fig. 2.—(1) A, flap separated from chest and sutured to arm; B, arm to be denuded. (2) A, cicatrix dissected away. (3) A, arm beneath skin of hip. (4) arm free from hip.

of 70°, the wrist to a right angle. A cicatrix extended from the shoulder to the metacarpophalangeal articulation. The entire circumference of the arm was involved, except a strip 2 cm. wide along its inner surface. The cicatrices at elbow and wrist were firmly contracted. Through the cicatrix at the elbow were seen the transverse cicatrices of the previous operation. There was an ulcer 1 cm. in diameter over the olecranon that had been there for over a year. Owing to the overflexion of the wrist, caused by the cicatricial contracture, the scaphoid and semilunar bones were dislocated and could be moved freely

slight area on the thigh unhealed. The elbow was practically straight, but the wrist was still slightly flexed.

Several times during the summer I have applied plaster-of-paris dressings to the wrist, holding it in as extended a position as possible until the plaster hardened, hoping thereby to get the carpal bones to return to their normal position. Each time there has been an improvement, so that now the wrist is

Before operation.

straight, as can be seen by the photograph, but complete extension is impossible.

In the beginning the arm and wrist were drawn in complete flexion and were useless to the patient. He would doubtless never have been able to have sustained himself. Now, although the arm is not as shapely as the other, yet it is nearly straight and is very useful. He is able to play games, can feed himself, and is learning to write. He can raise ten pounds weight with this hand and will be able to earn a living.

This manner of treating cicatricial contractures of the elbow and wrist may have been previously carried

After operation.

out, but I am unable to find any similar case described in literature. The only case in any way like this that I can find described is that of Schoeder's in the *American Journal of Medical Sciences*, October, 1900. (This article had not been seen by me until after completion of my case.) He raised a flap of skin from the thigh to cover the palm of the hand. In this article he states that in order that the flap may retain its vitality there must be no tension on it. In my case tension was of necessity put on the flaps by the passage of the arm beneath them, but it did not interfere in the least with their vitality.

## GLYCEROL OF IODIN.

An Old-new Remedy for Tuberculosis, Chronic Bronchitis, Chronic Pleurisy, Goiter, Etc.

BY

T. W. WILLIAMS, M.D.,  
of Milwaukee, Wis.

The modern tendency is too much toward new remedies, instead of improving older and better known ones. The object of this article is not to announce a newly-discovered remedy for the diseases mentioned, but to suggest experiments on suitable subjects with an old one in a new form. My observation during a practice of 40 years has convinced me that we have not in the entire range of the *materia medica* a more valuable therapeutic agent in strumous affections than iodine, provided we can bring it in conjunction with the diseased tissues in an assimilable form. In fact, therein lies the whole secret of its curative powers.

We are well aware of the destructive influence of iodine upon microorganisms of all kinds, from the most harmless bacteria to the most virulent anthrax, when added to cultures in a soluble form, and hence in that of infinitesimal division. But we also know that the extreme drawback to its general use has always been the apparent impossibility of administering it therapeutically in this form. But this difficulty I believe has been overcome by using it in the form of a glycerol, and I will give my reasons for my faith. Dissolve an ounce of iodine in a pint of alcohol, and you have the official tincture of iodine, a preparation which, at first blush, would seem to answer all the demands of a perfect solution and infinitesimal subdivision of substance. Yet we all know what an unsatisfactory substance tincture of iodine is for general therapeutic application.

The true reason of this is that an alcoholic solution of iodine is not a permanent one. The alcohol being much more volatile than the iodine is prone to part company with it on the very first opportunity, and deposit it in a metallic form, in which it is not oxidized and assimilated by the tissues. The same is true when tincture of iodine is painted on the surface. Quantities of it that would be absolutely poisonous if absorbed may be painted on the skin, in the region of glands, with perfect impunity, because the alcohol is speedily evaporated, and the metallic iodine is left on the skin, the only therapeutic effect secured being that of a counter-irritant.

But now let us combine that wonderful but indifferently appreciated substance, glycerin, with it and see what we will get. The alcohol goes where good alcohol is prone to go—off into the air—but glycerin, less volatile than the iodine itself, and a perfect solvent, remains, holding the iodine in such minute division as to render its particles absorbable, and they are absorbed by the venous and arterial radicals of the skin along with the glycerin, and in this way reach and enter into the tissues. We soon find that we cannot use the glycerol iodine *ad lib.* as we would the tincture; for although we can with perfect impunity introduce immense quantities of iodine into the system in this way, as compared with the small doses, 5 mg. to 16 mg. ( $\frac{1}{12}$  to  $\frac{1}{4}$  grain) that we can introduce hypodermically or per mouth, we will speedily induce symptoms of iodism if we push the remedy. My own method of administration is to apply from 4 cc. to 8 cc. (1 to 2 drams) of the glycerol iodine over the chest, in a streak along the sternum two or three inches wide, from the junction of the clavicles to the lower end of the sternum (in chronic bronchitis) or over the entire side, from the spine to the sternum (in old chronic thickened pleuras); and to repeat the application night and morning until symptoms of iodism appear, usually two or three days, then to omit a day, and resume with about the same dose once daily. It is not necessary to push it to complete

iodism, but stop as soon as buzzing and ringing in the ears and other nervous symptoms are complained of. In tuberculosis, with which my personal experience has been quite limited, I would make the applications over the seat of the dulness or localized tubercles. In goiter and enlarged glands, to which this method of administration is far preferable to hypodermic administration, I would apply it freely all over the gland.

A peculiarity of the glycerol iodine is that its application leaves no stain on the skin, like tincture of iodine, while it produces only a slight local irritation, which is due to the fact that the bulk of the metal is absorbed instead of being deposited on the surface.

My object is to call the attention of physicians who are conducting investigations along this line to this remedy, and thus reach those in a position to experiment clinically, as my own material is limited, owing to the fact that my practice is in a different line, and my opportunities for studying the effects of glycerol of iodine limited; so far, however, as I have had a chance to test the theory I have obtained some really astonishing results, especially in two cases—one a case of adenitis and the other of chronic pleurisy, both patients had thickened membranes of 20 years' standing. I have also had very promising results in two cases of chronic bronchitis, three cases of goiter, two cases of enlarged cervical ganglions, and one very obstinate case, in a negro, of enlarged glands in the armpit.

As to the effects of glycerol iodine upon the digestive organs, especially in cases of catarrh of the stomach and fermentive dyspepsia, I can vouch for their being most excellent. Digestion and assimilation in all my patients showed marked improvement, patients being able to eat with impunity foods that they dared not touch before, unless they supplemented the meal with artificial digestives. Some, in the habit of using digestive tablets after each meal for years, were able to dispense with them entirely. In fact, I may add digestion and general nutrition are invariably improved by glycerol iodine. I do not remember a single case in which this was not noticed.

Mercury in some form seems to be the best synergist of the iodine treatment, especially in diseases of the liver, and those in which syphilitic complication is suspected. I give .022 gram ( $\frac{1}{2}$  grain) mercury in the form of Moses Kidder's "Pearls" every night at bedtime for three days, then omit three days, to avoid the cumulative effects of mercuric iodide. As an eliminant, nothing is better than plain Epsom salts, one-half to one teaspoonful taken in the mouth dry and washed down with a few swallows of water. Quinine does not seem to be synergistic. In fact, malarial patients accustomed to using quinine would better discontinue it while using the iodine treatment. They do not seem to work well together. Many symptoms of iodism, in fact, are similar to those of quininism.

I trust this good, and simple, old-fashioned remedy, glycerol iodine, will be tested experimentally by those looking for new remedies for tuberculosis. It is possible that, like the king in the old story, wandering the world over in search of happiness which was to be found in his own breast—some are looking far afield for some magic serum that will kill the tubercle bacilli and heal the injured lung, while the thing sought, in the form of glycerol iodine, stands right by on your medicine shelf.

A few words as to my preparation of glycerol iodine, and I am through. Any physician with a pint flask such as is used for making chlorin gas, and a gas or alcohol stove, can make his own glycerol iodine. Put an ounce of iodine in the flask, and add 12 ounces of alcohol. Set the flask in a sandbath over your heater, and connect its neck, by means of a rubber tube, with a glass tube running down into a wide-mouthed bottle. The latter must stand in water kept cold with ice, or running water, to condense the vapors as they come over.

Use a gentle heat until the alcohol and as much of the iodine as it will carry over with it has been distilled over into the wide-mouthed bottle. All impurities in the iodine will thus be left in the flask, and you will have 12 ounces of alcoholic solution iodine which, when you have added to it four ounces of glycerin, commercially pure, will give you a pint of pure medicinal glycerol of iodine.

## CANCER OF MALE BREAST: REPORT OF A CASE.

BY

EDWARD A. BALLOCH, M.D.,

of Washington, D. C.

Assistant Professor of Surgery, Howard University; Surgeon to Freedmen's Hospital.

Believing that if all cases of cancer of the male breast were reported the proportion of these growths to similar growths in the female breast would be larger than that generally given (1-100), I desire to place on record the following case:

H. M., colored, aged 66, a farmer by occupation, was admitted to the Freedmen's Hospital, October 13, suffering from a growth in the right breast. He is a robust, well-nourished man, whose family and past history have no bearing on the present condition.

He states that three years ago the right arm became sore and painful and that soon after the right breast began to enlarge and has since steadily increased in size. When the enlargement was first noticed there was a discharge of a milky fluid from the breast, which, however, did not last long. There has never been any hemorrhage. No history of trauma could be elicited. There have been occasional attacks of lancinating pain and the breast has been painful when handled, especially the region about the nipple.

The patient is a man in vigorous health, all the vital organs being in normal condition. Both breasts are prominent. In the right mamma is a spherical, easily-defined growth 7 cm. in diameter. Two-thirds of the mass is hard and unyielding, but in the outer portion is a softened area, 2 cm. in diameter, containing fluid and suggesting the presence of a cyst. The nipple is retracted and painful to pressure. The mass moves freely on the pectoral muscles. Axillary glands not palpable, owing to excess of fat.

The growth was removed October 17, 1902, by the Meyer-Halsted operation, and the patient made a perfect recovery. Up to the present there have been no signs of recurrence, locally, in the viscera, or in the spine.

Macroscopically the growth is a greyish mass, with an apparent capsule. Running downward from the nipple and thence outward to the right is a hemorrhagic area, which communicates with the soft portion of the growth which was felt on palpation. This soft area contained dark fluid blood and some clots, as if a vessel had been opened by the extension of the growth and had caused hemorrhage.

The report of the microscopic examination, by Dr. Neil D. Graham, is as follows:

Under the microscope a section of the tissue reveals an alveolar arrangement of large, spheroidal cells, epithelial in character, which are irregular in shape and size. As a rule, no basement membrane is visible, but here and there cross-sections of acini may be seen, in which the epithelium has proliferated until the lumen is surrounded by several layers of cells. The surrounding connective tissue is somewhat dense and contains bloodvessels. Diagnosis: carcinoma.

The latest statistics on this subject are those of Warfield,<sup>1</sup> and to this compilation any one interested is referred.

**Criminal Statistics in France.**—Criminal statistics for 19 years, from 1881 to 1900, as officially presented by the Department of Justice, furnish interesting data for the study of criminology in that country. For several years previous to 1895 criminality in France augmented from year to year, but since 1895 there has been, on the contrary, a continual decrease. In 1900 the number of cases submitted to the jury was 2,283, as against 2,524 in 1899. Including cases submitted to the correctional tribunals, some 8,644 more cases were tried in 1899 than in 1900. Another point of interest is the progressive diminution since 1894 of the number of recidivists and also of first offenders. In 1899 the number of recidivists condemned was 89,594, which fell to 86,027 in 1900. Of first offenders there were, in 1899, 108,959; in 1900, 99,550. There has been a diminution in the number of accused persons completely illiterate and of those residing in rural communities.—[*Charities.*]

## CONGENITAL ABSENCE OF BOTH INFERIOR RECTI MUSCLES.<sup>1</sup>

BY

EDWARD STIEREN, M.D.,

of Pittsburg, Pa.

On August 22, 1902, Wilber S. A., a healthy, well-developed child, aged 6, was brought by his father, upon the recommendation of Dr. S. H. McKibben, to have his eyes examined preparatory to beginning school. His parents suspected "weak eyes," for the reason that the child would bend over and bring his face quite close to his picture book and toys. In other respects he appeared to possess good vision, recognizing distant objects as readily as did his parents. However, he would not run races nor romp with other children, and in this respect only did he appear different from his brothers and playmates. His parents attributed this to an aversion to becoming overheated, as he had suffered when 4 years of age an illness lasting about a week, said to have been due to a "sunstroke," in which he had not lost consciousness but had been rather apathetic for a few days, with some nausea and vomiting.

He had whoopingcough when 2, and measles when 3 years of age. There are two older and two younger brothers and a baby sister. All are healthy and sound in every respect, as are both parents.

*Examination.*—External inspection and palpation of the eyes reveal nothing abnormal. Globes are moderately prominent, lids have long curling lashes, irides are hazel brown, sclera, conjunctiva, and cornea are clear and glistening. Movements of both eyes inward, outward and upward are perfect. When asked to look down, however, the patient flexes his head upon his chest, his eyes not making the slightest movement below the horizontal plane.

The flexion of the head is not accomplished in one movement, but in several jerky nods, until the line of vision is sufficiently depressed to include the object sought, when the last nod centers his vision upon the object. Repeated commands to look at and name different objects (patient being illiterate) ranging in size from a silver dime to a felt hat, placed upon the floor from 4 feet to 8 feet in front of him, result in the same succession of downward nods, the article in every instance being correctly named. Ophthalmoscopic examination was negative, with about 0.50 D. hypermetropia in each eye. Pupils react normally to light and accommodation.

A local anesthetic (a solution of equal parts of adrenalin chlorid 1-1,000, and holocain HCl 1-500) was instilled into each eye several times and the conjunctiva grasped with fixation forceps at the lower corneal margin. Each eye could be drawn downward freely, but the upper lids, with the patient making efforts to look down, did not follow the downward movement of the eyeballs. The lower ocular conjunctiva was freely incised and retracted in a bloodless field, revealing a total absence of the inferior rectus in the right eye, nor could a small strabismus hook introduced find the slightest rudiments of an inferior muscle. A similar search in the left eye was refused by the child's father, but the condition must be without doubt the same; at any rate, there is no reason to suppose the existence of a paralyzed muscle in the left eye.

In presenting this case attention is invited to the rare occurrence of congenital absence of the extrinsic muscles of the eyeball. In the literature at my command I am unable to find a record of a similar case. A few of the textbooks make mention of congenital absence, but the absence of the same muscle in both eyes must always be a most remarkable anomaly. Yet, while its binocular occurrence is rare, it is more kind than monocular absence, since with the latter there would be troublesome diplopia with all its concomitants.

*Comparison of Brain Weights.*—According to a dispatch to the *Chicago Tribune*, Professor Marchand, of Marburg, has accumulated the largest number of brain weights ever published. He gives a thorough analysis of 1,169 cases. He says he finds the average weight of the brain of a male child at birth is 360 gms., and of a female child 353 gms. Although Professor Marchand shows a certain relation between stature and brain weight the relation is very inconstant. He concludes that the lesser weight of a woman's brain is not alone dependent on her smaller stature, as a comparison of both sexes of the same stature show that the male brain is invariably heavier. In a growing child, until it reaches a stature of 70 cm., the brain weight increases proportionately with the body length, irrespective of age or sex. After that the male brain begins to outstrip the female. The maximum brain weight is usually attained about the twentieth year, when the male's average is about 1,400 gms. The female maximum is usually reached about the seventeenth year, when the average is 1,275 gms.

<sup>1</sup> A case exhibited in the Section on Ophthalmology, Otolaryngology and Rhinology of the Allegheny County (Pa.) Medical Society, October 1, 1902.

## SPECIAL ARTICLES

### GLIMPSES OF THE PRACTICE OF MEDICINE AND DISEASES IN THE WEST INDIES.

BY

NICHOLAS SENN, M.D.,

of Chicago.

[Concluded from page 506.]

Jamaica is the largest and most valuable of all the British possessions in the West Indies. The last census showed a population of 706,344. Like in the other islands the negro population is increasing very rapidly, while the number of Europeans is rather on the decrease. A long range of mountains runs the entire length of the island from east to west. North of this mountain range rain is more abundant, the soil more fertile, the trees larger and vegetation more luxuriant than on the opposite, southern slope. The scenery along the north shore is superb, a Switzerland with palms. The many clear mountain streams and mineral springs add much to the attractions of this island for a perennial summer climate as a winter health resort. At the time of our visit the large hotels at Kingston and Port Antonio were crowded with visitors from the north. Port Antonio is by far the most beautiful spot in all the West Indies. The little city is nestled among gigantic palm trees at the base of the foothills, the narrow street is kept in excellent condition, the little huts of the negroes are quaint. The bread trees and bananas, the largest in the island, and the beautiful harbor present an exquisite foreground, while the forest-clad foothills overshadowed by the towering blue mountain ridge make a background such as cannot be equaled in grandeur and beauty in any other island of the West Indies. Port Antonio has the climate and the scenery to recommend it as a desirable winter resort.

Kingston, the capital of Jamaica, is a bright, wide-awake city of nearly 60,000 inhabitants. It has been decidedly progressive, as it is lighted by electricity and gas, has asphalted streets and a complete electric car service. The negro population, although poor, is not poverty stricken, as in most of the cities of the other West Indies. Outright begging is almost unknown. The sick and poor are well provided for by the Colonial Government. In all of the English colonies the poverty stricken are carefully looked after by the government, and in this respect have set an example worthy of imitation by nations which have similar obligations resting upon them. The organization of the medical service for the relief of the poor is deserving of the greatest praise, and should be studied as an instructive object lesson by our own country. The medical officers are appointed by and receive their pay from the government. In our country, as is well known, with very few commendable exceptions, the doctors are expected to give their services to the poor without any thought of recompense.

The Colonial physicians, by virtue of their office, are prominent in social and political circles, and receive a fair salary for their services. In none of the English colonies is the medical profession overcrowded. The admission to practise is well barred. In many of the British possessions only graduates of British medical schools are permitted to make application for license. In Jamaica, for instance, a graduate of any one of the Canadian medical schools would be required to take a post-graduate course in one of the European British schools before his application would receive consideration.

*Kingston Public Hospital.*—There are no private hospitals in most of the West Indies. France and England have well-managed colonial hospitals which, while they do not come up to our ideas of what a hospital should be, relieve a pressing need which the governments recognize. The Kingston Public Hospital is centrally located, easily accessible by electric car and is made up of a complex of buildings old and new, affording space for 350 patients. The large square around which the buildings are arranged is very attractive and is the gathering place for the convalescents. Dr. Charles W. M. Castle is the senior medical officer. The sick are cared for by eight female nurses, each of them assisted by one or two pupil

nurses. Provision is made for a limited number of private patients. The surgery practised here is the surgery of the English hospitals, rather antiseptic than aseptic. Among the most interesting operative cases shown were abdominal section for appendicitis, intestinal obstruction caused by bands of adhesions, radical operation for hernia, amputation at knee-joint, and trephining for intracranial traumatic hemorrhage. The last annual report (1902), Table V, gives a return of surgical operations performed with results—1,107 operations with 15 deaths. Certainly a very good showing when we glean from the same source that this table includes among other major operations a number of high amputations, abdominal section for ovarian tumors and myofibroma of the uterus. Chloroform is used exclusively as an anesthetic and carbolic acid is relied upon very largely as an antiseptic. On the other hand, the list of operations includes tooth extractions, operations on the eye, and counterirritations by the use of the actual cautery. The entire number of patients for the year amounted to 3,799. Among the most noteworthy diseases were typhoid, malaria, tuberculosis, and venereal affections, and their complications. The report alludes to the typhoid fever patients as follows: "There were 28 cases of this disease admitted with 12 deaths, a very high deathrate no doubt; but nearly all of the fatal cases were admitted in a very advanced stage of the disease, indeed little or nothing could be done for them." Malarial fever was most prevalent during the last five months of the year. The mortality from this disease was very small. Of 1,226 cases 18 proved fatal. The venereal cases numbered 206 and were classified as follow: Syphilis, 33; gonorrhoea, 90; chancroid, 83. The hope is expressed that the disease is on the decline. The five cases of tetanus proved fatal without an exception. Only one case of yellow fever is recorded and this patient died. In two amputations for elephantiasis of the leg the patients recovered. Elephantiasis and ankylostoma are rare affections here as compared with some of the islands further east and south.

*Cuba.*—The war with Spain has made us more familiar with Cuba than any other island in the West Indies. This event has given us ample opportunity to become better acquainted with its people and the diseases which afflict them. Our invading army reached the island at a time when the climate was most dangerous and the acute infectious diseases most prevalent. In a few weeks we lost nearly one-half of the fighting force by disease. The number killed outright by bullets was small compared with the loss from disease. The Spaniards passed through the same trying experience. It is well known that the Spanish army lost 50% of its fighting strength from the same cause in two months after landing in Cuba. The Spanish surgeon I met inside of the lines of the enemy, a few days before the surrender of Santiago, where we delivered to him, under a flag of truce, 16 wounded Spanish prisoners, informed us that when his part of the army reached Cuba the men were all in good health, and that then many were sick, and none well. He drew a sad picture of how their ranks were decimated by yellow fever, malaria, and dysentery. During the entire insurrection Cuba was at no time entirely free from yellow fever, and malaria is present more or less in most of the valleys and lowlands of the coast. Many of our soldiers were infected with typhoid fever in the home camps before they left for Cuba, and here all of the conditions were present for its rapid spread among the troops. Malaria, typhoid fever, and dysentery rapidly thinned out the ranks and file of our army, and when the troops returned every transport was a veritable hospital. American intervention has gained for Cuba not only the long-wished-for independence, but it has also brought another and perhaps greater blessing—almost complete eradication of yellow fever from this pest-stricken island. The wonderful results of modern sanitary methods are seen nowhere to better advantage than in the city made famous by the war.

*Santiago* is the oldest city in America, founded by Velasquez in 1514. Its present population is 40,000. It has now direct railway communication with Havana. Before and during the Spanish-American war Santiago was noted for its filth and pestilential air. The nearby Siboney, the base of our operations during the war, was shunned even by the coast fishermen, as it had gained an unenviable reputation as a neverfail-

ing focus of yellow fever infection. The moment the Americans took possession of Santiago a vigorous warfare against this disease was initiated and prosecuted without a let-up until this pest-hole was converted into one of the healthiest cities on the island. Dr. Leonard Wood proved himself not only a brave soldier but also a sanitarian of the highest merits. His sanitary measures have done more of permanent value for the Cubans in the city of Santiago and elsewhere than his bravery in the gallant charge on San Juan Hill. We arrived at Santiago Thursday, January 29. As we passed the famous Morro Castle the Cuban flag, a single star in the center of a red triangle, and the white and blue stripes, was displayed side by side with the familiar star-spangled banner, signifying that the single star owed its existence to and claimed the protection of the star-bedecked emblem of the great sister republic so near by. Any one who has not seen Santiago since 1898 would hardly recognize it today. The magnificent asphalt paved streets, the clean gutters and utmost cleanliness everywhere are in strong contrast with the conditions found here after the surrender in 1898. No such radical changes would have taken place in the same length of time had the Cubans succeeded in gaining their independence without outside assistance. Santiago is now a healthy city, made so entirely through the energetic efforts of the Americans during the few years of their occupation and rule of the island. Even now the odor of carbolic acid pervades the air in many parts of the city where disease had formerly its stronghold. A mountain stream supplies the city with an abundance of pure water. Business has improved, new industries are being established, and a general awakening is apparent everywhere.

Will the Cubans ever appreciate to the fullest extent what has been done for them by a modern form of government, the direct outcome of American intervention? Will the object lessons in practical sanitation witnessed by them during the last five years yield the expected fruit in the future? The future can only decide. To me the most interesting place in Santiago was the Civil Hospital.

*Civil Hospital.*—This, the only hospital for civilians, was formerly the Spanish Military Hospital. Material improvements and changes have been made to fit it for its present purpose. It is a very large, square, one-story brick building with a large open plaza or court inside for a number of large wards and ample space for the convalescents. The rooms of the outer or wall part of the building are largely devoted to the administrative part of the institution, offices, pharmacy, operating and dressing-rooms and a number of small wards. Here are also found those suffering from mental diseases. These patients are brought here for observation for a period of 30 days when, if found insane, they are sent to the Insane Asylum at Havana for treatment and further safekeeping. The medical staff consists of four attending physicians and two resident interns. An American trained nurse is at the head of the training-school for nurses. The training of the native nurses consists in lectures by the attending physicians and recitations and demonstrations by the head nurse. They are required to pursue their training and studies for three years; at the end of this time they are subjected to a rigid examination and if found qualified receive a certificate to this effect.

It is the expectation of the managers of the school that a sufficient number of trained nurses can soon be supplied to the well-to-do patients in the hospital and private homes. Provision is made in the hospital for private patients at the rate of \$1.25 a day. There are at present 252 patients in the hospital. During the last year it cared for more than 4,000 patients and 520 operations were performed. The operating-room is large, well lighted and equipped with all necessary appliances for modern surgical work. We were fortunate in finding Dr. Ramon Neyra, a member of the attending staff, on duty. He is a graduate of Bellevue Hospital Medical College, New York, and until recently practised his profession at Panama. He is a progressive man and takes a deep interest in the success of this new institution and the welfare and comfort of his patients. The scrupulous cleanliness throughout the institution speaks well for the industry and intelligence of the foreign and native female nurses. Among the more interesting cases shown was a case of chronic tetanus. The patient was treated by antitetanic serum and chloral hydrate and was on the way to recovery

after an illness of more than six weeks. Second, a case of gunshot wound of the neck. In this case a 30-caliber bullet entered the mouth, penetrated the tongue near the tip and was extracted the day before our visit through an incision in the posterior part of the neck. Also a number of radical operations for hernia and several cases of laparotomy for different indications were shown.

*Havana.*—The tourist who visited Havana before the Spanish-American war will be astonished and pleased at the remarkable changes which have taken place since. I saw Havana two years before the American army landed on Cuban soil. The Spanish flag then waved over Morro Castle and Spanish troops paraded the streets of the city. A guerrilla warfare was then in progress with the discontented, oppressed Cubans. Business was dull, and the merchants looked with apprehension into the uncertain dark future. The harbor reeked with filth, the streets were dirty, all improvements at a standstill. The water supply was contaminated, and sewerage was either entirely lacking, or at any rate very defective. Yellow fever had a firm and permanent foothold on the soil and in the many unsanitary dwellings of the poor. I visited the Spanish Military Hospital at that time. It was an immense ancient pile of stone and cement, without any indications of what modern surgery had accomplished. It contained a number of yellow fever patients, some of them in a dying condition. In the surgical wards I found a large number of wounded. All wounds were suppurating. Erysipelas, phlegmonous inflammation, osteomyelitis and necrosis were the rule in gunshot wounds of the bones. The surgeons who made their rounds used the same probe in examining the wounds, as they proceeded from ward to ward, without even taking the pains of subjecting it to ordinary cleansing, to say nothing of disinfection. Hands were washed when the work was done. What I saw at that time was the surgery of half a century ago. It is remarkable what changes have taken place since the American troops took possession of the city. The Spanish colors have disappeared from the flagstaff of Morro Castle, and its place has been taken by the flag of the newborn republic of Cuba. Back of Morro Castle, on an eminence rising from the sea, the Stars and Stripes wave over the camp of several companies of our soldiers who still remain to protect the interests of our country.

The wreck of the "Maine" sleeps in the clear water of the harbor as a silent reminder of the immediate cause which provoked the final struggle of the island for liberty and independence. Havana is now a prosperous, progressive city with 250,000 inhabitants. The well paved streets are models of cleanliness, the sewerage and water supply are the best in the world. Business is thriving and a general air of prosperity is noticeable on every side. Old buildings are being renovated and many new ones are in process of construction. Yellow fever no longer hangs over the city like a threatening cloud. A vigorous battle against its bacterial cause, inaugurated and prosecuted with unremitting energy by American sanitarians, has wiped out of existence this scourge from this part of the island. The Spanish Arsenal has been converted into a modern university, and the Spanish Military Hospital is now the General Hospital for the poor of the city, greatly improved and well managed. The "General Wood Laboratory" is a scientific institution of which a much older country might well be proud. Old Havana has discarded its ancient dress and has taken a place in an entirely new attire, well to the front in the ranks of the healthiest, most interesting and progressive cities of the present day. The marvelous changes which this city has undergone have been as radical as they have been speedy. Five years is a short time for a stagnant old city to pass through such a complete renaissance. All of this has been accomplished largely by American assistance, American intelligence, and by American energy and enterprise. It remains now for the Cubans to take up the work of maintaining what they have gained, and now and in the future to imitate the example of their well-meaning strong ally, to whom their gratitude should be sincere and lasting.

*Centro Asturiano Hospital.*—To the medical visitor the hospital facilities of Havana offer the greatest interest. The city is well provided with hospitals, private and public, nine in all.

In all of the places we had visited before during the cruise among the West Indies, none of the hospitals had desirable accommodations for private patients. In a few, pay patients were received, but none of them had private rooms. In Havana there are two public hospitals devoted to the care of the sick poor, the rest are private hospitals established and maintained by mutual aid societies. Of these the Centro Asturiano is decidedly the largest and the best. After visiting the Santiago Public Hospital, a most excellent institution, I was prepared to find a still better one in Havana. A visit to the Centro Asturiano, however, was a complete surprise—a revelation. I found here a model hospital equipped with all known modern improvements, a hospital which has no equal anywhere, excepting perhaps the Hamidié at Constantinople. We have many splendid hospitals in our country, public and private, but not one of them can compare with this magnificent structure in the infant Cuban republic. It is the property of the Central Asturian Society, an organization to which Cubans and Spaniards are eligible alike, all of the members of which pay \$1.50 a month, for which consideration they are entitled to free medical treatment at the dispensary and hospital. The branch

Fig. I.—Administrative building, Centro Asturiano Hospital. Fig. II.—Operating pavilion, Centro Asturiano Hospital, front view.

of the society which built and supports this hospital numbers 14,000 members, and has therefore an annual income of \$252,000. The present capacity of the hospital is 250 beds, and the number of patients 178. It is next to impossible to give a description of this hospital that will do it justice. The uninitiated visitor finds something new and novel with every step he takes. In the first place the site of the hospital is a well chosen one. It is situated on a tract of land which comprises no less than 100 acres, near the southern limits of the city, made readily accessible by an electric tramway. The hospital occupies the highest point of the hill, but is hidden out of sight by tall trees which line the avenue leading from the entrance to the buildings. As one enters the arched, artistic gate, he finds himself in a beautiful park with indigenous trees, shrubs, and a great variety of tropical flowers. Near the center of the park is an artificial lake, spanned at one end by an arched bridge of exquisite architectural design. Eighteen pavilions make the present group of buildings, arranged around a large park-like court. All of the buildings are one-story structures with solid stone walls of roughly hewn stone coated on both sides with cement, painted on the outside a faint blue and salmon color, and all of the door frames azure blue, which adds much to their attractive, pleasing appearance. The

inside walls and ceilings are frescoed, the details of which exhibit the good taste and great skill of the artist. All of the wards have a broad open space or passageway the entire length of the room with the comfortable cozy little private rooms with one and two beds on each side opening into it. The inner wall of the rooms is a frame partition with a space of at least five feet between it and the high ceiling, thus affording every facility for free ventilation of every room, or rather compartment. The wide central hall or passageway is furnished with chairs and small round tables. Here the patients who are not confined to bed take their meals, from one to four at each table. All of the floors are made of tiling.

At the time of our visit the principal meal of the day was served. The table ware was as good as in any first-class restaurant. The dinner consisted of roast beef, stewed Spanish peas, excellent white bread, vegetables, and a glass of Spanish claret. The operating pavilion is a study in itself. From a central passageway doors lead into the sterilization, disinfecting, instrument and anesthesia rooms. The large operating-room is reserved for aseptic cases exclusively and is faultless in its construction. The collection of instruments, all of them imported from Paris, contains everything the surgeon will ever need in performing any operation and much to spare. The instrumentarium alone represents the cash value of a small fortune. The sterilization-room is perfection itself. It is certainly a great privilege to operate under such perfect conditions and it is not difficult to understand why the results should not be within the range of all that is attainable in this age of successful surgery. One large pavilion is used as a storehouse, another for the reception of patients and sterilization of clothing and bedding. The kitchen is a separate building, equipped with every possible convenience. The washhouse contains the most modern machinery. The pride of the institution, however, will be the bathhouse that is nearing completion. All around the central, porcelain-lined swimming bath are bath-rooms for special baths, such as Turkish, Russian, douche, electric and medicated baths. It is impossible to conceive of a more perfect bathing establishment than this, and it is doubtful if it has an equal anywhere. A Chicago firm was the successful bidder for the construction of this part of the hospital, and the firm needs no better recommendation than the work done here. It would require too much space to describe in detail the many unique features of this wonderful institution for the sick, it must be seen to be understood and appreciated. Not a dollar has been foolishly expended, everything is simple and yet elegant and eminently practical. It will be for a long time an object lesson for all architects who are to prepare plans for new hospitals in our as well as more distant countries. The society employs three physicians at salaries ranging from \$150 to \$300 per month, and two resident internes. The number of female patients so far has been very small and these are cared for by a trained female nurse; the remaining nurses are males, most of whom received their training in the Spanish and Cuban armies. A corps of well-trained female nurses is all this hospital requires to place it at the very head of all institutions of its kind. The hospital on the present large scale was commenced six years ago, and new buildings are being added as the demands upon it increase. A few interesting points concerning the surgical work, I have taken from a report published in 1901. The chief operator is Dr. Manuel V. Bango. The statistics embrace all operations performed from March, 1897, to July, 1901. The number of operations was 2,066. Of these 2,057 patients recovered and only 9 died. This is certainly a record it would be impossible to duplicate elsewhere. The results undoubtedly are unexcelled, but it must not be forgotten that among the operations we find furuncle mentioned 152 times; cold abscess, 237; felon, 51; hemorrhoids, 39; enucleation of inguinal glands, 168; hydrocele operations by injection and incision, 327; fistula in ano, 29; gradual dilation of the urethra in stricture, 62; and many other minor surgical procedures which should not be attended by any mortality. Of the 120 Bassini operations for hernia 1 patient died; of 2 laparotomies for gunshot wound 1 patient died, and of 3 operations for strangulated hernia 2 patients died. During the same period of time the number of patients was 18,435. Of these 18,073 recovered and 362 died, a total mortality of 1.96%.

*Real Hospital de San Lazarus.*—The Royal Hospital of St. Lazarus is the asylum for lepers. It is an old two-story square stone and cement building, divided in the middle by a connecting wing which separates the open square or court into two spaces of equal size and which separates the male from the female patients. It has been the home for this unfortunate class of patients since the founding of the institution 50 years ago. Its inmates are under the watchful, tender care of the Sisters of Charity St. Vincent de Paul.

At present seven Sisters, with a long and trying experience, remain faithful at their post. Their willing hands and cheerful faces have done much in modifying the gloom that necessarily hangs over the inmates of such a home where there is so little hope of recovery or escape. The present number of lepers is 117. A second asylum for lepers, with 40 inmates, is located at Santiago. The laws of Cuba make segregation compulsory. A person suspected of having the disease is examined by a commission of three physicians, and if declared a leper is sent to one of the two asylums, where he is held until he dies or recovers. The Sister Superior made the statement that during the last three years two or three patients were discharged cured. In these cases it would be well to place an interrogation mark behind the diagnosis in the records of the hospitals. The youngest patient in the hospital is a boy of 12. One of the inmates, a Cuban by birth, claims he contracted the disease during a prolonged residence at Key West. He said he was covered with boils all over the body. His skin is now clear and he presents no evidences of being affected with the macular form of the disease. Visitors, relatives and friends are permitted to enter the hospital at any time of the day, but the patients are strictly confined. They are well cared for and appear to be as contented with their unhappy lot as circumstances will permit. The building is situated on the seashore drive, where the patients receive the benefits of the cool, refreshing ocean breeze.

*New Providence.*—New Providence is one of the Bahama group of islands, and is well known as a popular winter resort for tourists and invalids from the north. The number of inhabitants does not exceed 15,000. The little island is flat but is very attractive with its tropical foliage, graceful palms, ciba, cedar, silk cotton and tamarind trees, and luxuriant vegetation. Nassau is the seat of the English colony of the Bahamas. The Colonial Hotel, an American enterprise, is an immense and beautiful building facing the harbor. During the three winter months it is open to the public. For a midwinter rest it would be difficult to find a more soothing climate than Nassau and a more comfortable hotel than the Colonial. Dr. W. E. Bullard, a well-known New York physician, spends his winter vacations here and attends to the medical needs of the patrons of the hotel. His genial disposition and medical skill have earned for him a well merited reputation as a successful physician here and in New York. The city itself is quiet and orderly, and during the winter months the climate is delightful. The many beautiful drives, the sea bathing and yachting, the wonders of the unique sea garden, and the mysterious fascination of the "Lake of Fire," afford pleasing attractions for recreation and mental diversion and rest.

*New Providence Asylum.*—The Colonial Government of the Bahamas has to deal with a somewhat mixed method of taking care of its sick and poor. The New Providence Asylum, Nassau, is the only public institution for the dispensation of public charity. It is situated near the center of the little city on ample grounds, which have been improved only in part. It hardly deserves the distinction of a hospital. It was founded in 1832 and was at first intended as a home for the poor. In the course of time provision had to be made for the insane and lepers, so that by a gradual process of evolution it has become a combination of poorhouse, insane asylum, hospital, and leprosy, retaining, however, its original purpose as the preponderating feature. This complex and certainly very unique institution is in charge of Dr. L. D. Parsons, a charming personality. Dr. Parsons is a graduate of Edinburgh and has been at the head of the management of the asylum for a year. He has already made many important changes, and has in contemplation many more calculated to bring the asylum up to the standard of present requirements. The possibilities in this direction are

great and we wish our colleague the very best success in his humane endeavors. The buildings are all two-story stone and cement pavilions. The one that serves as a hospital has 40 beds. A trained English nurse with three colored helpers is in charge of all of the inmates of the asylum. The young colored women do not take kindly to nursing, as they do not look upon the occupation of a nurse as a profession. The greatest difficulty is encountered in securing the material, as the women prefer housework to hospital work. As soon as a probationer has been instructed in the performance of her simplest duties she is apt to leave as soon as a prospect of a more congenial employment presents itself. The nursing in all of the West India hospitals is very unsatisfactory, and will remain so until the colored women can be made to understand and realize the dignity and high standing of the profession of nursing. The last English nurse here held out for three years, when her health broke down from overwork, and the same fate awaits the one who has taken her position.

The poorhouse proper is the best building on the grounds, and Dr. Parsons has taken the necessary steps to convert it into a hospital and remove the inmates to the present hospital building, a most desirable change. The insane asylum in the same enclosure occupies the top of the hill, and has at present 40 inmates. A number of the male patients were engaged in chopping wood under the supervision of a guard. The lepers, 14 in number, live in a separate building, but are allowed to mingle freely with the other inmates of the asylum, and are permitted to leave and enter the asylum during the daytime when they choose to do so. There is no compulsory segregation in the colony of the Bahamas.

There are few abdominal sections performed, as the colored women suffering from myofibroma and ovarian tumors who occasionally enter the hospital invariably refuse to be operated upon. New Providence appears to be out of range of the tropical diseases we found so common in the more southern of the West India islands. Elephantiasis as an indigenous disease is almost unknown, and ankylostoma and abscess of the liver very rare. The most common disease is tuberculosis. Malaria of a mild type and its complications make up a large part of the statistics of the diseases of the islands. The water supply is cistern and well water, and although Nassau has no sewerage its soil is free from typhoid infection.

On board "Kaiserin Maria Theresa," Harbor of New York, February 6, 1903.

## HOW CAN THE STANDARD OF THE MEDICAL PROFESSION BEST BE RAISED?

BY

GEORGE V. N. DEARBORN, PH.D., M.D.,

of Tufts College, Boston, Mass.

In discussing this question it is quite unnecessary to demonstrate that the profession of medicine requires raising. What standard is high enough for the ambition of men and women who hold in their hands the issues of human life and death? The duties, responsibilities, and privileges of the physician exceed those of all other men save only, possibly, those of the ministry, and from certain points of view, instinctive but universal, to save or to prolong human life is the most precious privilege men know. Although, of course, the medical profession is made up of individuals, this problem of raising its standard is in no sense a personal question, but rather a very broad one of public utility, of economics. It is an unduly self-satisfied man, a person living in the spirit of trade rather than in that of a liberal and altruistic profession who can see no higher possibility for medicine than at present it often exhibits. It is no detriment to the best to say that the worst and even the average should be improved. Development is constant and progressive, but it comes only by thought and effort, and seldom or never by chance.

When one sets out to define in what particular respects the standard of practical medicine might be raised, seemingly with universal advantage, he has little way to seek. Sometimes, in pessimistic moods, it seems as if, with the multiplication of medical schools, this standard were trending downward at more

than a moderate pace. But in these following respects, at least, there may apparently be pointed out actual harmful tendencies in the profession, given here in the inverse order of their importance: 1. Many medical students are practising medicine legally, having passed their State license examination sometimes years before they attain to a medical degree. These are usually men clever beyond the average, but lacking necessarily in experience and competency. Here is a direction in which the antivivisectionists might seek new legislation to the public benefit, rather than to the public harm. 2. One observes too often in the medical graduate practitioner a youthfulness naturally incompatible in almost every case with his high and responsible calling. 3. One repeatedly has forced upon him the conviction that too often, even from a multitude so numerous as ours, there fall members of the profession into various abysses of quackery, and even of crime. 4. Many observers miss in medical men the ancient dignity which alone is appropriate in a profession of human life and death, which of all things are most dignified. 5. One sees the spirit of commercialism more common and more vigorous than the normal altruism of the real physician, which has always made him feel himself "his brother's keeper." This commercialism (in many directions outside of medicine the curse of our times) finds its chief expression in the great and increasing competition among physicians, thus intensifying their "struggle for existence," when for the best public interest there should be little of such competition. 6. Physicians do not often enough take an interest in public affairs, thus depriving the State of a point of view which would be of great value to it. 7. One feels that almost always in medical education the personal, individual element of influence is wholly lacking. One suspects that sometimes the instruction is too mechanical and too seldom devoted to the purpose of making the graduates cultured gentlemen as well as competent physicians technically. 8. Above all, one is continually aware, in recent years especially, of a general technical unfitness among the newer licentiates quite inconsistent with the ever-enlarging scientific art of medicine. The science expands much faster than it is acquired by its pretended masters.

The causes of these (increasing?) tendencies in the medical profession of America are hardly less obscure than the tendencies themselves. These causes are certainly fundamental and need careful consideration, if they can secure it, from us here. It is possible that a careful analysis of the business and social relations of the mass of practitioners would expose secondary influences at work which might, to some extent, account for certain of the unfortunate tendencies just enumerated. It is certain, too, that the propensities of society at large affect the medical profession as well as all other classes; one may instance the hurry and overeagerness for an immediate monetary success and the abnormal demand for enervating luxury. But these tendencies, as has been hinted, seem to be secondary and the primary conditions at fault further back in the mode of education of the physician. Once more, apparently one sees H. Spencer's "vibration tendency in events" exemplified, the pendulum, having swung from the old-time personal, preceptor system, has gone nearly to its opposite limit, and medical education has become too much a mechanical process, infused (as what is not?) with the hurry and the unadaptability of the machine. This is the more unfortunate because in no other profession is the practitioner the direct and immediate product of the curriculum by which he is "educated" in the degree that the physician is so. Aside from purely temperamental qualities, a man's or woman's fitness to care for human beings in disease comes directly and almost wholly from the courses he or she mastered in the medical school. The high degree of technicality now demanded in the preparation to practise makes this inevitable. The curriculums of these schools vary widely, no two being alike. In the old days, when practical work and the student's manual and ocular experience were at a minimum, this variation mattered comparatively little, for the textbooks and lectures of one school were as apt to be pedagogically good as those of another. Now, however, it is otherwise, and a medical school's usefulness to its students depends quite as much on its laboratories and their equipment and on its clinical opportunities as on its recitations and its lectures. One sees

demonstration of this in the disproportionate growth of the medical schools in the larger cities. Thus ever more important becomes the laboratory outfit of a school; proportionally better is the old and famous and hence wealthy college, and relatively worse fortune is it "to be compelled by circumstances" to attend an inferior school. But the large part of the 5,000 medical graduates each year in the United States come and will continue to come from institutions relatively poor in endowment and relatively lacking in equipment, and with entrance requirements adjusted to the demands of students with only a high school preparation. This is the average medical school, and these have average students—let us try to get their point of view of their medical studies. Considerable personal acquaintance among the students of four of our largest medical colleges forms the basis of these opinions.

The most universal feeling among the students of our best medical schools is that they are obliged to work very hard to carry out successfully their courses. Too many nights of every week are required for the average student, so he thinks, to keep up his theory when the practical work takes up almost all the day. To mere hard work no one can make objection, for it is useful necessary training for the grind and strain and wear and tear of practice. But overwork is a far different matter, and it does seem probable that a large percentage of our medical students may fairly be said to be overworked, especially during the first year or two of the course. Whether such a general statement could be substantiated or not, it is surely true (as in the public schools similarly in most cases) that too little allowance is made for the slower, but not therefore inferior, students. Overwork tends to nerve exhaustion and learning incapacity, and every medical instructor appreciates very well the difference between the capacity in this respect in October and that in May; one sees a distinct deterioration too often verging on exhaustion. But even overwork is not the worst that may be said of the student's notions on these matters. There is everywhere in all vigorous schools a deplorable sense of hurry, of insufficient time for even insufficient work, a feeling which of all things leads to mental indigestion. Medical education, fitting men and women for a serious lifelong profession, should not be conducted on the already decadent "quick lunch" plan, but it should rather be the stately, restful dinner as full of unhurried dignity as of solid nutriment and various flavor; human, not mechanical. One sees in many phases, if he look, the evil issues of this allpervading cramming system; the most useful knowledge is not thus acquired. The medical publishers know and are glad to advertise how many thousands of "quiz-compend" they sell, and the figures are a striking indication of the senseless hurry of the times; they indicate: Get facts, get them as quickly and as concisely as you can, or you won't have time to get enough to "pass" on. This is what the quiz-compend urge, and the students largely have accepted the advice. Indeed, urged by the hurried overwork, all they wish is facts with the illustrations to make them more easily remembered, and with a minimum of theory to make them understood. They are disciples of "Gradgrind." For the most part small interest do they take in well-founded hypotheses as yet unproved; it seems to many of them worse than a waste of precious time to study that productive mass of scientific and philosophic theory which alone makes medicine a profession full of the realities of life rather than the art of a manual trade. For these the average student thinks he has no time, since he knows that the technical facts are so numerous that relatively few matriculates have amassed even a moderate store. "Give us facts" they think, "for facts are tradeable for dollars if we have good luck, and they are practical and practicable; we would like, indeed, to know the theory of everything, and to understand it, but we haven't time." They largely seek medical knowledge, and not that better medical wisdom which feels and understands. If such is the average student's viewpoint (and is it not?), is the student at fault? The examinations tend to the same result of hurry and worry and unrelated systems of facts undignified by that broad viewing of things which should enlighten the student days of every medical candidate. What do many, too many, medical students wish even their facts for if not that with them as a sort of legalized "crib" on the sulci of their brains they may pass the dreaded "exams,"

and later on have fair warrant for the collection of their fees?

Besides this most unscholarly and sordid sense of hurry and of a desire for little else than marketable facts, many medical students deplore the mechanical nature of most curricula and this tends ever to force him to the average product's form rather than to develop that in him which he could best do. Sexual differences in the coeducational colleges get no consideration, nor the differences in the students due to various ages; still less does any course consider yet individual differences proper. To develop a medical course which shall take cognizance of this fundamental variety of individuals is a problem of the future, as it is in every other branch of human education. In the three-year or four-year course there can be no opportunity for adjustment even as basal as are these. This is no plea that specialism should begin in the medical school course, nor even a suggestion that specialism seems beneficial at all. Far from it. It is not what any student would become in practice that concerns us in this criticism, but only what he empirically is as a student, namely, an individual different from every other in his college and perhaps in fundamental respects the very opposite of some. Educators cannot remember too often that the "type," biologically, despite its usefulness in description, is a myth, an "idol of the theater," which the less it dominates any system of education the better for that system's success. Without discussing here the sexual differences in medical students (for our medical colleges for women are relatively few), we may note as the individual differences which chiefly concern us in this regard the great differences in manual aptitude and skill, and the diversity, certainly not less marked, in the individual capabilities of understanding relations, *i. e.*, in "common sense." With rapidly increasing force does the former consideration affect medical pedagogies, for the need of mechanical interest and skill increases rapidly with the development of elaborate laboratory courses and of many ever more complicated instruments of diagnosis and treatment. The latter circumstance, the individual differences in understanding, is of course a universal consideration, but it concerns no field more vitally than that of medical education. The average medical student feels he is unduly constrained in some direction or directions, and that his faculties would develop better and more broadly if given their own bent to some extent, and especially, perhaps, if he did not have to keep pace in all respects, particularly speed, with his better, or at least differently, endowed neighbor.

A fourth feeling occasionally observed to exist among medical matriculates, is that of a general unfitness for the work of the profession they have begun. This usually manifests itself in an indifference if not a positive dislike for medical art and science in some or other of their branches. Of these students many naturally drop out of the race before the time of graduation, commonly at the end of the first year or of the second; others persist for one reason or another and finally graduate. It cannot be doubted that from the number of these, misplaced in the occupation, many of the low-standard physicians come, for, uninterested in legitimate practice as a scientific pursuit, they naturally turn to one or more of the various degenerate excrescences of the profession. A moderate amount of personal attention to these while yet students would either afford them the needful interest in their work; adapt them to it, each according to his need and inclination; or show him very early in his course the mistake in his choice of a life pursuit, and so cause his withdrawal from it.

If these may fairly be claimed as feelings or opinions common among the students of our hundred and fifty-odd medical schools, there are other impressions which occur sometimes to their instructors. For example, the teacher of one of the fundamental sciences at the base of medicine is apt to be almost discouraged when he realizes how little of what every physician should know (and that before he attends his first serious case) the schools are able really to impress upon him as a student. The old practitioner, white-haired in the service of the suffering, knows that the same principle obtains in regard to the medical course as a whole; he knows what medical education really is, feeling strongly that it has been his experience of practice, and not his brief study in the medical school that has

taught him what (relatively) little he knows about normal and diseased humanity. This is the sort of man who best realizes the complexity of animal, and especially of human, life, for he has been taught by repeated baffling and phenomena quite unexplained that science still is young, however long has been the evolution of mankind. He it is who knows the utter inadequacy of even the best and longest medical curriculums today to educate the student to practise. The instructor also must be aware that however elaborate and numerous his illustrated lectures, however detailed and severe the recitations on the textbook, however long the laboratory work may continue, hurrying through as much practical work as possible, still that he has furnished to the student only a foundation on which he may build, if he care to do so, from the literature of the subject and from his experience; it is a mere syllabus of his one branch of instruction. Were this a question of general culture merely, or say of mining engineering, or even of theology, it would not matter so much, for the chance would be relatively slight that life and death would hang upon the knowledge or the ignorance of a given fact or principle. In medicine it is far different, for every added principle or bit of understanding, or of skill, or every fact that the physician knows may mean directly the saving some time or other of a human life or of useful years of happiness. The student rarely appreciates this serious side of the profession of medicine before his graduation (it comes to him soon enough afterward!) and he loses thereby one of the strongest incentives he could possibly have to thoughtful and conscientious work with brain and hand. The average medical student is not apt to rise to the importance, the responsibility, the dignity of his profession—he is never taught it—the curriculum affords no time! But it is just then, and usually only then, that a feeling of this dignity (made up of privilege and responsibility) would be of benefit in urging to him the necessity of fitness to the limit of his powers.

In another direction, but one of vast importance to the welfare of the profession, an instructor in a medical college has impressions once in a while and sees them corroborated oftener in the public press and in the executive committee meetings of the medical societies. Every medical school has students from time to time who are morally not fit to be physicians, to have the privileges, and especially the opportunities for evil, of the practitioner. The medical faculties in general scarcely rise to their responsibilities in this respect; they find no time in the course for personal acquaintance with the students, but are glad to shift responsibility of this sort on the clergymen or the physicians who present their signatures on the printed certificates of "good moral character." This is not a sentimental matter altogether, it has commonplace professional dignity behind it. The profession is disgraced alike in public opinion by the shame-faced abortionist, or worse, down to that lesser but not less wrong offense of advocating antivaccination in an epidemic of smallpox or of carrying a neuropathic zöophily to the stage of publicly advocating discontinuance of the production of antitoxins and the abolition of all animal experimentation. To pick out the morally defective from a class of students without much more than the present amount of personal instruction and familiarity, is of course impossible in its literal sense, but it is certain that were there time and arrangements made much of both public and professional good might be done in this direction in keeping responsibility from the irresponsible, and opportunity for crime from those who would probably use it, despite their Hippocratic oath. In this direction we see another argument favoring a degree of more leisurely personal supervision of medical students.

Another thing many medical instructors sadly miss is opportunity for research, and time for a degree of what one might call more medical culture. In the hurried rush of our present methods these are practically out of the question to the mass of the medical faculties. So exacting and interesting are most researches (especially to their performers) that they who do "original work" neglect their teaching duties more or less, while usually those who are good and conscientious teachers have no time for production. Thus the interests of the students in our present system and the advance of medical science are at variance, which should not be the case.

If one were to suggest the cause underlying these various

unwholesome conditions in present medical education no other word would probably express and explain so much as *hurry*. The keynote of our recent American life generally, this "motif," has gradually crept into and dominated even the instruction of those whom we would engage to save the very lives of our children and of ourselves. It matters little if the theologian missed from his seminary course a portion of the ages' dogma; it matters less if the lawyer has been denied access to some hundreds of cases, perhaps, which might had he known of them have saved him a client or two. But it does matter if the physician, final arbiter oftentimes of important issues in a scale of values which have no equals, gets less of information, of experience, of medical culture than he might obtain. Of all places the medical course is the last where there should be injurious haste, or mechanical instruction, or superficial practical, that is, clinical observation. Only one of these probable failings seems necessary in the present order of medical pedagogics, but on that one the others chiefly depend, and were that one remedied the others would quickly right themselves, so sound is the educational theory of our colleges today. That one is "hurry." It is the leading thesis of this paper that medical students need more time in which to fit themselves for the responsibilities of practice. Given this time some things would improve which now are the source of complaint from the student, his instructors, the physician, and the public. Give the students time to develop into practitioners. Give their instructors a chance, thereby, to get at them individually, that each may be accommodated to his needs, be given some degree at least of medical culture, absorb something of the dignity and responsibility of our ancient but ever renewed profession. So will the "good old times" of the personal preceptor in part come back again into the tremendously efficient system of our modern schools. In a word, it is high time that medical educators made an effort, as the physician of old made it, to develop in the future practitioners of the land a degree of individuality involving the careful learning and wisdom of the cultured and responsible gentleman.

*That to materially lengthen the course for the degree of doctor of medicine beyond its present maximum is both necessary and expedient is our contention.* We have already offered certain considerations showing that it is in general terms necessary; let us now more briefly discuss the arguments for its expediency. What changes in the economics of medical affairs would this further step in the successful progress of individual education bring about? First let us consider the financial relations of the question both as concerns the schools and the practitioners. Were the course increased from four years to say six, the annual tuition fee would have to be greatly increased or the schools would cease to be what they now are, self-supporting institutions, because at first the number of students might decrease markedly. But this is more or less problematic because it is certain that the college first making this obviously great advance would attract that large fraction of candidates who always wish the best on the sound business principle that, other things equal, the best is really the cheapest. The same consideration applies to the decrease in students, which many would anticipate because of the lengthened course aside from the increased money expenditure. Experience in this matter has shown that the best schools have the most students. The reliable common sense of the public has never been at fault in these directions and more of the best schools today are troubled by too many students than are worried by too few. Indeed, this is one of the arguments in favor of lengthening the time requirement—it might decrease the number of students and of graduates; as we have suggested already, however, it might not do so after two or three years.

If any one complains that to raise the fees of the medical schools will shut out many promising young men from the profession because of their lack of funds one may confidently answer that this fear is theoretic and not liable to be justified. College experience constantly shows that the best students, those excelling in moral, mental, and physical strength, are often the poorest. Such material only is adequate to supply the medical profession. The strong ambitious man dependent on his immediate productivity for living and college expenses is not going to be debarred from studying his chosen profession

by a thousand dollars added to his educational expenditure. The unambitious poor man medicine does not wish any more than it desires the unambitious rich man. Ambitious strength should be the criterion and given this minor obstacles are no bar. Yet, other things being equal, the son or the daughter of the well-to-do family makes a better physician than does the child of poor parents, and simply because his equipment for living, and especially his general culture, has been on a more liberal scale. For many, then, and those of the *a priori* best grade, the raising of the fees, and the extension of the years of the course would be relatively unimportant. Thus, apparently for the strong and ambitious poor man and for the well-to-do the added monetary expense would be far from disadvantageous, and these are the classes the profession needs.

The impression is widespread that the public welfare could get along with considerably fewer physicians. If then, making the medical course more costly and harder did reduce somewhat the graduate output for a few years the public would not suffer, while present practitioners would considerably benefit both in income and in experience. It would be a fair presumption, however, that the output would not materially decrease, for this has been the lesson of similar steps in the evolution of our present serviceable system.

Whether or not the supply of physicians decreased or increased, their *quality*, that is, their standards of attainment, of responsibility, of general usefulness in any community, would inevitably improve were they compelled to devote six years to preparation for public service, provided (as would doubtless occur) the additional time were devoted to educating influences and instruction practically lacking now. All through the course it would give opportunity for a thoroughness and a necessary culture due man's one profession of life and death.

The present agitation in favor of a three-year or of a two-year academic course such as President Butler, of Columbia, is said to support, bears importantly on the general proposition of this article, but it does not and cannot solve the situation. So far as we have plead for a higher standard of culture and of dignity in the just-graduated physician the "elevation" of medical schools to graduate schools would certainly solve the problem. Students who have the privileges of a bachelor course have a far wider and a far deeper understanding of things in general, of the proper values expressed in the term physician among the rest. But aside from this, because mainly of the high technicality of medical science, the college course, whether two or four years, has less to offer the expectant medical doctor than one might suppose; little indeed in the way of professional knowledge of a practical sort, although very much in the direction of psychophysical training for attacking the vast problems of medicine.

Whether or not the general adoption by medical schools of entrance requirements equal to a college education would raise the standard of the profession is after all beside the question, and for the reason that such general adoption is altogether improbable within a moderate length of time. Many youths have a predilection and a talent or a genius for medicine and surgery to whom a general college course would be tedious; the history of medicine points to many examples of this tendency, and one sees it today repeatedly, youths who have brought themselves up eager for this profession as a life-pursuit. Practical considerations appeal strongly to others, perhaps unduly for the general good, causing them to enter the medical schools as soon as they can possibly get in, with the intention, of course, of becoming self-supporting at the earliest possible day. Discouragement should meet this general attitude toward the profession of medicine, and the medical colleges can best provide it, and to their own benefit.

One cannot deprecate too strongly that often expressed feeling of regret that "our young men in the professions do not become self-supporting before the age of thirty." This is but part and parcel of that same commercial tendency previously deplored which wishes to make of the practice of medicine a means of wealth-getting and of an easy livelihood even to the inexperienced youth—at what expense of health and, at times, of life the victims only know. It has long been a scandal of the ministry that this tendency may be seen there, too, occa-

sionally; the times seem ripe that this should be deemed scandalous in medicine as well. It is not the mass of the practitioners of medicine that merit any such reproach, for few physicians indeed in middle life in one's acquaintance value their fees above their humanitarian and scientific interest in their life work. Provided with a competence for himself and his family, the average practitioner is content. It is the educationists looking too constantly with the eyes of the economist who deplore so frequently the late independence of the young professional man, and they do it at the expense of true philanthropy. A sufficient number of competent physicians is what the public good demands, and not, with short-sighted economy, an ever-increasing multitude of men self-supporting in their early twenties at the expense of their ill-served patients. Medicine demands the best of our manly and womanly intelligence, and loses caste when it allows its priceless knowledge and traditional dignity to become so cheap in time and money, the acquirement of an unchosen multitude of youth who see in medicine and surgery only a trade to be learned. It is going backward several centuries to the days of the barber-surgeon and the medical-apothecary, quite ignoring that earlier period, happier for the dignity of the profession which wars with death and pain, when the monk from the monastery practised medicine for the love of God and of man.

It is due the profession, not less than the public, that the average medical man should not be too early a successful money-getter. This is not a fault of the times, but rather one of the times' ways of expressing the proposition that professional men are manufactured too cheaply, and that a better fitness than heretofore is required to serve the public well. Medicine advances apace, far faster than does the system by which, alone, men and women may acquire acquaintance with it that they may serve mankind. The commercially-minded and cheaply-made practitioner of medicine is a public menace, when the physician should be society's most indispensable and wisest counselor and man's best friend. These he certainly is already in large part and will be, and yet it sometimes seems that he does not always rise to the achievement of his high privilege.

**County Commissioners to Establish General Hospitals.**—A bill has been introduced into the Indiana Legislature which gives a county commissioner authority to build, equip, and maintain general hospitals with or without the cooperation of private hospital associations. In case such an association does not exist, the commissioner is authorized to receive donations, legacies, etc., to maintain the institution. However, when an association does exist the governing board of such association will control the hospital and may select its own officers to govern it. Indigent patients are to be taken care of at public expense, while private patients will be charged the usual rates obtained in first-class hospitals. The cost of maintaining such an institution, over and above amounts received from private sources, is to be borne by the county.

**Serum Treatment of Typhoid Fever.**—The *Lancet* is authority for the following: "Sporadic cases of typhoid fever still occur every winter in Cairo and Alexandria, generally in English families where the greatest precautions are taken to prevent it. The water can hardly be the cause, but it is fair to suspect the milk-supply because the dairies are not yet under any government supervision. Professor Chantemesse, of Paris, during his recent visit to Cairo, drew the attention of physicians here to his method of treating the disease by anti-typhoid serum. He compared 1,478 cases treated in 15 Paris hospitals during the last two years by cold bathing and ordinary symptomatic treatment, which gave a mortality of 19.3%, with 186 cases treated at his hospital during the same time with only 3.7% of deaths. The only difference in the treatment was that he used serum in addition to cold bathing and other means. The serum does not, however, prevent perforation, for death occurred in three of his cases from this complication. He is extremely anxious to inaugurate one necessary reform in Paris, which he was pleased to find already existing in Cairo, that typhoid fever cases should be treated in special wards and not in general wards with too careless disinfection of excreta. Dr. T. Courmont, of Lyons, claims to have discovered the bacillus of Eberth in the blood of typhoid fever patients, even when the Widal reaction is not positive. In 33 cases he has now found it at times varying from the fifth day to the twentieth day, but he has never found it in any patient later than the third week. The method is simplicity itself, a culture is made of from 2 cc. to 4 cc. of suspected blood in from 300 cc. to 500 cc. of broth. A positive report can generally be given in 24 or 48 hours, but it is not safe to give a negative report until the fifth day of the culture."

9. Progressive Bulbar Paralysis. ALFRED C. COTTON.

**1.—Fractures Into and About the Elbow-joint.**—J. H. Barbat calls attention to the importance of a knowledge of the development in children of the ends of the bones involved. The Röntgen rays show the ossific center as a rule one year sooner than the date given in textbooks. Diagnosis of fractures cannot be accurately made without the Röntgen rays, and in this location the parts must be exactly approximated. The skiagraphs must be made in two places, with the arm extended and the two condyles on the same plane as the plate in one, at right angles with the arm flexed in the other. In those under 18 years of age pictures of the sound as well as of the affected side must be taken. It may be difficult to tell whether there has been dislocation of one of the epiphyses by either palpation or x-ray if there is no deformity. In these cases it is better to keep the arm splinted for two weeks if the child complains of pain or shows a disinclination to use it. Fractures of the olecranon are best treated by driving a long wire nail through the tip of the process down into the shaft of the bone without cutting if the fragment can be adjusted and there is no blood between the pieces. Steel staples may be used for broken off condyles, one prong in the shaft, one in the fragment. In cancellous bones, previous drilling is not necessary. [H.M.]

**3.—Points in Nephrorrhaphy and Herniotomy.**—F. P. Canac-Marquis, after incising the capsule of the kidney, passes a continuous silkwormgut suture down along each side, the ends entering and emerging through the skin at a distance from the incision. By pulling these taut the capsule is drawn apart, exposing a raw surface. The muscles are drawn over this surface by two or more figure-of-eight sutures, entering through skin and fat, crossing over and taking in all the muscles of the opposite side, then recrossing over the surface of the kidney to take the muscles of the side whence the suture started, recrossing again and taking in the fat and skin of the opposite side. A lead nickel-plated shield is threaded and shot and the shot crushed on the sutures. The "hooks" of Dr. Michel serve to make linear apposition of the skin. On the twelfth to fifteenth day the shot and shields are removed, leaving the sutures to loosen by the respiratory movements, so as to avoid pain or breaking in the final removal a few days after. In hernia, after freeing the sac, a continuous suture is inserted at the neck, following around the contour to the opposite side. A second suture is passed through the fundus. A Doyen needle is inserted 4 cm. above the pillars of the inguinal canal and 3 cm. internal, passing through skin, fascia, and muscles, and guided by the finger to the incision. The first suture is threaded to this and carried out at the point where the needle entered. The other end of it is carried out 1.5 cm. external to the first; 3 cm. external to the last point the second suture is carried out in a similar manner. When drawn taut the hernial sac is thus held between the parietal peritoneum and abdominal wall, making a bulwark above the ring. The wound is closed by the figure-of-eight sutures already described. The author also pictures an operation for shortening the round ligaments in which the inguinal ring and canal are sutured by means of the ligament itself. [H.M.]

**4.—The Mosquito as a Carrier of Disease.**—J. S. King thinks the experiments conducted in Cuba by the board for the "Study of the Etiology and Prevention of Yellow Fever" insufficient to warrant some of their conclusions, as the non-

immunes who escaped contagion from fomites prove no more than the nonimmunes who fail to develop the disease after being bitten by culex mosquitos which have been in contact with the diseased. All who are exposed to yellow fever do not take it, which is true of other infectious and contagious diseases. The mosquito theory does not adequately explain the erratic movements in infected districts, neither does it account for the transmission of malaria over the vast prairies and bottom lands of our rivers in former times. [H.M.]

7.—See *American Medicine*, Vol. III, No. 25, p. 1063.

**8.—Operative Treatment of Cystocele and Procidencia Uteri.**—E. C. Dudley describes these operations almost entirely by references to the illustrations. He figures two crescentic denudations on the lateral vaginal walls which he sutures in a direction perpendicular to their length, thus drawing the cervix backward toward the hollow of the sacrum. He makes an incision in the anterior wall extending from the cervix to the urethra, stripping the edges from the vesical wall by sponge pressure and removing the loose flaps with scissors, the edges being then united. The redundant vaginal wall near the urethra is best disposed of by uniting that part of the wound in a transverse direction, making the whole T-shaped when completed. These operations must be supplemented by a perineorrhaphy. In extreme relaxation of the pelvic floor he denudes around the front and sides of the cervix, drawing the posterior ends of the denuded area forward in order to bring the loose tissue on each side in front of the cervix, thus forcing the latter into the hollow of the sacrum. [H.M.]

1. The Clinical Significance of Arteriosclerosis. REGINALD H. FITZ.
2. Cesarean Section for Placenta Prævia, with Report of a Case. P. E. TRUESDALE.
3. Further Remarks on the Treatment of Placenta Prævia. FRANK A. HIGGINS.
4. Notes on X-light. WILLIAM ROLLINS.

**1.—Arteriosclerosis.**—R. H. Fitz considers it convenient to consider this affliction in its relation to the three groups of arteries, viz., central, peripheral and visceral. In central arteriosclerosis, in which are affected the aorta and its larger primary branches, excepting those of the heart and kidneys, the diagnosis depends on the age and the examination of the branches. Although most people over 50 have more or less aortic arteriosclerosis, there are numerous exceptions, and youthful individuals may have the disease. In peripheral arteriosclerosis the physical examination of the accessible arteries leads to diagnosis, although the evidence of an enfeebled circulation is usually furnished by the sense of discomfort—even severe pain and numbness in the extremities, and by the rapidly induced fatigue and cramps in individual muscles or muscular groups. The diagnosis of visceral arteriosclerosis depends upon the recognition of the various disturbances of function and the discovery of evidence of central or peripheral arteriosclerosis. [A.B.C.]

**2.—Cesarean Section for Placenta Prævia.**—P. E. Truesdale, from a comparison of many statistics, finds in complete placenta prævia an average mortality of 18.9%, and fetal mortality between 65% and 70%. It is this high mortality which it is aimed to reduce by cesarean section. In partial placenta prævia the maternal mortality by version scarcely exceeds 5%, but in obtaining this half the babies are sacrificed by obstruction of the circulation through the placenta and slow extraction; and the question arises cannot this fetal mortality be reduced by cesarean section without materially increasing the death of mothers? He says lateral insertion of itself does not justify a cesarean section. As a rule, simply rupturing the membrane suffices to stop hemorrhage, but cesarean operation would seem to be the best treatment for placenta prævia, complete or partial, when the child is viable, and when the diameters of the pelvis or the conditions of the soft parts render the operation of dilation and version, performed with sufficient rapidity to save the child, a dangerous procedure for the mother. [W.K.]

**3.—Treatment of Placenta Prævia.**—F. A. Higgins reports five cases of placenta prævia, in which all the mothers made good recoveries and the infants were born dead or died soon after. In only one case was there any possible chance for the child's life, and he had proceeded in all with the one aim of making the operation as absolutely safe for the mother as possible. Brief sketches of the cases are given, from which the writer is more than ever convinced of the comparatively low maternal mortality, even in complete prævia, when the patient is taken in charge and receives proper treatment immediately after the first hemorrhage, and that the chief danger lies in repeated or continuous hemorrhages. The great objection to slow extraction is that it means the death of the fetus, but until we have some other expedient equally safe for the mother we shall continue to advocate and practise this method. Perforating the placenta to do version he has found to be an easy matter, causing no maternal hemorrhage and very little to the fetus. He has yet to see a case in which he would think cesarean section advisable or justified; and he thinks the only occasion for it is complete placenta prævia with mother and child both in good condition, before the occurrence of severe hemorrhage, and with the os uteri undilated. Higgins also reports the case of a young primipara in which there had been considerable hemorrhage, but the fetus was at term and in good condition, os dilated two inches and completely covered by placenta. He judged the mother would stand immediate delivery; version was performed with immediate extraction and a living child obtained, but the mother died from shock and hemorrhage. This he attributes to an error in judging the patient's condition, and thinks he could have saved her life by slow extraction, sacrificing the child. [W.K.]

#### Medical Record.

April 4, 1903. [Vol. 63, No. 14.]

1. Observations on the Plague in the Philippines and India. Major CHARLES B. EWING.
2. Imperative Conceptions: A Study in Differential Diagnosis. L. HARRISON METTLER.
3. Examination of Milk by the General Practitioner. HENRY LARNED KEITH SHAW.

**1.—The Plague.**—C. B. Ewing was able to detect the bacillus pestis in the blood of only about 3% of cases when the examination was made at all early in the disease, but growing the blood on culture media gave positive results in some 30 cases in which it was impossible to determine its presence by staining blood smears. It was found in the blood in 90% of cases just before death. After continued suppuration for several days the organism ceased to be found in the buboes. Most Filipinos have enlargement of the glands, which must not be confounded with that due to plague. He found polymorphonuclear leukocytosis in all the 50 cases examined. This and the increase in blood plaques serve to distinguish the disease from malaria and typhoid. The writer discusses the bacteriology and types of the disease, the method of making Haffkine's prophylactic and the preventive and curative serum of Yersin-Roux. He does not consider Lustig's vaccine and serum as efficacious as the latter. Other treatment is symptomatic. Mortality is modified by hygienic surroundings and is greater among the Chinese than Filipinos, the latter being less dirty. Among Orientals ignorance, religion and caste tend to swell the large mortality list. [H.M.]

**2.—Imperative Conceptions.**—According to L. H. Mettler, the general practitioner should be well acquainted with this symptom of nervous debility, for he will see it in many patients not affected enough to require consultation with a specialist. A sharp distinction must be made between the imperative conceptions of the sane and insane. In the former the judgment is unimpaired. Insane delusions rule the patient; imperative conceptions can be at times controlled by him. Hallucinations and illusions rarely, if ever, bear directly upon the imperative conceptions of the sane; volition is free, while it is enthralled by insane delusions. Imperative conceptions of the sane do not lead to the taking of life. They may be a forewarning of mental breakdown, but are not necessarily indicative of existing insanity. A neurasthenic may be reasoned with about his fixed ideas; a victim of insanity may show only irritability

and disgust at your doubt in regard to his delusions. Treatment for the eradication of these imperative conceptions is both medical and disciplinary. Every organ in the body should be carefully interrogated. Insane delusions are the result of a diseased cortex; imperative conceptions are the result generally of disease outside the brain. Medicinal treatment alone will not avail with some patients. The habit once formed is hard to get rid of. They need advice frequently as to the character of their reading, studies in art, scientific amusements, etc. [H.M.]

**3.—Examination of Milk.**—H. L. K. Shaw writes with the purpose of outlining a rapid and simple method of examining either human or cow's milk. For analyzing mother's milk the whole quantity should be removed from the breast. Cow's milk should be well mixed. Milk containing many bacteria will have a high acidity. He describes easy tests for the percentage of acidity, for specific gravity, discussing its relation to the amount of cream and of watering, and tests for the percentage of fat, and gives a formula for the calculation of milk solids and a method of detecting formaldehyd. [H.M.]

#### New York Medical Journal.

March 28, 1903. [Vol. LXXVII, No. 13.]

1. Syphilitic Pseudotabes. Report of a Case; the Differential Diagnosis of Tabes. JOSEPH COLLINS.
2. Streptococcus and Staphylococcus Bronchitis. JOSEPH M. PATTON.
3. Intestinal Resection and End-to-end Anastomosis with the O'Hara Forceps in a Case of Tuboovarian Abscess with Appendicitis: Recovery. GEORGE GRAY WARD.
4. The Special Dispensary as a Factor in the Combat of Tuberculosis as a Disease of the Masses. S. A. KNOPF.
5. Opium in Surgery. EDWARD WALLACE LEE.
6. Retinoscopy. DANIEL H. WIENSER.
7. On the General Characteristics of Corneal Astigmatism. H. DAVISON SARIL.

**2.—Streptococcus and Staphylococcus Bronchitis.**—J. M. Patton discusses bacterial bronchitis, and presents three case histories in illustration and support of the occurrence of a form of bronchitis due to infection by streptococci or staphylococci or both, and probably primary, which exhibit more or less characteristic clinical features, and in some cases simulate the early clinical features of tuberculous infection. The cases observed by Patton in which staphylococci appeared to be the chief or only causative agent, as a rule, have shown a tendency to chronicity, mild type, scanty expectoration, persistent cough, and at times dyspnea of an asthmatic character. The cases due to streptococcus infection have shown the most definite clinical features. These are: A persistent and rather high temperature; a more or less generalized bronchial involvement presenting marked physical signs of bronchitis; a persistent and troublesome cough; rather free expectoration of heavy mucopurulent sputum, occasionally tinged with blood; occasional night-sweats; moderate rapidity of pulse; and aside from the disturbance from cough, a freedom from subjective discomfort rather suggestive in relation to the continuous, and at times, high temperature. Bronchitis may result from pneumococcus infection and be local in extent, moderately severe or mild in type, and with little disposition to extend. The most satisfactory results were obtained through tonics and alterative expectorants and the employment of soothing and stimulating local medication by deep inhalation. [C.A.O.]

**3.—Intestinal Anastomosis with O'Hara Forceps.**—G. G. Ward reports a case of successful intestinal resection and end-to-end anastomosis with the O'Hara forceps in a case of tuboovarian abscess with appendicitis in a woman of 26. Some of the advantages claimed for this forceps are: 1. One forceps only is required for any size of intestine. 2. It is not necessary to ligate or clamp the bowel as with the button or other methods as the forceps keeps the intestine closed at the site of the resection throughout the operation. 3. No manipulation or work inside the bowel is done, so that the advantage of cleanliness is one of the strongest points in its favor. 4. Perfect control of the work, the slippery intestines being held with great ease and allowing accuracy of suturing. 5. Its application is simple. [C.A.O.]

**4.—Dispensary for Tuberculosis.**—S. A. Knopf gives cuts showing the general plan and the entrance of the Emile Roux Dispensary at Lille, and puts in an earnest plea for special dispensary classes, or, better yet, specially constructed dispensary

buildings in our large cities for indigent ambulatory tuberculous patients. Such dispensaries would serve admirably as clearing houses from whence cases most suitable for other institutions could be selected, early cases that cannot find accommodation in existing sanatoriums could be cared for. They should serve to the patients who have left sanatoriums improved or with the disease arrested as a safe place to go to, not only in case of a relapse, but also to receive competent advice and guidance whenever necessary. [C.A.O.]

**5.—Opium in Surgery.**—E. W. Lee believes that opium and its alkaloids have a definite place in surgical therapeutics, and maintains that it is the injudicious use of this powerful therapeutic agent that has brought it into disrepute. He states that morphin is especially indicated in fractures, and that morphin hypodermically or opium by rectal suppository will often relieve spasmodic contraction of the vesical sphincter when catheterization is not only painful, but almost impossible. It is indicated in burns and is the first remedy indicated in traumatic or surgical shock if accompanied by pain or hemorrhage. It not only controls the existence of shock, but is a very potent factor in preventing secondary shock. The author's observations on opium habitues tend to disprove the assertion that the administration of morphin prevents the healing of tissue. Morphine hypodermically is indicated before the administration of anesthetics. Especially is this true if the individual is addicted to alcoholic stimulants and suffering from fever and nervousness. Obstinate and exhausting vomiting after ether or chloroform is often relieved by morphin given hypodermically, and if in the first 24 hours after operation pain becomes so severe as to cause uncontrollable restlessness this pain should be relieved by morphin. In abdominal surgery the administration of morphin should be attended with great caution and its effects closely watched, but it should not be withheld when by its proper use great relief and benefit may be gained. [C.A.O.]

**6.—Retinoscopy.**—D. H. Wiesner says that while the retinoscope is an accurate test of the refractive conditions of the eye, with slight exceptions, and while it is possible to measure the amount of error with the mirror and the plus and minus lenses it must never be the sole test for the prescribing of correcting lenses, but this in combination with the ophthalmoscope, the ophthalmometer, and the test lenses must determine the true correction. The purpose of this paper is to draw attention to the fact that in retinoscopy the physician who is not a specialist in ocular conditions has a test that, with some patience and practice, he can acquire skill enough to determine the refractive errors present in the case under examination. [A.B.C.]

**7.—Corneal Astigmatism.**—H. D. Saril regards astigmatism symptomatically and prescribes glasses accordingly. If the error is the cause of marked indistinctness of vision or causes regularly attendant asthenopia, lenses should be worn constantly. Should there be inconvenience, particularly when studying, reading, or using the eyes for near work, with approximately normal vision, glasses should be used only at such times. For the intermediate cases careful judgment is required. The patient's ocular comfort is the main criterion in determining the strength of the lenses. The full correction always harbors on the side of danger, with the result that the intended improvement proves as fatiguing as did the error uncorrected. Under correction in the myopic form and less than the full correction of the manifest error in the hyperopic variety is to be aimed at. [A.B.C.]

8. Expert Evidence: A Reply to Hon. John Woodward. WILLIAM LEE HOWARD.

**1.—Internal Secretions.**—O. T. Osborne has found thyroid one of the best treatments in scaly eczemas, the secretion of this gland seeming to control the softness and pliability of the skin. With atrophy of the gland between 45 and 50 the skin changes of old age begin, also endarteritis leading to atheroma. It relieves conditions due to high tension. In the opposite condition resulting from shock suprarenal hypodermically is indicated. The condition in the last stage of opium poisoning suggests its use as also the vasomotor ataxia of neurasthenia. The writer thinks the manifestations of hysteria may be due to misbehavior of the thyroid. In delayed menstruation with or without anemia he has found no drug so efficient. He has seen children with flabby skin, dull features, chronic eczemas, erosions and fissures, and enlarged cervical glands do better on thyroid than anything else. In diabetes suprarenal has diminished the glucose, diacetic acid, acetone and ammonia. Hyperthyroid feeding in Graves' disease has caused glycosuria. In gout thyroid not only relieves but is preventive. The headaches of acromegaly are relieved by pituitary feeding. Thymus, containing a large amount of nuclein, is valuable in tuberculosis. Theoretically it is indicated in hemophilia, scurvy and rickets. Osborne presents a case whose history strengthens the belief that red bone marrow produces red corpuscles and that feeding it will supply a deficiency in the latter. [H.M.]

**2.—Significance of Oxaluria.**—J. B. Ogden states that oxalic acid is a normal constituent of the urine to the extent of 0.02 gram in 24 hours. It exists in combination with calcium as calcium oxalate, which normally is held in solution by the monosodic acid phosphate. If the calcium oxalate is excessive it is precipitated from solution in the crystal form. Oxaluria may be very transient, or it may persist. Articles of food containing oxalic acid may be responsible for the oxaluria. Among these are sorrel, rhubarb, tomatoes, asparagus, spinach, onions, cabbage, etc. Baldwin has shown experimentally on dogs that the ingestion of meats and a large quantity of cane sugar or glucose caused a pronounced oxaluria. Partial or complete absence of HCl in the gastric juice, acute or subacute gastritis, and fermentative changes in the alimentary tract, are all attended by oxaluria. Indican, a normal urinary constituent, is much increased by fermentative changes in the gastrointestinal tract, which increase the indol, from which indican is elaborated. Such increase in indican is usually attended by oxaluria, and a common cause is probable. Calcium oxalate crystals may be primary—the large octohedral and most of the oval and dumb-bell forms—formed within the body; and the secondary or small crystals of the same form formed after the urine is voided. Mechanically, the crystals may cause irritation and the formation of calculi. [A.B.C.]

**3.—Prognostic Value of the Diazo-reaction in Pulmonary Tuberculosis.**—F. C. Wood's report is based on examinations and observation in 363 cases, in nearly all of which the tubercle bacilli were found. His conclusions are: 1. If the urine of a phthisic case shows no diazo-reaction and a kidney erosion can be excluded the prognosis is favorable. Only 10% of the moderately severe cases gave the reaction and in a number of these it disappeared on treatment. Early cases do not give the diazo-reaction. 2. If the urine of a phthisic case shows an occasional diazo-reaction the prognosis is not necessarily grave, as only 66% of the patients showing an occasional positive reaction die. 3. If the urine of a phthisic case shows a continuous strong diazo-reaction the prognosis is very grave, since a large proportion of such cases die within six months. 4. The presence of a diazo-reaction on the first examination of a patient should not debar the case from a thorough trial of climatic treatment in a proper sanatorium. [A.B.C.]

**4.—Hyperacidity of Urine.**—This article, by T. W. Hastings, deals somewhat technically with the chemistry of the acids in the urine. Little, however, is added which is of clinical importance. In his experience the best method of estimating the acidity quantitatively is that recommended by Nægeli, similar to the method for determining the total acidity of the gastric contents, using phenolphthalein as an indicator and titrating with a decinormal solution of sodium hydroxid. The normal acidity of the urine is due to the acid salts of phosphoric

acid. Of 40 patients, in which various diseases were represented, all complaining of disturbance of micturition, an examination shows the urines of 30 to be normal as to acidity. The 10 with hyperacidity suffered no more inconvenience than the others. In 19 cases of urethral and bladder disturbance suggestive of inflammation, no cause other than a neurotic individual and hyperacidity of the urine was found, and relief followed attention to the nervous condition and the administration of alkalis. In 21 cases of neurasthenia, all complaining of disturbance, among other things of micturition, 14 were found to have hyperacidity of the urine, corrected by persistent administration of the alkalis. This suggests a neuropathic origin for hyperacidity in many cases. [A.B.C.]

**5.—Prognostic Significance of Albumin in the Urine.**—E. W. Lambert expresses his views from the standpoint of a medical examiner for life insurance of many years' experience. He has little faith in the so-called physiologic albuminuria. The albuminuria of adolescence occurring from 17 to 30 is for the most part temporary, and the prognosis is relatively good. The microscope gives less aid to correct prognosis than is commonly supposed, for casts of any variety may occur temporarily and without serious import. Hyaline and granular casts are not infrequent in urine free from albumin. Indicative of the frequent transient character of albuminuria and casts, the author states that experiments made upon members of the medical staff with which he is connected showed it rare for any member to go for six months without transient albuminuria and casts. Prognosis depends more upon the daily life of the individual than upon the findings in the urine. Intemperance in any of its many forms compels a bad prognosis in any case in which albumin appears in the urine, especially after 30, whereas many patients with albumin live for years, the habits of life being corrected. [A.B.C.]

**6.—Narcotic Abuse.**—J. B. Mattison believes that narcotic inebriety in America is on the wane. There has been a steady decrease of late years in the use of these drugs by medical men. The danger now lies in the lawless sale of many nostrums in which morphin and cocain play the largest part for harm. We need an act making it illegal to sell these alkaloids except on prescription, which is not to be refilled save by order of the attending physician, and another compelling the maker of every nostrum to print the formula on the wrapper, with the amount of cocain and morphin to the dose in those preparations containing the latter. [H.M.]

**7.—Formalin Injections in Septicemic Rabbits.**—W. H. Park and W. A. Payne find as a result of their experiments that even after large doses of formalin streptococci and pneumococci can still increase in the blood. All the rabbits receiving formalin died before those receiving the streptococci alone. The fatal outcome of septicemia in man after diluted formalin injections should cause us to be guarded in using it. An intravenous injection of water plus sodium chlorid may prove better. [H.M.]

**8.—Expert Evidence.**—W. L. Howard admits that the medical profession is partly responsible for the present status of expert testimony. Its indifference and the lack of a national educational standard allows unqualified individuals to pose as representatives of progressive medicine. But the attitude of lawyers tends to drive conscientious men away from the courts. Lawyers often demand facts which the medical man considers professional secrets. In some States it has been decided that an unlicensed physician may testify as a medical expert, thus opening the way for osteopaths, Christian scientists, etc., to be pitted against a regular practitioner. It is the long and tangled hypothetical question put to the expert witness that displays the misunderstanding of the lawyers and apparently makes a fool of the doctor. The physician knows it would be possible to establish a reasonable degree of truth were not everything done to prevent it. The expert realizes that he is permitted to know only one side of the question. He should have without reserve the facts from both sides. From the medical viewpoint there is no reason why the experts on both sides should not have a conference and formulate a joint opinion. The methods of "ambulance chasing" lawyers tend to bring into court only those physicians whose opinions can be molded into the attorney's shape. [H.M.]

## Philadelphia Medical Journal.

1. Movable Right Kidney as a Cause of Pancreatic Diabetes: With a Report of Cases Cured by Nephropexy. SHERMAN THOMSON BROWN.
2. Impressions of Differences in Practice at Low and High Altitudes. WILL H. SWAN.
3. A Critique of the Logical Processes of Medicine. W. B. KONKLE.
4. Subcutaneous Emphysema from Perforation of the Pleura by Extension of Tuberculous Ulceration from the Lung. STARLING LOVING.
5. Mouth Infection, Due to Natural Teeth. D. D. SMITH.

**1.—Movable Right Kidney as a Cause of Pancreatic Diabetes.**—S. T. Brown details the anatomy of the pancreas and its relationship to surrounding organs, and the role played by a movable right kidney in producing pancreatic diabetes. The following cases are reported: Case I.—Female, aged 23. During the second month of a pregnancy in 1897 she had an attack of malaria, and during the fifth month of this pregnancy was salivated with calomel. This patient in 1902 had 10% or more of sugar in the urine. The amount of urine secreted in 24 hours ran from 20 to 40 ounces. She had a floating right kidney for which nephropexy was performed, resulting in a cure of the diabetes. Case II.—A female, aged 26, whose urine showed large amounts of sugar. Nephropexy was performed upon her right kidney in May, 1902, and no sugar has appeared in the urine since. [F.C.H.]

**2.—Impressions of Differences in Practice at Low and High Altitudes.**—W. H. Swan gives a detailed list of the answers he has received to questions which he asked of some 392 physicians practicing in the high altitudes of the Western States. The following may be said regarding the high altitudes. The mortality in acute lobar pneumonia is lower; typhoid fever runs a shorter course; the more frequent occurrence and more intractable nature of the functional nervous disorders, with an exception in the case of migraine; chorea is comparatively infrequent and of short duration in Colorado, and the belief that high altitudes has a serious and unfavorable influence on the disease is not justified with facts; debilitated, anemic individuals sleep better than at a lower level; biliousness and digestive disorders are of less frequent occurrence; there are more frequent indications for the salicylates and drugs, which are supposed to aid in the elimination of uric acid; convalescence in general is apt to be more prompt. [F.C.H.]

**4.—Subcutaneous Emphysema.**—S. Loving details a case of subcutaneous emphysema from perforation of the pleura by extension of tuberculous ulceration from the lung. The patient was a male mulatto, aged 33. He had an attack of pneumonia five years ago. He came under the author's care in January, 1902, at which time the sputum contained a number of staphylococci, but no other specific organisms. The following month the pulmonary lesions had increased, and tubercle bacilli were present in the sputum in large numbers. Six months subsequently, after a prolonged paroxysm of coughing, the patient noticed a swelling in the right armpit, which on the next day had increased and extended inward to the right front of the chest. By the third day the swelling had extended from the axilla and lower border of the clavicle of the right side downward and to the crest of the ilium. There was no change in the respiration, no discoloration of the skin nor pain. The swelling was easily compressible, crackled on pressure, resonant on percussion, and on auscultation yielded a coarse, crepitant rale with both inspiration and expiration. Punctures through the skin allowed air to escape, but did not reduce the swelling. During the next few days the swelling increased in divers directions, even down the right arm to the wrist. Fifteen days subsequent to the development of the subcutaneous emphysema the patient died. At autopsy many small cavities were found in both lungs with pleuritic adhesions, especially upon the right side. In the upper lobe of the right lung, opposite to the fourth interspace, about the center, a cavity an inch in diameter was found, from which ulceration had extended through the adjacent pleura and the chest wall to the subcutaneous connective tissue. The opening was small, and the passage, which was sufficiently large to admit a grooved director, somewhat tortuous. [F.C.H.]

**5.—Mouth Infection Due to Natural Teeth.**—D. D. Smith firmly believes that relief from mouth infection is to be afforded through dentistry alone. Germicides will not, cannot

accomplish it. There must be positive and frequent removal of all septic conditions of the teeth and all environmental states which promote toxic stagnation and germ culture in the mouth, and a general maintenance of the most perfect state of asepsis for the entire oral cavity. This can be accomplished only through the most skilful manipulation of educated, intelligent dentistry. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN                      A. O. J. KELLY

### REVIEW OF LITERATURE

**Peritonitic Pathogenesis of Hepatic Colic and Painful Epigastric Crises.**—There exists considerable discordance between the classic picture and the clinical observations of hepatic colic and the explanations given for these contradictions are far from satisfactory. It has been taken for granted that the colic is due to the passage of biliary calculi. R. Tripiet and J. Paviot,<sup>1</sup> however, claim that this view is incorrect and that all the symptoms may be referred to a local peritonitis. Their clinical and postmortem observations have led them to the deduction that affections of the abdominal organs only give rise to painful crises when their enveloping peritoneum is acutely or subacutely inflamed and that the pain varies inversely with the amount of liquid exudate. The authors in a previous paper have shown this to be true of appendicular crises and now claim that the same holds good for hepatic colic. The pain of hepatic colic is therefore in their opinion due to a local inflammation of the peritoneum in the region of the liver or gallbladder. The simulation of appendicitis and other inflammations by gallbladder affections is thus easily explained by a propagation toward the appendix or other organs of a peritonitis having origin in the gallbladder. [N.K.]

**Aortic Aneurysm of 25 Years' Duration.**—This case is reported by J. L. Hirsh and M. C. Robins.<sup>2</sup> The patient was a man of 62, a bricklayer, who 25 years previously had been struck by a beam over the upper part of the sternum. He was in a hospital for some weeks, when a small lump was found on the right side of the sternum at the second rib. Three years later this had increased slightly in size and was painful. The patient continued at his work until a few weeks before his death, although pressure symptoms from the aneurysm had been quite marked for a period of 18 months. At times a small amount of fluid and occasionally a small fragment of fibrin came through a thin place over the tumor and rupture was feared, but the ulcerated area would then heal for a time. Autopsy showed two perforations of the sternum and an aneurysm the size of a large cocoon, involving the entire ascending and transverse portions of the aorta. Special points of interest in the case are: (1) The long duration, 25 years. The longest previously reported was 16 years; (2) the comparative comfort of the patient, which was due to the aneurysm extending forward and upward, thus exerting little pressure on the esophagus and trachea; (3) the existence of intercurrent diseases—pneumonia and influenza; (4) the symptoms and signs, giving the classical picture of the disease without depriving the patient of his ability to do manual labor up to within a few weeks of his death. [A.G.E.]

**Repeated Attacks of Hemiplegia of Uremic Origin.**—J. Le Calve<sup>3</sup> reports the case of a man of 45 without syphilitic or alcoholic antecedents who suddenly complained of double vision. The urine was free from albumin and recovery soon followed. Several months later he had a violent attack of migraine with nausea, followed by complete right-sided hemiplegia. At the end of a period varying from a few minutes to half an hour the symptoms of hemiplegia disappeared to recur repeatedly. The urine at this time contained albumin and was greatly reduced in quantity. Under treatment consisting in venesection, drastic purgation, sinapisms to the limbs, absolute milk diet, and graduated hot baths, the patient made a complete recovery. The author considers the hemiplegia uremic in nature, and adopts the mechanicotoxic theory for its explana-

tion, holding that the paralysis was due to a localized edema induced by vasomotor disturbances of toxic origin. [D.R.]

**An Analysis of 26 Cases of Mongolism.**—J. Muir<sup>1</sup> discusses mongolism from the standpoint of literature, nomenclature, geographic distribution, etiology, symptoms, physical development, prognosis and treatment, and reports 26 cases observed in London and its suburbs. Mongolism he defines as a type of mental feebleness, always congenital in origin, characterized by certain constant cranial, and later by lingual changes. The condition probably exists everywhere, and no white race is exempt. In London it is at least four times as common as cretinism. Tuberculosis of the parents was present in 38% of Muir's cases, and syphilis in 3 of 26. Bad health of the mother during pregnancy occurred in 15 of the series. A valuable bibliography is appended to the article. [A.G.E.]

**Position of the Stomach Ascertained by Means of Inflation.**—From a series of detailed investigations A. K. Fevert<sup>2</sup> draws the following conclusions: 1. Inflation of the stomach with small quantities of gas gives the same topographical results as do other methods (percussion combined with auscultation, palpation in regard to splashing sounds, etc.). Nevertheless inflation has advantages of its own; it enables us to ascertain not only the lower but also the right and occasionally the upper border; moreover the empty stomach may be outlined equally well. As emphasized by Michaelis, it is very important to ascertain the right border for the early diagnosis of gastric dilation. 2. Inflation of large quantities of gas displaces the limits of the organ and shows the outline of an artificially distended stomach. This method is invaluable in locating the descended or otherwise displaced organ. 3. When inflated the stomach does not expand uniformly in all directions, the right border shifting more than the lower. [L.J.]

**Chronic States of the Circulation Simulating Heart and Kidney Disease.**—G. Steel<sup>3</sup> calls attention to a class of patients whose symptoms are often misinterpreted. They complain of shortness of breath and ultimately, if neglected, develop dropsy and venous engorgement of the liver. Examination of the heart fails to reveal disease of that organ. The pulse is usually slow and regular—a small pulse with prolongation of the tidal wave. The heart is weak only relatively to its burden. Derangements of metabolism have increased peripheral resistance. Typical cases are met about the climacteric period. In the presence of great venous stasis even large quantities of albumin in the urine with casts do not suffice for the diagnosis of Bright's disease. Albuminuria occurs not only in high, but in low arterial tension. The latter is found often in young male subjects whose pulse-curve is very like that often met in ordinary anemia, its special features being its large percussion wave and very small tidal wave and the low position of the aortic notch. These individuals are usually weakly. The albumin is less or absent in the morning, and increased by prolonged standing. High arterial tension should be treated by restricting farinaceous foods and alcohol, and limiting fluids at the midday and evening meal. Digitalis is contraindicated. It is better to let the heart alone, depending on diet and active elimination. Iodid of potassium is beneficial. In low tension general tonics are best. Digitalis seems to be indicated for its action on the arterioles. [H.M.]

**Nocturnal Elimination of Urine in Heart Disease.**—M. Pehu<sup>4</sup> publishes a note on the nocturnal elimination of urine in cardiovascular affections. When the relation between diurnal and nocturnal urinary elimination is higher than 100:90 then it exceeds the normal limit. He terms this condition "nycturie." He concludes that "nycturie" is the result of an insufficiency of the myocardium and constitutes a sign of "neipragie cardiaque." Insufficiency of the cardiac muscle may be thus diagnosed in a certain percentage of cases of cardiovascular disease before the appearance of those symptoms, which would then make "nycturie" of superfluous diagnostic value. [J.H.W.R.]

**Orthostatic Albuminuria.**—This condition is exhibited by a man of 25, a cigarmaker of a nervous and weak constitu-

<sup>3</sup> Medical Chronicle, December, 1902.

<sup>4</sup> Lyon Médical, February, 1903.

tion, the case being reported by Beck.<sup>1</sup> Life insurance was refused because of albumin in the patient's urine. Repeated examinations of the urine showed that the morning specimen was free from albumin, and that the evening specimen, obtained after the patient had been standing half an hour, contained 1% of albumin. Appropriate treatment, with change of habits, has practically cured the man. In discussing the case, Dr. William Osler said that the reciprocal relations of neurasthenia and albuminuria were very interesting. Transient albuminuria is frequently prevented in neurasthenics, and neurasthenia is often a consequence of albuminuria. In one case in Baltimore, five minutes in an erect posture causes a trace of albumin in the urine. Sitting up in bed to eat breakfast causes albumin to appear. Dr. Osler states that too much stress is often laid upon the mere presence of albumin in the urine, when attention should be paid to the casts, specific gravity, the state of the arteries and the pulse. [A.G.E.]

**Nephritis After Taking Potassium Chlorate.**—A. Loran<sup>2</sup> reports a case of acute nephritis following the administration of potassium chlorate. He believes that in each case of nephritis following an infectious disease a study of the relation between this and the administration of certain drugs, such as sodium salicylate, potassium chlorate, etc., should be made. [J.H.W.R.]

**The Diagnosis of Chronic Interstitial Nephritis.**—C. L. Mix<sup>3</sup> speaks of the diagnosis of chronic interstitial nephritis based on physical signs, chiefly cardiovascular. He states that cases of this type make up from 2% to 4% of the general physician's practice. A thorough knowledge of the physical changes in this disease, although it is a protean one, enables the physician to make the diagnosis without immediate recourse to the examination of the urine. Indeed, the diagnosis should in all cases be based upon physical findings and not upon chemical and microscopic analysis. The urinary findings should be used merely as confirmatory evidence. Cases are cited to show possible errors from urinary examination. Changes in the vessels and heart and their physical signs are considered at length. Mix regards a palpable pulsation in the suprasternal notch as of much value in hinting the presence of chronic interstitial nephritis. [A.G.E.]

## GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### REVIEW OF LITERATURE

**Cancer of Tongue.**—H. T. Butlin<sup>4</sup> reports the result of operation in 129 cases of cancer of the tongue. Of these 32 have been absolutely cured, all having passed the three year time limit. Of the remainder, 12 patients died of other diseases than cancer within the three years, leaving the number 117. Counting on this basis, the percentage of recovery is 27. The author is somewhat discouraged at the high mortality, but states by way of encouragement that his percentage of recovery until three years ago was only 20. He knows of no statistics of a large number of operative cases in which the percentage is better than his own, discouraging as that may be. The author states there is no part of the body in which early operation for cancer is attended by better results than that of the tongue. Early diagnosis should be made in nearly all cases because of the ready access of the tongue for constant observation and examination, not only for the patient himself, but for the physician as well. A pathologic condition of the tongue which has lasted for any length of time should be looked upon with suspicion. Superficial glossitis, red patches on the dorsum and border of the tongue, patches of a dauby white appearance, leukoplakia, warty excrescences, cracks and fissures, all should lead at least to the suspicion of beginning cancer. The author calls particular attention to warty growths on the tongue, asserting that they strongly dispose to cancer. Their early removal by elliptical incision is demanded. It is surprising with what ability patients are able to articulate their words after a great portion of the tongue has been removed. [A.B.C.]

**The Use of Steam in Surgery and Gynecology.**—M. F. Koslenko<sup>1</sup> illustrates the progress made by steam treatment since its introduction fifteen years ago by V. F. Snegirev, who employed the method originally for hemostatic and antiseptic purposes in gynecologic practice. Others began to utilize steam on a larger scale in various operative hemorrhages, in ocular inflammations, nasal affections, etc. The originator himself discovered in 1900 that his method is an excellent hemostatic in cases of parenchymatous hemorrhage, especially in operations upon the spleen and liver. An instrument was accordingly devised, the steam-saw, which allows steam to escape through its teeth and thus arrests bleeding simultaneously with the act of cutting. The styptic action is instantaneous, a crust being formed under the influence of heat and acting as a barrier to further escape of blood. Very recently the same author operated by means of his steam method upon a pyelitic kidney without losing one drop of blood. Further developments may be confidently expected. [L.J.]

**Disarticulation of the Hip for Sarcoma of the Femur.**—A. E. Halstead<sup>2</sup> reports a successful case of hip amputation for sarcoma of the lower end of the femur, and adds valuable remarks upon the diagnosis and prognosis in sarcoma of the femur. The patient was a girl of 21 who had a swelling of the left knee with the history of a few days' pain in the joint after a fall from a carriage 10 months before, and of continuous pain for eight months. The diagnosis of sarcoma was made and the limb amputated at the hip-joint. At the present time, three years and seven months after the operation, there is no evidence of return of the disease. The tumor proved to be a peripheral ossifying spindle-celled sarcoma. The differential points between this variety and the myelogenic type are discussed. The latter represents the lowest degree of malignancy of any of the bone sarcomas. The most constant symptoms of sarcoma of the femur are pain, enlargement of the bone, and spontaneous fracture or fracture from slight trauma. Albumose can usually be found in the urine in cases of bone sarcoma, but cannot be used as a means of differentiating malignant from benign tumors, nor chronic infections of bone from newgrowths. In regard to the rule that freedom from recurrence for three years should be considered as a cure, Halstead states that this is further from the truth in sarcoma of bone than in other malignant tumors. Local recurrences have occurred as late as 12 years after amputation, and in one case lung metastases were first evident 25 years after the tumor began to develop. [A.G.E.]

**The Treatment of Hydronephrosis.**—J. W. Bovée<sup>3</sup> writes of the treatment of hydronephrosis, basing his remarks on a consideration of the numerous causes of that condition. Surgery is the only treatment to be suggested. Bladder conditions are of importance. Benign, and many malignant, tumors may be removed. When the disease is apparently yet confined to the bladder, but involving it in nearly its entirety, nothing but cystectomy is indicated. This operation is not a severe one, but disposal of the free ends of the ureters requires great judgment. In the treatment of renal diverticulums often the most satisfactory method will be kidney resection, removing the diverticulum. This generally means the loss of a portion of excreting tissue, however, and always demands serious consideration. It may be possible in some cases to so drain the diverticulum that danger of distention is removed. This should not be done if the parenchyma has been destroyed. [A.G.E.]

**Carcinoma of the Liver.**—Herbert R. Bachell and W. Mitchell Stevens<sup>4</sup> report two cases of carcinoma of the liver which are of interest. They state carcinoma of the liver is rapidly fatal, the duration being about 12 weeks after the occurrence of the first symptoms. In the first case reported the illness was short, of eight weeks' duration. There was no wasting. The only symptoms present were jaundice and ascites. At the necropsy no organs other than the liver could be found involved, so that the disease was primary in the hepatic tissues. The liver was enormous in size, weighing 17 pounds. In the second case the disease was primary in the

<sup>1</sup> Maryland Medical Journal, March, 1903.

<sup>2</sup> Jour. Médical de Bruxelles, March 5, 1903.

<sup>3</sup> Medicine, March, 1903.

<sup>4</sup> British Medical Journal, February 14, 1903.

<sup>1</sup> Russki Vrach, January 18, 1903.

<sup>2</sup> Medicine, March, 1903.

<sup>3</sup> Northwest Medicine, March, 1903.

<sup>4</sup> British Medical Journal, February 14, 1903.

pylorus, extended to the liver, which was almost universally involved. The authors call attention to the difficulty of differentiating carcinoma of the liver from alcoholic cirrhosis. In the second case there was no jaundice but well marked ascites. The liver was not palpable. There was no pain nor tenderness, consequently the condition could easily have been mistaken for alcoholic cirrhosis. [A.B.C.]

**Fractures in or Near the Joints.**—A. G. Gillette<sup>1</sup> says that bony ankylosed joints following fractures in or near them are not nearly frequent enough to demand the worry and warning the subject receives. Properly reducing the fracture is the most important part of the treatment, the joint being opened without hesitation if necessary. After reduction the parts should be kept in one position until good union has taken place, usually not less than six weeks. Then active instead of passive motion should be allowed the patient. The nonunion of intracapsular fractures of the femur is due almost always to lack of reduction, thorough immobilization and continued apposition of the fractured ends. Peculiar physiologic changes in the bones of the aged are not the cause of nonunion, the writer having had one ununited intracapsular fracture in a boy of 12. In fracture of the spine, immobilization is the principal treatment, whether laminectomy is or is not done. For this reason the waterbed is unequivocally condemned, as every movement of the patient sets the entire body in motion, causing pain and further injury. [A.G.E.]

**Large Angioma of the Liver.**—Alfred Mantle<sup>2</sup> reports the case. The patient was a male, who two years previously noticed some enlargement of the upper abdomen. This steadily increased in size. Early in 1902 he began to suffer from gastric disturbance, especially after taking food. There was no specific history, nor was he an alcoholic. When first seen by the author there was slight jaundice, the apex beat was displaced to the left, the abdomen was much distended, and there was definite bulging in the intercostal space on the right. An incision was made from the ninth costal cartilage downward for three inches. Serous fluid escaped. A tumor, deep-red in color, and cystic without pulsation, was apparently attached to the right lobe of the liver. An exploratory needle withdrew blood, and on removing the needle blood spurted from the wound. A suture ligature failed to control the hemorrhage, merely tearing through the mass. Alarming hemorrhage supervened. The patient died two hours later of internal hemorrhage in spite of packing. Necropsy showed the right lobe of the liver to consist of an enormous tumor extending into the right iliac fossa. It was of the consistency of a placenta. Its length was 12 inches, its widest part 8 inches. It was found to be an angioma involving only the right lobe. The other organs were normal. [A.B.C.]

**The Treatment of Fecal Fistula.**—C. C. Grekor<sup>3</sup> prefers enteroanastomosis after Maisonneuve to complete exclusion of the intestine in the treatment of fecal fistula. The latter operation is more difficult and prolonged, and although it promptly checks all fecal discharge from the fistula, yet a mucous discharge persists and renders spontaneous healing extremely sluggish. To close the opening artificially would mean to cause retention of the excretions with the wellknown sequels, such as peritoneal irritation, collapse, etc. This troublesome circumstance is entirely obviated by enteroanastomosis after Maisonneuve because the excluded segment preserves its communication with the remaining intestinal lumen. Thus we need not wait for spontaneous closure of the fistula, but may without fear of causing retention resort to artificial obliteration of the opening by means of caustics, excision, suturing, etc. This local treatment may even be undertaken immediately after the chief operation, sparing the patient much tedious subsequent interference. A curious occasional result of complete exclusion of the intestine is prolapse or eventration of the excluded segment through the fistula. This complication is far less apt to occur after Maisonneuve's operation. Future safety demands a secondary resection of the excluded portion, which the author has done in a case of his own and recommends as a safeguard in all similar intestinal operations. [L.J.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**The Significance of Vesicovaginal Fistula as an Obstetric Indication.**—Emil Kraus<sup>1</sup> gives the history of several cases of labor complicated by the scars of a repaired vesicovaginal fistula and from these and those cited in literature he concludes (1) that cases of labor in which the possibility of normal delivery seems to be called in question on account of vesicovaginal scars we must first wait to see whether the stenosis of the soft parts conditioned upon the cicatrix diminishes so in the course of normal labor that the expulsion of the fetus may be expected without special difficulty. 2. If this is not the case and an undue distention of the uterus occurs then delivery by laparotomy is indicated. 3. Forced dilation and deep incision of the scarred part in order to overcome or remove the stenosis are to be avoided (a) on account of the danger of tear and severe hemorrhage; (b) on account of danger of formation of a new fistula. [W.K.]

**Twin Tubal Pregnancy in the Same Tube.**—Ersilio Ferroni<sup>2</sup> presents a case of twin pregnancy. In the third month of gestation the condition of the patient required relief, and left ovariopalingectomy was performed with recovery. The tube removed contained two fetal sacs apparently unconnected, and the portion of the tube between them in a normal condition, but both openings were stopped with blood clots. The two fetal sacs were unequal in size, and showed different stages of development. It appeared that in the larger sac abortive changes with the death of the embryo had occurred while the other remained undisturbed in its growth and advanced to a later stage of development before a fresh lesion led to further abortive changes and symptoms requiring operation. The question whether both ova came from the same or different ovaries at different times is also discussed. The symptoms of the patient were those of an ordinary ectopic gestation, and it was only the anatomic examination which made known the existence of a twin pregnancy. [W.K.]

**Cesarean Section on the Dead.**—Weisswange<sup>3</sup> reports the case of a pregnant primipara who, within two weeks of term, was taken with sudden pain at the heart and severe dyspnea. A midwife was sent for, who at once summoned the physician. He found the woman dead, but the fetal heart-beats were still perceptible. He therefore performed cesarean section as quickly as possible, and 17 minutes after the mother's death delivered a living child, which, though somewhat asphyxiated, was soon restored. One case has been reported of a living child delivered 23 minutes after the death of the mother. That this is rare, however, is shown by the fact that of 331 similar cases reported in 100 years in only six was the result favorable for the child. In Weisswange's case the mother's death was caused by rupture of the aorta. [W.K.]

**Colpohysterotomy for Retroverted, Incarcerated Gravid Uterus.**—G. Wennerstrom<sup>3</sup> reports the case of a woman of 28, who at the fifth month of pregnancy suffered from a bloody mucous discharge and retention of the urine. Examination showed the cause was an incarcerated, retroverted uterus. The os could not be reached, the distended bladder extended almost to the navel, and the sigmoid flexure was filled with hard material. After emptying the bladder and intestine attempt was made to reduce the retroverted uterus, but in vain and some more effective operation became necessary. The posterior vaginal wall was drawn down and cut through, the posterior uterine wall was incised, and a badly macerated fetus with placenta delivered. The peritoneum was not opened; the patient made a good recovery, and two years later was delivered of a full-term child. The writer says the result of the operation left nothing to be desired and he was convinced that the method selected was the best for an incarcerated irreducible retroverted gravid uterus. The opening of the Douglas sac, avoided in this case, would in many instances be necessary. [W.K.]

<sup>2</sup> Zentralblatt für Gynäkologie, February 23, 1903.

<sup>3</sup> Zentralblatt für Gynäkologie, March 7, 1903.

**Prolapsus Uteri Inversi.**—E. Funke<sup>1</sup> reports the case of a secundipara, aged 27 years, who during her second pregnancy suffered from pain in throat and other symptoms which led to a diagnosis of tuberculosis of the larynx. The symptoms, however, abated under treatment, and pregnancy proceeded undisturbed until term. During labor Funke was summoned in great haste, and found the patient in a dying condition. He was informed that while in labor she was seized with a severe fit of coughing, during which the child was quickly born, the coughing continuing some time longer. An examination showed extending from the vulva a sausage-shaped body, and protruding from this the placenta with the amniotic membrane. During the coughing this body, which proved to be the uterus, had evidently been expelled from the abdomen, accompanied with considerable blood, resulting in the collapse of the patient and her almost immediate death. The causes of prolapse of the uterus inversus are tension on its inner surface such as results from undue tension on the navel cord, and external pressure such as abdominal pressure in manual expression of the placenta. The external pressure seems to have been the cause in the case reported, that pressure resulting from the fit of coughing, augmented by the tension of the adherent placenta. [w.k.]

**On Prolapsus Uteri; An Operation for Reproduction of the Sacrouterine Ligaments.**—E. S. Bishop<sup>2</sup> describes an operation whose aim is to obtain as nearly as possible a return to the normal condition in which the uterus can move freely within certain limits and is capable of development in all parts during pregnancy. After opening the abdomen a thread is passed through each broad ligament, enclosing tube and round ligament. These are used as tractors to draw the fundus forward. A sound in the posterior fornix renders the latter prominent. A thick thread is passed vertically through each side, avoiding the mucous lining, so that each protruding end is half an inch distant from the other, and the whole loop a half to three-quarters of an inch from the cervix. The fornix is now applied to the sacrum, and a spot chosen directly opposite, free from vessels, nerves, and ureter and well outside the rectum, where the needle carrying the suture is entered deeply so as to embrace the periosteum, and brought out half an inch above. Before tying this suture a narrow strip of peritoneum is removed, both from the fornix and the wall opposite. The round ligaments are then shortened by Olshausen's method. He has performed this operation on ten patients. He discusses at length the function of the sacrouterine ligaments, and points out the disadvantages of other operations for replacing the uterus. [H.M.]

**Drainage.**—M. Hofmeier<sup>3</sup> disagrees with Olshausen in his condemnation of drainage in any form as superfluous and often positively harmful. He considers drainage in many cases a proper precautionary measure, whose importance it may be difficult to prove positively, but from which when properly performed he has never seen any injury. He discusses methods of drainage, apparently in most cases preferring an open tube to a gauze drain, yet adapting methods to the peculiarities and necessities of each case. [w.k.]

**A Case of Calcification of the Ovary.**—J. Milander<sup>3</sup> says that the pathologic metamorphosis of the corpus luteum is a frequent appearance, but its calcification rarely occurs, and is usually the result of an inflammatory process. He cites a number of cases from various authors, and reports a case from his own practice. Ovariectomy was performed for the removal of a cyst of the right ovary. The left ovary could not be found, but a hard substance was found free in the left side of the Douglas sac, which proved to be a calcified ovary. This case differed from those cited in that more stones were found corresponding to the corpora lutea in the ovary; the calcified ovary came, through spontaneous amputation, into the Douglas cavity; and the corresponding tube was atrophied. Also in this case there had evidently been no previous infection process, and the cause of the calcification must be sought in the nutrition disturbed by the rapid growth and pressure of the cyst. The cause of the atrophy of the tube is difficult to determine. [w.k.]

**Does Uterine Rupture Indicate Cesarean Section in Succeeding Pregnancy?**—H. W. Freund<sup>1</sup> discusses this question and gives the history of a woman who suffered uterine rupture in her sixth delivery. The tear, which extended to the height of the vesical vertex, was sutured and healed satisfactorily. In the eleventh month the woman was again pregnant. In the fourth month there were signs of dangerous distention of the uterine segment in the vicinity of the scar, and artificial abortion was performed. This treatment was repeated until the twelfth pregnancy, when Freund considered the uterine muscle strong enough to justify waiting until there was a possibility of saving the child's life. In the thirty-third week, as the os uteri was penetrable by the finger, labor was induced and the delivery of a living child was followed by a normal puerperium. Freund thinks when pregnancy occurs in a short time after uterine rupture whether early abortion should be induced depends upon the conditions incident to each case, the constitution and development of the uterine muscle in the lower segment, and movability of the uterine scar. Uterine rupture is more likely to occur in a multipara when there has been an abnormal distention in previous deliveries, weakening the uterine wall. This was shown in the case reported, in which several deliveries preceded the rupture. His experience teaches Freund that in cases in which repair of the rupture promises to be practicable and complete, total extirpation is not justifiable. That very extensive injuries can be successfully healed is also shown by this case, but repeated ruptures indicate total extirpation or supravaginal amputation. [w.k.]

## TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR. L. F. APPLEMAN

## REVIEW OF LITERATURE

**Treatment of Vulvar Pruritus.**—Robin and Dalche<sup>2</sup> review the treatment of pruritus occurring in old women at the time of menopause or as the result of nervous phenomena depending on rheumatism, gout, diabetes, Bright's disease, or gastric disturbances. Among the means employed are mentioned prolonged hot applications of 1 to 1,000 solutions of corrosive sublimate, 10% solutions of chloral hydrate, and 5% to 10% solutions of cocain. The following powder may be applied locally:

Powdered orthoform . . . . . }  
Powdered diiodoform . . . . . } of each, equal parts.  
Powdered talc. . . . . }

The anesthesia produced by orthoform lasts longer than that by cocain. The following ointment may also be used:

Menthol . . . . . 0.05 gm. (  $\frac{1}{4}$  grain)  
Guaiaicol . . . . . 0.3 gm. to 1.0 gm. (  $\frac{1}{2}$  to 15 grains)  
Zinc oxid. . . . . 10.0 gm. (2  $\frac{1}{2}$  drams)  
Vaselin . . . . . 30.0 gm. (1 ounce)

Ichthylol may be used in 10% aqueous solution or in an ointment containing 15%. Ruge, of Berlin, washes the parts with soap, then with a solution of corrosive sublimate, followed by an application of 3% or 5% carbolized vaselin. Leredde uses a 5% ointment of methyl salicylate. When there is dyspepsia with fermentation, Robin prescribes erythrol with calcium fluorid, as follows:

Erythrol . . . . . 0.02 to 0.1 gm. (  $\frac{1}{4}$  to 1  $\frac{1}{2}$  grains)  
Calcium fluorid . . . . . 0.02 to 0.1 gm. (  $\frac{1}{4}$  to 1  $\frac{1}{2}$  grains)  
Calcined magnesia . . . . . 0.1 gm. (  $\frac{1}{2}$  grains)

For one cachet. One cachet at the end of each meal.

Erythrol is particularly indicated in butyric acid fermentation; if lactic acid fermentation is present, ammonium fluorid should be substituted, as follows:

Ammonium fluorid, 0.1 to 1.0 gm. (  $\frac{1}{2}$  to 15 grains)  
Water . . . . . 300 cc. (10 ounces)

One dessertspoonful during the two chief meals. [L.F.A.]

**Glycerin in Tuberculosis.**—A. F. Pilcque<sup>3</sup> advises the use of glycerin in tuberculosis. It supplies the fat necessary to

<sup>2</sup> Le Mois Thérapeutique, Vol. III, No. 9, 1902, p. 104.

<sup>3</sup> Jour. Méd. de Bruxelles, February 26, 1903, page 120.

nutrition, and acts as a good vehicle for the administration of creasote and tannin. [J.H.W.R.]

**The Laxative Action of Purgatin.**—The series of synthetic pharmacologic products has been recently enriched by the addition of "purgatin," a yellow, odorless and tasteless powder. The new remedy found employment in habitual constipation and allied disorders. K. U. Bergman<sup>1</sup> studied the action of purgatin on dogs and rabbits. His experience with the drug in man coincides with that of other observers. He warns against excessive expectations, and emphasizes such drawbacks as high price, habituation to the drug, red or violet discoloration of the urine, etc. Experiments with sulfur have given equally good results in dogs. The laxative dose of purgatin in man is 10 to 30 grains. Untoward by-effects were not observed. [L.J.]

**Oxalic Acid as an Expectorant.**—Poulet<sup>2</sup> considers oxalic acid an excellent expectorant, and gives the following mixture:

Oxalic acid . . . . . 2 grams (30 grains)  
 Infusion of tea . . . . . 175 cc. (6 fluidounces)  
 Syrup of orange peel . . . . . 75 cc. (2½ fluidounces)  
 Dose.—One tablespoonful hourly.

This drug is also of value in bronchial asthma, and its use is followed by no untoward results. [W.E.R.]

**Theobromin.**—H. Huchard<sup>3</sup> considers theobromin one of the best diuretics that we have. It does not affect the heart; it causes only slight changes in the bloodvessels or in arterial tension; it acts chiefly as a stimulant to the renal epithelium. He prefers the pure theobromin to agurin (sodioacetate of theobromin) or to diuretin (sodiosalicilate of theobromin), because these two compounds, especially the last, are not only unstable preparations, but sodium salicylate may irritate the kidneys. Pure theobromin may be combined with lithium, sodium phosphate or caffeine; with caffeine it is used when an effect on both heart and kidneys is desired. Theobromin sometimes causes slight headache, which may be overcome by giving smaller doses or divided doses. It does not cause vomiting or other digestive disturbances if the pure drug is employed. It is given in capsules or cachets in the dose of not more than 0.5 gram (7½ grains) daily. [L.F.A.]

THE PUBLIC SERVICE

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 4, 1903:

**Changes in the Medical Corps of the U. S. Army for the week ended April 4, 1903:**

FORD, First Lieutenant CLYDE S., assistant surgeon, is relieved from duty at Fort Wadsworth, and will proceed to Fort H. G. Wright for duty, to relieve First Lieutenant Howard W. Beal, assistant surgeon.

TURNBULL, First Lieutenant WILFRED, assistant surgeon, is relieved from duty at Fort Myer and will proceed to Fort Monroe for duty, to relieve Major William F. Lippitt, surgeon. Major Lippitt will proceed to San Juan, P. R., for duty, to relieve Major Euclid B. Frick, surgeon. Major Frick will proceed to Fort Snelling for duty, to relieve Major Edgar A. Mearns, surgeon. Major Mearns will proceed to San Francisco, Cal., for transportation to the Philippine Islands, where he will report for assignment to duty.

ASHFORD, Captain BAILEY K., assistant surgeon, is relieved from further temporary duty at San Juan, P. R., and will proceed to Cayey, P. R., for duty.

TRUBY, First Lieutenant WILLARD F., assistant surgeon, upon his arrival in New York City, will proceed to Columbus Barracks for temporary duty.

WILLIAMS, First Lieutenant ALLIE W., assistant surgeon, is relieved from duty at Cayey, P. R., and will proceed to Fort Greble for duty, to relieve First Lieutenant Weston P. Chamberlain, assistant surgeon. Lieutenant Chamberlain will proceed to Cabana Barracks, Havana, Cuba, for duty, to relieve First Lieutenant John R. Devereux, assistant surgeon. Lieutenant Devereux will proceed to Fort Columbus for duty, to relieve First Lieutenant Eugene H. Hartnett, assistant surgeon. Lieutenant Hartnett will proceed to Vancouver Barracks for duty in Alaska.

WOOD, H. L., contract surgeon, leave granted March 4 is extended one month.

<sup>1</sup> Russki Vrach, February 8, 1903.

<sup>2</sup> Lyon Médical, October 30, 1902.

<sup>3</sup> Journal des Praticiens, Vol. xvii, No. 9, 1903, p. 138.

STOCKARD, JAMES K., contract surgeon, is relieved from duty at Fort Delaware, to take effect upon the return to duty at that post of Contract Surgeon William J. Enders, and will then proceed to Fort Dupont for duty, to relieve First Lieutenant Samuel L. Steer, assistant surgeon, who will proceed to Hot Springs, Ark., and report at the Army and Navy general hospital for duty.

BEAL, First Lieutenant HOWARD W., assistant surgeon, resignation has been accepted to take effect May 31, 1903. Leave to include May 31 is granted.

EDIE, Major GUY L., surgeon, is relieved from duty at Columbus Barracks, to take effect upon the arrival of Lieutenant Truby at that post, and will then proceed to Monterey, Cal., for duty.

WINTER, Captain FRANCIS A., assistant surgeon, will report on April 1 to Major Louis A. La Garde, surgeon, president of the examining board at the Army Medical Museum Building, Washington, D. C., for examination for promotion.

MCCULLOM, FRANCIS M., contract surgeon, is granted leave for one month from about April 1.

DOUGHERTY, J. C., contract surgeon, is granted leave for one month, with permission to apply for an extension of one month.

So much of orders of October 18 as relieve First Lieutenant Edwin W. Rich, assistant surgeon, from duty at Camp McKinley, Honolulu, H. T., is revoked, and Lieutenant Rich will remain on duty at that post until further orders.

DEVEREUX, First Lieutenant THOMAS, assistant surgeon, is relieved from attendance at the Army Medical School, to take effect April 7, and will then proceed to San Francisco, Cal., for assignment to duty as surgeon on the transport Sumner.

The following-named assistant surgeons will, upon the completion of the course of instruction at the Army Medical School, proceed to San Francisco, Cal., for assignment to duty as surgeons on the transports designated after their respective names, to relieve the contract surgeons now on duty on those transports: First Lieutenants John W. Hanner, Sheridan; William T. Davis, Logan; Robert L. Carswell, Kilpatrick; Cary A. Snoddy, Sherman; William A. Powell, Thomas.

The following-named assistant surgeons will, upon the completion of the course of instruction at the Army Medical School, proceed to the posts designated after their respective names for duty: First Lieutenants Harry L. Gilchrist, Fort Screven; Reynold M. Kirby-Smith, Fort Barrancas; George L. Collins, Fort Adams; Haywood S. Hansell, Fort Monroe; Jesse R. Harris, Fort Myer; Robert M. Blanchard, Fort Thomas; James Bourke, Fort Sheridan; George H. R. Gosman, Fort Duchesne; Samuel M. DeLoffre, Fort Assiniboine; Levy M. Hathaway, Vancouver Barracks; Robert H. Pleson, U. S. general hospital, Fort Bayard, to relieve First Lieutenant Horace D. Bloombergh, assistant surgeon; Junius C. Gregory, U. S. general hospital, Washington Barracks; William M. Smart, Fort Leavenworth.

The following-named assistant surgeons will, upon the completion of the course of instruction at the Army Medical School, proceed to Plattsburg Barracks for temporary duty and to accompany the Twenty-third Infantry to the Philippine Islands: First Lieutenants John A. Clark, Jacob M. Coffin and James D. Fife. Upon their arrival in Manila, Lieutenants Clark, Coffin and Fife will report to the commanding general, division of the Philippines, for assignment to duty.

The following-named assistant surgeons upon the completion of the course of instruction at the Army Medical School will proceed to San Antonio, Tex., and report for assignment to duty to accompany the Fourth Infantry to the Philippine Islands, where they will report for assignment to duty: First Lieutenants William H. Moncrief, Charles F. Morse and Clarence H. Connor.

The following-named assistant surgeons upon the completion of the course of instruction at the Army Medical School will proceed to Vancouver Barracks and report for assignment to duty to accompany the Seventeenth Infantry to the Philippine Islands, where they will report for assignment to duty: First Lieutenants Louis C. Duncan, Philip W. Huntington and Noel I. Barron.

The following-named assistant surgeons upon the completion of the course of instruction at the Army Medical School will proceed to Denver, Colo., for assignment to duty to accompany the Fourteenth Cavalry to the Philippine Islands, where they will report for assignment to duty: First Lieutenants Samuel J. Morris and Harry S. Purnell.

TALBOTT, First Lieutenant EDWARD M., assistant surgeon, upon the completion of the course of instruction at the Army Medical School will proceed to Fort Clark for temporary duty, and to accompany the Second Squadron of the Twelfth Cavalry to the Philippine Islands.

PYLES, First Lieutenant WILL L., assistant surgeon, upon the completion of the course of instruction at the Army Medical School will report at Washington Barracks for temporary duty and to accompany the engineer troops to the Philippine Islands.

LAMBERT, First Lieutenant SAMUEL E., assistant surgeon, upon the completion of the course of instruction at the Army Medical School will proceed to St. Paul, Minn., for assignment to temporary duty at Fort Keogh, and to accompany the Second Squadron, Thirteenth Cavalry, to the Philippine Islands. Upon his arrival at Manila Lieutenant Lambert will report for assignment to duty.

GAPEN, First Lieutenant NELSON, assistant surgeon, upon the completion of the course of instruction at the Army Medical School will proceed to San Antonio, Tex., for assignment to duty to accompany the First Squadron, Twelfth Cavalry, to the Philippine Islands. Upon his arrival at Manila Lieutenant Gapen will report for assignment to duty.

STEWART, WILLIAM J. S., contract surgeon, upon his relief from duty as surgeon on the transport Logan, will report for assignment to duty as surgeon on the transport Dix, to relieve Contract Surgeon H. Newton Kierulff.

SCOTT, First Lieutenant GEORGE H., assistant surgeon, upon the completion of the course of instruction at the Army Medical School will proceed to San Antonio, Tex., for assignment to temporary duty at Fort Clark and to accompany the Third Squadron, Twelfth Cavalry, to the Philippine Islands. Upon his arrival at Manila Lieutenant Scott will report for assignment to duty.

The following-named assistant surgeons upon the completion of the course of instruction at the Army Medical School will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands, where they will report for assignment to duty: First Lieutenants Leon T. LeWald, Alexander Murray, Edwin D. Kibbourne, and Jay W. Grissinger.

The following-named contract surgeons upon their relief from their present duties will report to the commanding general, department of California, for assignment to duty, or for orders to proceed to their respective homes for annulment of contract if their services are not required: H. Newton Kierulff, John P. Kelly, Stephen Wythe, Homer C. Moses, and Joseph J. Shafer.

The following-named officers will report to Major Louis A. La Garde, surgeon, president of the examining board at the Army Medical Museum Building, District of Columbia, for examination for promotion: First Lieutenants Weston P. Chamberlain, Edward R. Schreiner, Ira A. Shimer, Douglas F. Duval, Clarence J. Manly, David Baker, Albert E. Truby, Eugene H. Harnett, Clyde S. Ford, assistant surgeons.

BAKER, First Lieutenant DAVID, is granted leave for four months from about May 1.

NEWGARDEN, Captain GEORGE J., assistant surgeon, having completed the duty for which he was ordered to Washington, D. C., will proceed not later than April 11 to Fort Mason and turn over the public property for which he is responsible, and upon the completion of this duty will join his proper station at Fort Harrison.

BACON, ALEXANDER P., contract dental surgeon, will proceed to Vancouver Barracks and report to the commanding general, department of the Columbia, for assignment to temporary duty with the Seventeenth Infantry, and upon the completion thereof will return to his proper station in the department of Dakota.

#### Changes in the Medical Corps of the U. S. Navy for the week ended April 4, 1903:

HARMON, G. E. H., medical inspector, detached from the Naval Hospital, Fort Royal, S. C., and ordered home to wait orders—March 27.

KERE, D. B., passed assistant surgeon, detached from the Wabash and ordered to the Buffalo—March 27.

PAYNE, J. H., assistant surgeon, detached from the Naval Hospital, Newport, R. I., and ordered to the Wabash—March 27.

DORSEY, B. R., assistant surgeon, ordered to the Naval Hospital, Newport, R. I.—March 27.

STREETS, T. H., medical director, commissioned a medical director from January 31, 1903—March 25.

ELY, C. F., appointed assistant surgeon, March 6, 1903—March 25.

STONE, M. V., assistant surgeon, ordered to Naval Hospital, Mare Island, for treatment—March 30.

HURD, I. N., pharmacist, retired from active service on account of disabilities incurred in the service March 28, 1903—March 30.

HOEHLING, A. A., medical director, retired, ordered to duty as a member of the Medical Examining Board, Navy Yard, Washington, D. C.—March 31.

BRADLEY, G. P., medical director, detached from duty as a member of the Medical Examining Board, Washington, D. C., and ordered to duty at the Naval Hospital, Washington, D. C.—March 31.

DEAN, R. C., medical director, retired, detached from duty as president of the Naval Medical Examining Board, Washington, D. C., and to duty as member of the Naval Retiring Board, Navy Yard, Washington, D. C.—March 31.

GUNNELL, F. M., medical director, retired, detached from duty at the Bureau of Medicine and Surgery, and to be president of the Naval Medical Examining Board, Washington, D. C.—March 31.

GRAVATT, C. U., medical director, detached from duty as a member of the Naval Retiring Board, and ordered to report for examination for retirement, then home to wait orders—March 31.

DEVRIES, J. C., acting assistant surgeon, ordered to recruiting duty—March 31.

MCCORD, D. P., acting assistant surgeon, ordered home to wait orders—March 31.

Assistant Surgeons R. H. Michels, J. L. Nelson, M. W. Baker, H. Shaw, B. F. Jenness, J. H. Halloway, R. A. Bachmann, H. F. Strine, F. M. Munson, E. M. Brown, J. P. Traynor, R. E. Hoyt, detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to their homes to wait orders to sea—April 1.

SPATLING, L. W., surgeon, detached from the Naval Hospital, Portsmouth, N. H., and ordered to the Navy Yard, New York—April 2.

HAAS, H. H., passed assistant surgeon, ordered to the Naval Hospital, Portsmouth, N. H.—April 2.

#### Changes in the Public Health and Marine-Hospital Service for the week ended April 2, 1903:

MCINTOSH, W. P., surgeon, to proceed to Sabine Pass, Texas, for special temporary duty—March 27, 1903.

FRICKS, L. D., assistant surgeon, granted leave of absence for three days—April 2, 1903.

ROBINSON, D. E., assistant surgeon, granted leave of absence for three days from March 28, 1903, under provisions of paragraph 191 of the regulations.

ADAMS, F. B., acting assistant surgeon, granted leave of absence for twenty-five days from April 7—March 31, 1903.

BULLARD, J. T., acting assistant surgeon, granted extension of leave of absence from March 15 to 29, inclusive—March 23, 1903.

FRASER, A. C., acting assistant surgeon, granted leave of absence for thirty days from March 27—March 23, 1903.

#### Promotions.

LUMSDEN, L. L., assistant surgeon, commissioned as passed assistant surgeon (recess), March 31, 1903, effective March 14, 1903.

THURSTON, E. J., pharmacist of the second class, promoted to be pharmacist of the first class—March 13, 1903.

VOL. V, No. 16.

APRIL 18, 1903.

\$5.00 YEARLY.

**Exemption from Taxation Requires Governmental Inspection.**—There are about 170 charitable institutions in the State of Massachusetts allowed to go free by the tax-collector, and yet, so far, there is no legal proviso that these institutions are in reality charitable. Judging from the experience of other States, some of these institutions may be as much the reverse of charitable as selfish cunning can make them. In Pennsylvania, the banner State for feeding at the public crib, millions of dollars—a sum greater than that expended by all the other States put together—are annually spent in this way primarily for the advantage of the political bosses. But the exemption from official inspection is almost as complete as the exemption from taxation. There must yet be incorporated in the laws of all States the fundamental principle that freedom from taxation implies a guarantee on the part of the government that the institutions thus favored are not run in the interests of selfishness, and are in truth performing services to the community in return for their privileges. In the meantime a vigorous tightening of the public purse-string would secure the passage of the highly desirable law looking to a scientific and stringent oversight of the thousands of institutions now silently doing as they please with public funds. Spending other people's money without accounting is not conducive to honesty or to the public benefit.

**For a Better Understanding Between Profession and Public.**—One of the most fundamental causes of quackery and medical humbuggery is the failure of the common people and the newspaper world to understand professional ethics. What we hold to be axiomatic, *e. g.*, as to self-advertisement, success, nostrums, etc., seems to the average workman or business man nonsense and even hypocrisy. He is likely to think that if we are sincere we are *pro tanto* stupid, and he really admires the "enterprise" of the charlatan and the secret or open advertiser. The more ignorant and trustful of the common people do not awaken to the trickery of the charlatan who controls by advertising the papers they read, even the editorial columns, and who owns the drug store he associates with medicines and the medical profession. To victimize these simple ones is the game of the sharpers, and there is no thoroughgoing public agency or well-administered law to protect trustful ignorance. To expose such impostors and im-

sitions in a medical journal fails of its purpose because such publications do not reach those who need the warning. One of the remedies left would be courses of free lectures on popular medical, hygienic, and ethical subjects delivered by representative physicians. Better still, perhaps, would be the publication in the daily press of short, unsigned articles on medical and hygienic subjects, written by physicians and vouched for editorially. The majority of lay newspapers and popular magazines are owned or controlled by the advertising fellows opposed to medicine, and entrance to their columns would be denied to those advertising real medical science and truth. But not all have fallen so low. In these could be easily exposed a number of glaring frauds which beset the unthinking, and both the public and the profession would be the gainers.

**Our national drink bill**, if the figures may be trusted as given by the *American Grocer*, was for all "stimulating beverages" in 1902, \$1,369,098,276. This was a per capita expense of \$17.33; or, supposing that the drinkers are one-fourth of the total population, the 1902 expense to each of these 20,000,000 was \$69.32. Going more into detail the statistics are as follow:

Alcoholic drinks . . . . .	\$1,172,565,235
Nonalcoholic stimulants—	
Coffee . . . . .	\$149,891,030
Tea . . . . .	39,642,011
Cocoa . . . . .	7,000,000—
	196,533,041
<b>Total, 1902 . . . . .</b>	<b>\$1,369,098,276</b>
Total, 1901 . . . . .	1,273,212,386
Total, 1900 . . . . .	1,228,674,925
Total, 1899 . . . . .	1,146,897,822
Total, 1898 . . . . .	1,177,661,366

The quantities of the four leading beverages consumed during the year ending June 30, 1902, were as follow:

	Gallons.
Coffee . . . . .	1,498,910,304
Beer . . . . .	1,381,875,437
Tea . . . . .	396,420,115
Spirits and wines . . . . .	157,206,554

Since 1880, says the *American Grocer*, the use of alcoholic beverages in the United States has nearly doubled, having increased from 10.09 gallons per capita to 19.48, a gain of over 93%. The use of coffee has increased over 52%, while tea has decreased about 48%. The liquor bill for 1902 was \$129,989,281 more than for 1901,

showing how quickly prosperity results in an increased use of alcoholic drinks, but chiefly in wine and beer. It has, in fact, been contended that in panic years the use of the stronger drinks (whisky, etc.) mounts up, while in years of prosperity that of wine and beer rises in excess. We wish some statistician would give us the figures as regards tobacco. Tobacco and coffee consumption seem to be closely related the world over.

**Ophthalmology at the New York State Reformatory.**—The Elmira report for 1902 contains the report of Dr. Case, the oculist of the Reformatory. It is of exceptional value, both positively and negatively, and well merits the scrutiny of the general and specialist physician, as well as of the penologist; 1,048 inmates applied for relief for ocular disease or defect, and 471 were "found to have practically normal eyes, or the abnormality was so slight as in no way to interfere with vision." Of the remaining 577, 126 are given as having simple hyperopia, 86 simple hyperopic astigmatism, 40 compound hyperopic astigmatism, 65 simple myopia, 22 simple myopic astigmatism, and a few cases of compound myopic astigmatism. Of anisometropia there were 32 cases. In the first place many of those who did not apply were surely eyestrain patients. Secondly, many of the 471 practically normal eyed certainly had ocular defects of as great pathogenic importance as any of the 577, but it was concealed because a cycloplegic was not allowed to be used. Dr. Case would probably agree that for scientific purposes these statistics are valueless. There are not over several cases in 100 with simple hyperopia, or simple myopia, or simple astigmatism, almost all cases being of the compound varieties of astigmatism. And, likewise, almost all patients are anisometropic. The explanation of the valuelessness of such statistics lies, of course, in the fact that a cycloplegic was not used in making the tests. This omission, we hasten to add, is due to no fault of Dr. Case. Had it been made possible for him to use the cycloplegic every one of his figures would have been changed. Without its use there is not only no accuracy, but no approach to accuracy in estimating ametropia.

**All statistics of errors of refraction estimated without a cycloplegic are worthless,** and this fact makes a vast deal of work which has been done in the examination of school children's eyes of no value whatsoever. We have seen the reports of such examinations running into thousands and tens of thousands of cases, specifying so many hyperopes and so many myopes, and of what use the reporters could have thought such figures could be to medicine or to humanity is beyond the reason of man to find out. The common way has been to suppose that ametropia of any kind is diagnosed by the subnormal acuteness of 20 foot vision as estimated by the test-letters. It is strangely supposed that this subnormal acuteness especially singles the patient out as needing the specialist's attention. For it is now well known that the optical defects of the eye which do the most harm are precisely those which coexist with normal acuteness when measured without a mydriatic. The worst reflexes come from the astigmatism and anisome-

tropia which can be temporarily neutralized by the accommodation. This is the very condition of eyestrain. The duty of the State and of the trustees of many public institutions is to give oculists such funds and opportunities as will render their work of some scientific value, and of service to those under their charge. What an egregious blunder to limit an oculist to such conditions as are revealed in the following quotation: "Examinations were necessarily made at night, and the best results could not be secured on account of the disturbing influences of reflection from the electric lights necessary in the room. On an average, thirty men would appear for examination during the evening. It is therefore evident that only the manifest errors could be detected and only approximate accuracy obtained in many of the cases." Reading between the lines, we judge that Dr. Case's report is in reality a plea for such authority to do good work. Whether so intended or not, it is a powerful plea.

**The Duty and the Policy of the State Should be to Relieve Eyestrain of Institutional Inmates.**—Dr. Case says that at Elmira the object of examinations of the eyes is for the purpose of removing a disability which would prevent the inmate from performing his duties in trades school, military, etc., and not for the purpose of removing any asthenopic condition that might exist. He has no doubt that if the object had been to relieve eyestrain, with all its attendant symptoms, the number receiving glasses would have been much greater and beneficial results both immediate and remote would have followed. In this connection Dr. Case makes a statement which is most noteworthy and which should arrest the attention of every penologist, indeed of every taxpayer. He says that the hyperopia was of a high degree, averaging from 2 to 4 diopters in those to whom glasses were furnished. If this is true the significance of the fact in a hundred ways is tremendous. The abnormality of mind and life of the patient, and especially of the young patient, which such a horrible amount of hyperopia as this would induce is amazing. The State, and all the States—again if the fact is but half true—could save thousands of times the expense of crime by the easy prevention of the morbidity-producing eyestrain. Immediate investigation by governmental scientific commissions should at least be instituted.

**The Prophylaxis of Crime.**—The great word of modern medical science is prevention. In sociology it is also the thought that motives effort, but in penology the idea has hardly entered the minds of students. Examinations of the eyes of epileptics brings out the fact of an enormously high proportion of astigmatism and anisometropia, and the statement of Dr. Case, of the Elmira Reformatory, to which reference has been made, is an epoch-making discovery, both in penology and in medicine. We have heard not a little of late that ocular optical abnormality is due to, or concurrent with, cranial asymmetry and orbital malformation. The emphasis of this theory seems to be a part of the old fatalism of disease. At least it can have no influence upon the thera-

peutics or the cure of ametropia and muscle-imbalance. The sole lesson from it would appear to be that such osteopathies must be given to the surgeon to operate upon, or to the osteopath to massage. Those interested in the prevention and cure of the patients thus afflicted may reply that the eyeball, muscles, and ocular appendages are soft structures, of great plasticity and adaptation to the bony parts. If the bony malformation is the cause of hyperopia, that does not lessen our duty to give the patient vision and stop morbid reflexes by means of the correction of the hyperopia, astigmatism, etc. The fact remains that if so many young criminals have such high degrees of ametropia, it is of unparalleled significance in causing crime. There is hardly a mind in the world that can remain moral and normal under such an affliction. Let us end the criminal folly of ignoring and belittling the importance of eyestrain. There is none that exaggerates so much as he who sneers at the exaggeration of the eyestrain specialist.

**"Index Medicus."**—The appearance of the first number of the new *Index Medicus* is an event of momentous importance which will cause rejoicing among medical men the world over. In other countries attempts have been made to publish a medical index since the original one in this country became defunct; they have not, however, been successful. The French Index is a failure; on account of the use of the cumbersome decimal system and the defective indexing it is of very little value in bibliographic work. The present *Index Medicus*, under the editorship of Dr. Robert Fletcher and Dr. Fielding H. Garrison, follows the well-tried plan of its American predecessor. It begins with January, 1903, though a few references from the literature of December, 1902, are incorporated in it. We find a slight error on page 1, in that the article by Ubert (Ueber Hämochromatolyse mit Pankreasatrophie und Diabetes) does not belong under the caption of Bibliography, History, Literature. The thanks of the profession are due to the Carnegie Institution, without a grant from which the publication of this invaluable work would have been impossible.

**The Civil Sanitarium at Baguio, Benguet, in the Philippines.**—From Dr. Jerome B. Thomas, attending physician, surgeon, and superintendent of the sanitarium, we learn that in the opinion of those who have spent several years in the Philippines the establishment of the sanitarium solves the problem of the prolonged residence of Americans in the islands, and will therefore add greatly to the efficiency of our civil service. It is the continuous high temperature of Manila that enervates, and if white men and their families can spend even a month or two of the year in Baguio, the remaining months should be passed in Manila in health and comfort. With fair railroad service from Manila to Dagupan, and the completion of the mountain trails, one should be able to make the trip with comfort in 48 hours. The climate is said to be fine and bracing during the entire year, and almost without exception the convalescents who come up from the tropical lowlands react to it promptly and return after a month or two

with a considerable amount of surplus energy stored up. At the height of the winter season of 1902–1903 the thermometer fell every night to 42°–50° F., but rose to 70°–75° in the middle of the day. The U. S. Commission intend to transfer the seat of government temporarily from Manila to Baguio, and will of course bring their families and their corps of assistants with them. They will probably remain during March, April, and May, which are the most trying months in Manila. The main building Dr. Thomas says will accommodate 60 people, and is finished with the exception of a part of the furnishing. Five large cottages will be finished within a month, and will constitute an annex. Patients are beginning to arrive, but he does not expect many this season on account of the long, expensive, and difficult journey necessary to reach there. However, the government is expending large sums of money on the construction of roads and trails, and before the expiration of six months there will be a good road connecting the sanitarium with San Fernando, on the coast of the China Sea. In another column we republish further details of the sanitarium.

**For Lessening the Dispensary Abuse.**—The Rhode Island Hospital at Providence, according to Dr. Johnson Peters, in *Charities*, has adopted a simple and effectual method. It was inaugurated in 1896. Opposite the entrance is a prominently displayed placard:

Patients are admitted to this department between 9 and 10 a.m. on weekdays only. The services of the physicians in attendance are given free and are

FOR THE POOR ONLY.

Patients who are able to employ a physician will not be treated in this department. All patients wishing to receive treatment, should bring a letter of recommendation from some physician in good standing, from the agent of some charitable association, or from some person known to the hospital agent.

If the patient does not bring such a recommendation he will be required to sign a statement that he is unable to pay for professional services, and that he requires charitable aid.

This rule applies to all cases except recent accidents, cases of emergency, or of sudden sickness. Patients will be charged a nominal sum for medicines, dressings, ointments, apparatus, and appliances.

Each applicant is taken in turn and privately questioned by a paid agent who is in attendance daily. If the agent is in doubt as to applicant's ability to employ a physician, and if the case is not an emergency one, he tells the patient he is not able to admit him and asks him to come again with a letter from some clergyman, physician, or other person of responsibility stating that the applicant is unable to pay for a physician's services. If the patient is admitted, the agent gets the following data: Name, address, occupation, number of children and their ages, the wages earned by the applicant and each of the children, by whom recommended, and the reason for applying, all of which is indorsed by the patient's signature. During the first six months after the system was inaugurated 30% of the applicants were rejected. The yearly average of rejected applicants since that time has been 12%. Only about 9% of those referred for letters of recommendation returned with such letters. During the six months previous to the operation of the system, 5,038 applicants applied for

admission to this department, while during the first six months after this plan was put into use the number dropped to 2,952, a decrease of 40%.

**The Case of Performing Wild Animals.**—Last week the papers contained an account of a woman being terribly injured, perhaps killed, by the enraged leopards she had been abusing in the Bostock "show." Last year one elephant killed his fourth trainer. Every year there are probably several men killed by the enraged animals of "shows," but these victims would deserve none of our sympathy were they themselves not the tools of a debased public. We affect indignation at degenerate Spain and her bull-fights, but our own degeneracy is in this respect greater as our animal shows are a more weak and cruel relic of the old vile barbarism which culminated in the Roman gladiatorial spectacles. We say *more cruel* advisedly. The bulls and horses used by the Spanish barbarians are killed speedily and are not subjected to a life of long-dragged-out suffering. The captivity of wild animals is bad enough, is indeed sufficiently cruel, even in our zoological gardens. But there is compensation there because of the comparative freedom of the animals, but especially because good comes to the thousands of onlookers in the knowledge and sympathy gained and aroused. In the case of the wild animals who are forced by torture and fear to perform feats utterly against their nature there is a worse than uselessness, there is a real gloating by the human animals over the poor beasts and an arousing of the passion of cruelty. The hot irons, the goads, the wire ropes, the drugging, and other nameless cruelties, are not easy to prove but are not myths. There is more cruelty in one day in any one of a hundred traveling animal shows in the world than in all the medical laboratories of all time. And yet the antivivisectionists—but we forbear!

The football controversy receives a clearer light from some statistics gathered by Professor Dexter in the *Educational Review*. His figures are based upon returns from 60 colleges, cover 10 years of time, and include the records of 1,374 separate teams. Out of the 22,766 men who had been members of these college elevens 654, or 2.9%, had received injuries serious enough to necessitate absence from college exercises. Professor Dexter estimated the ratio of permanent injuries at one for every 2,846 players. Professor Dexter thinks the deaths and serious injuries are so few as to be "practically negligible." We are not inclined to agree that 654 serious injuries is a matter too trivial to be noticed. The ratio of increase with each year is the important thing, and this is passed over in silence. It is, beginning with 1893 and ending in 1902, as follows: 40, 46, 40, 48, 52, 52, 67, 90, 76, 143, and this although the number of men playing is decreasing. There is another question that is left in silence, What is the gain, to offset the 654 serious injuries by football, that could not be also attained by more gentlemanly and sportsmanlike games? And lastly is another untouched question, Are the morals, direct and indirect, of this form of sport such as one would like to see ruling in our business and social life?

## AMERICAN NEWS AND NOTES.

### GENERAL.

**"Cantus Transcendentalis."**—Professor Karl Hahn hopes to demonstrate at the St. Louis World's Fair next year that music hath charms to soothe the savage beast by means of the "cantus transcendentalis," an instrument he has invented for peculiar use in hypnotizing melancholia patients and "aiding missionaries to the heathen." The instrument resembles a small organ and is said to duplicate the human voice.

**American Medical Association.**—Among the attractions which will be offered the members of the American Medical Association and their friends at the meeting to be held in New Orleans May 5 to 8, is an excursion from New Orleans through the sugar-cane, rice and oil fields of Louisiana and Texas to San Antonio, where the old Alamo, the shrine of Texas liberty, is preserved by the State, and where are many valuable relics. The rate will be low, and will include berth in a Pullman car and the exclusive use of the same for three days, the length of the trip. Particulars may be had from Dr. J. W. Head, San Antonio, Texas.

**Reduced Rates to Congress of American Physicians and Surgeons.**—The Committee of Arrangements announces to the members of the Congress that they have secured from the various passenger associations a reduced fare of one and one-third rate for them and for their friends attending the Sixth Triennial Congress, May 6 to 14. Tickets cannot be procured earlier than May 8, nor later than May 13, but will be good until May 16. In the circular containing this announcement is a list of the principal hotels of the city, together with the range of prices per day. Information on this subject can be had of Dr. A. R. Shands, chairman, 1319 New York avenue, Washington, D. C.

**Use of Oleomargarin.**—It is stated that the law passed by the Fifty-eighth Congress requiring that oleomargarin be properly labeled and placing a duty on its manufacture is not causing that decrease in the consumption of this article which was confidently expected, especially by the dairymen throughout the country. This failure, to a certain extent, is shown by the Commissioner's figures, which show that a total of 50,000,000 pounds of oleomargarin have been sold in eight months ended February 23, a decrease of only 30% from the corresponding period of the previous year. This decrease is probably accounted for, to a large extent, by a curtailment in the manufacture of this product immediately after the passage of the bill rather than by a marked decrease in its consumption.

**Untrustworthy Mortality Records.**—Frank L. Hoffman, a statistician of the Prudential Insurance Company, calls attention to the crude and irregular erratic mortality figures reported on death rates representing the different parts of the country, and says the death rate can rarely be relied upon to make comparison of the mortality of different communities, although it is a fairly satisfactory indication of local conditions where the mortality of a given city is compared with itself for a period of years. The death rate at the age period of 25 to 34 years for Natchez, Miss., is given as 35.1 per 1,000 against a death rate of only 9 per 1,000 for Newark, N. J. Again the death rate of white males of the age period 40 to 49 in Washington is given as 16.2 per 1,000, whereas for Havana, Cuba, it is placed at 31.8 per 1,000.

**Congress of American Physicians and Surgeons.**—The Committee of Arrangements of the Congress of American Physicians and Surgeons, to be held May 12, 13 and 14, 1903, at Washington, D. C., have sent out a circular calling attention to the importance of registering on the part of members. Blanks are being sent out to this end. In lieu of a banquet the committee have arranged for a "smoker" which is to be given on the evening of May 14. On the evening of the smoker, in an adjoining hall, will be given an informal demonstration of pathologic specimens and lantern slides as follows: "Lantern slide demonstration of the ring bodies in the blood of anemic patients," by Dr. R. C. Cabot, of Boston; "Lantern slide demonstration of 21 cases of Paget's disease (osteitis deformans)," by Dr. E. A. Lock, of Boston.

**The Tallest People.**—In a comparative table of stature, arranged according to nationalities, the United States Indian stands higher than any other race of the world, though the Patagonian runs him very close. The white citizen comes next. The United States negro ranks fourteenth in the scale, and of all the countries in the world considered the Portuguese are found to be the shortest. It has always been proverbial among anatomists that blond nations are greater than their darker neighbors. This is due to the geologic positions of the blond races. They are characteristic of the north, and on account of the lower degree of temperature are induced to take more exercise, which throws them more in the open air. At the top of the list of countries, arranged in order of stature, the first seven, after the United States white men, are Norway, Scotland, British America, Sweden, Ireland, Denmark and Holland, all northern nations.

## EASTERN STATES.

**Generous Easter Gift.**—Included in the list of contributions for the Convalescent Home of the Children's Hospital of Boston was an anonymous Easter offering in the sum of \$10,000, of which the hospital was in very great need.

**Fall River to Have a New Hospital.**—Mrs. Elizabeth R. Stevens, of Swansea, is said to have given \$100,000 for the erection of a new hospital in Fall River. The condition attached to the gift is that \$100,000 be raised in some other way, and substantially that sum is now provided. The whole matter is in the hands of the board of trustees and the new hospital will soon be constructed.

**Moth Extermination.**—After a three weeks' campaign the work of the school children of Lynn in exterminating the brown-tail moth has ended for the season. With one school's returns not yet received, the total number of nests collected and burned is 417,389. The Board of Trade offered cash prizes for the schools that did the best work, and for the separate rooms that led in the different buildings. These prizes are to be devoted to school purposes, purchases of pictures, statuary, for school decoration, or some needed educational appliance.

**Tenement Reform in Hartford.**—The Charity Organization of the city of Hartford, which has for its object among other things investigation of all reported unhygienic conditions and surroundings, has reported and discussed the following: First, that we in Hartford have examples of wretchedly bad buildings; second, that the badly constructed buildings are at present unprofitable to their owners; third, that some well-constructed tenement regulations would prevent the construction of tenement houses that lack the air and light necessary for health, without encroaching upon the interest of the landlords.

## NEW YORK.

**Association of Medical Librarians.**—The next meeting of the Association of Medical Librarians will be held in New York, May 16.

**Valuable Teeth.**—Richard K. Fox, proprietor of the *Police Gazette*, is suing the Metropolitan Street Railway to recover \$10,000 for the loss of two teeth as the result of a fall he received when alighting from a One-hundred-and-twenty-fifth street car in December, 1900.

**Vaccination in Private or Parochial Schools.**—The *New York Sun* says that Attorney-General Cunnenn has given out an explanation of his opinion in the Dunkirk parochial school vaccination case. He holds that the State law does not compel the authorities of parochial schools to exclude unvaccinated children but that the local board of health may, if it deems it necessary, issue an ordinance directing general vaccination and providing a penalty for noncompliance.

**Skin-grafting.**—It is stated that although 1,346 pieces of skin have been grafted on the body of Cashier Wilson Frederickson, of the United States Express Company, who was one of the victims of the Plainfield railroad wreck, the doctors at the Muhlenberg Hospital have decided that more grafting is necessary. Forty-five men have already submitted to the operation of having portions of epidermis removed from their arms and legs in behalf of the injured man, and still further grafting is necessary.

**Politics in Hospital Management.**—A bill has passed the Legislature of New York and received the signature of the Governor which completes the scheme as mapped out by the Governor of that State for the centralization of the entire control of the State hospitals, placing them all under one general board of control, this board being responsible to the Governor alone. A purchasing agent is to be appointed who shall, each year, buy all the supplies that are to be distributed to each of the State hospitals, his office being in Albany.

**Child Criminals in New York.**—The grand jury of Brooklyn has been especially impressed with the fact that so many of those charged with crime are boys and girls under age. In their report they say: "There are several reformatories and societies in the county for reform and rescue of children, and their number should be largely increased. Manual training schools should be multiplied. Education and industry are the great saving influences. The Brooklyn Society for the Prevention of Cruelty to Children is especially commended for its splendid work, having cared for about 39,000 children since its organization. In this connection our people are to be congratulated upon the passage of the act establishing a Children's Court in this county, and that there is a prospect of the early enactment of the 'Children's Labor bill,' which specially restricts the hours in which children may labor, and the ages at which they shall be permitted to do so." In concluding the grand jury says: "We trust that there may soon be an awakened and enlightened public opinion upon whose all-powerful influence we can alone depend to bring about the needed reforms in our city."

## PHILADELPHIA, PENNSYLVANIA, ETC.

**Appropriation to Hospitals.**—Governor Pennypacker has signed bills passed by the Legislature granting \$260,000 to Jefferson Medical College Hospital; \$260,000 to the Medico-Chirurgical Hospital; and \$175,000 to the University of Pennsylvania Hospital. The money in each instance is to be used for the construction of new buildings and for maintenance.

**Doctor Sues for \$10,000.**—It is averred that Dr. Rhinehart, of Pittsburg, has entered suit against W. C. Jute, of that city, to recover \$10,000 for medical services. The plaintiff avers that he was physician to the Jute family, and some time ago it became necessary for him to give up all other medical practice and accompany the defendant to Europe as his physician, service being rendered from July 8, 1902, to September 26, 1902.

**Osteopathy Not Legalized in Pennsylvania.**—The bill which during the early part of the winter was introduced in the Pennsylvania Legislature to legalize the practice of osteopathy and to provide a board of examiners for this so-called school of medicine has been defeated. There were 24 physicians and 2 druggists among the members of the House, and it is said that they contributed effectually to the defeat of the measure.

**To Combat Tuberculosis.**—The New Jersey Legislature has appropriated \$300,000 for a sanatorium in which the tuberculous poor may be treated. This is in furtherance of the plan adopted more than a year ago, when the Legislature appropriated sufficient money for acquiring a site for the necessary buildings. The present appropriation will give means for the construction of buildings and the inauguration of a systematic attack on tuberculosis.

**Appropriation for Hospitals.**—The following appropriation bills passed finally: Temporary Home for the Aged, Allegheny City, \$3,000; Corry Hospital, \$7,000; Home for the Aged, Philadelphia, \$4,000; Wood's Run Industrial Home, Allegheny, \$1,500; Hayes Mechanics' Home, Philadelphia, \$3,000; German Hospital, Philadelphia, \$30,000; Philadelphia Orthopedic Hospital, \$31,000; Wilkes-Barre Hospital, \$38,000; Soldiers' Monument at Middlespring, Cumberland county, \$4,000; Hamot Hospital, \$16,000; Home for the Friendless, Allegheny, \$6,000.

**Home for Convalescent Children.**—The Gwynedd Home for Convalescent Children has been completed at Gwynedd, Pa. The object of this home is to take children between the ages of 4 and 10 who have been treated in hospitals throughout the city, and although well enough to leave these institutions, have not sufficiently recovered strength to make it advisable for them to go back to their homes. The home is to be absolutely nonsectarian and will be open both winter and summer. As the expenses of building the home have been defrayed by the philanthropists who are behind the movement a request has been made that charitably disposed persons contribute toward the home's maintenance. It will cost about \$4,000 a year to maintain the new institution.

## SOUTHERN STATES.

**Celebration of the Reappearance of the "Index Medicus."**—Professors Osler and Welch, of Baltimore, will give a dinner at the Maryland Club this evening, April 18, to celebrate the reappearance of the *Index Medicus*. The Editor, Dr. Robert Fletcher, will be the guest of honor.

**Sues for Loss of Sleep.**—A Tennessee woman has filed suit against the Pullman Company, asking \$1,999.99 damages, because she was compelled to ride in a sleeping-car from Nashville to Memphis, in which were a number of boisterous Tennessee legislators. She alleges that she was unable to sleep and subjected to much humiliation and annoyance from the Tennessee Solons.

**Private Maternity Institution.**—Brent-Mar Private Maternity and Lying-in Home is an institution located in Washington, D. C., for the convenience of patients before and during confinement. This institution is in no sense a public hospital, but a private home, which is open for the accommodation of women about to be confined, and is managed in such a way that it has received the approbation of ethical physicians.

**Human Beings With Charbon.**—From New Orleans comes the information that at Prairie Nammou, in Acadia parish, a number of persons are believed to have anthrax. It is stated that about 225 head of stock have died. The small farmers, ignorant of the virulence of the disease, skinned some of the dead animals and sold the skins. As a consequence there are thirteen human beings sick of charbon. A veterinary surgeon set to work to vaccinate the healthy animals against charbon, but found it impossible to convince many of the farmers of the necessity of this treatment. They were afraid that vaccination would make the animals sick and interfere with the ploughing, which is now well under way. The police jury of Acadia has been called together in extra session for Tuesday to take some action to stamp out the disease.

## WESTERN STATES.

**State Medical Association of Missouri.**—The State Medical Association will hold its regular annual meeting at Excelsior Springs, Mo., April 21, 22, and 23.

**Anticigaret Measure in Utah.**—The new cigaret measure introduced by a woman legislator in the Utah Legislature has been signed by the Governor. It provides a fine of \$5 or five days' imprisonment for any person under 18 years of age who has in his possession any cigaret, cigar, tobacco or opium.

**A Denver Academy of Medicine.**—At a call meeting held March 31, 1903, the Denver Academy of Medicine was organized, the main object of which is the building of a home for the medical profession, where all medical associations may meet and where a library and society room may be maintained. The appropriate officers were elected.

**Plague Reported in Kansas.**—It is stated that the secretary of the Board of Health has gone to Rice county to investigate the cause of nine sudden deaths among a gang of railroad employes. There is a report that the deaths are due to bubonic plague, though it is stated that it may be smallpox. The surrounding territory is under strict quarantine.

**Rabies in Chicago.**—The Bulletin of the Health Department of Chicago for the week ended April 4, 1903, says that rabies in mild form is still prevalent in some parts of the city. During the winter three dogs have been sent to the laboratory and postmortem of the animals showed them suffering from hydrophobia. A cow bitten by a rabid dog has been detained to await the results of the bite.

**Smallpox in Old Clothes.**—A young woman of Scipio, Ind., recently died of smallpox and an investigation showed that two weeks before she was taken ill she opened an old trunk in an attic, which contained clothing that had been worn by her father just previous to his death from smallpox 39 years ago. The health officers believe that she contracted the disease from handling the infected clothing.

**Deathrate in Chicago.**—It is said that with one exception, that of March, 1895, last month's deathrate in Chicago was the highest since 1893, the World's Fair year. The cause is accounted for by the general prevalence of influenza. The average March deathrate for the previous 10 years was 15.93 per thousand population, but for this March it was 16.94 or 6.3% higher than the 10 year average. In 1893 it was 19.18, 1895 it was 17.88, and 1899 it was 16.75.

## CANADA.

**Canada to Bar Cigarets.**—The House of Commons has voted affirmatively on a measure declaring for the prohibition of the importation, manufacture and sale of cigarettes in the Dominion of Canada. The bill met with violent opposition, but was finally passed.

## FOREIGN NEWS AND NOTES

## GENERAL.

**"Water Cure" Forbidden.**—In furtherance of an act of Congress approved January 30, 1903, "to promote the efficiency of the Philippine constabulary, etc.," General Davis, commanding the division of the Philippines, has issued instructions to the Philippine scouts. Among other things, his instructions say: "Sections 2 and 3 of Act 619 of the Philippine Commission, entitled 'An act to promote good order and discipline in the Philippine constabulary' makes it a crime if any member of the constabulary whips, maltreats, abuses, subjects to physical violence or tortures by the so-called 'water cure' any person for the purpose of extorting from him any confession or inducing him to give information whatsoever or countenances, allows or permits such acts. The principle of these sections will apply to members of the Philippine scouts ordered to assist the constabulary under the above act of Congress, and they will be brought to trial and punished under the articles of war if they commit any such offenses. The contents of this paragraph will be made known to members of scout companies in their native language."

## GREAT BRITAIN.

**Ventilation of the Cornish Mines.**—The Home Office in England is considering the ventilation of the Cornish mines. It is said that at Dolcoth mine, where upward of 700 men are employed, during the past six years or more a number of cases of prolonged anemia associated with skin affection has attracted notice, and eventually a detailed investigation was entered upon. The general condition of the mine, the symptoms of the workers, the symptoms of the disease were studied. It was found that the anemia was due to ankylostomiasis and that this parasite was responsible for most of the troubles in the mines, aside from such as could be relieved by a thorough system of ventilation which is advocated.

## CONTINENTAL EUROPE.

**Madrid Medical Congress.**—Many American physicians and surgeons are looking forward to the fourteenth International Medical Congress of Physicians and Surgeons, to be held in Madrid from April 23 to April 30. A number of Americans will attend this meeting.

**Students in Russia.**—News from St. Petersburg states that in the recent revolt of women students against the new examination regulations of the medical institute, 317 young women were reprimanded and 23 others were severely punished and excluded from the institute. Sixty male students also were expelled. The medical institute and the university were temporarily closed, but now have been reopened.

**Serum Treatment for Scarlet Fever.**—Professor Baginsky, the eminent physician in charge of the Children's Hospital in Berlin, writes, under date of March 22, that he has treated about 100 cases of scarlet fever with Aronson serum, that he can say the serum is not unworthy a fair trial and is in some degree successful, but the number of cases is not great enough to decide the question. The administration of the serum is without danger to the patient. Serum is made from the blood of horses which have been rendered immune by the injection of a culture of streptococci obtained from the blood of scarlet fever victims.

## OBITUARIES.

**Isaac S. Tanner**, of Shepherdstown, West Virginia, died in that city April 10. Dr. Tanner had been a physician and surgeon of ability until his retirement several years ago. He was in his eighty-fifth year. He entered the Confederate army as First Lieutenant of Company F, First Virginia Cavalry, at the breaking out of the war. He was promoted to the rank of Surgeon after the first battle of Bull Run, was on the staff of General Joseph E. Johnston, and finally became Chief Surgeon of General Hoke's division. He was a close student of economic problems as well as of medicine and contributed a number of written articles on financial subjects.

**Edgar Perry**, of 1120 Boylston street, Boston, Mass., died suddenly at his home April 7, of apoplexy. He was graduated at Brown University in 1880, and was employed upon various newspapers until 1898, when he was graduated from the Harvard Medical School and began to practise medicine in the City of Boston. He was a member of the Massachusetts and of the Boston Medical Societies.

**William H. Curry**, died April 10 at his home, 904 North Stricker street, Baltimore. His death was said to be due to heart failure. Dr. Curry was born in Parkton, Baltimore county. He was a graduate of the Maryland Medical College. He practised for several years, but finally entered the insurance business, in which he continued to the time of his death.

**Hobart Cheesman**, of 171 W. Ninety-fifth street, New York City, died in St. Luke's Hospital on April 11, of a complication of diseases. He was 59 years of age and was graduated from the New York University in 1878 and for twenty years had been one of the chief examiners of the Equitable Life Insurance Society.

**William G. Allen**, of Mansfield, Mass., died April 4. He was educated at Woodstock Academy, Vt., and at the Albany Medical School. He was at the time of his death District Department Grand Master of the Twenty-second Masonic district.

**Bernard Stuve** died at his home in Springfield, Ill., April 11, aged 73. Dr. Stuve was one of the best known physicians in Sangamon county until his retirement several years ago. He was prominent in the State Historical Society.

**William A. Durrie**, of Prospect street, East Orange, N. J., April 8, aged 80 years. He had practised many years in Jersey City, but moved to East Orange. Of late years he had retired from active practice.

**Gny Bryan Miller**, of New York, died in Paris, France, April 7, in his thirty-first year. Dr. Miller was a graduate of the New York University and of the College of Physicians and Surgeons in 1898.

**Henry D. Kerfoot**, a prominent physician of Berryville, Va., died April 9, aged 57 years. He served with distinction in the Confederacy, having been associated with Col. John S. Mosby.

**Charles T. Sompers** died at his home at Blythedale, Cecil county, Md., April 9, aged 82. He suffered from apoplexy several years ago, from which he never fully recovered.

**L. G. Archambault** died in Woonsocket, R. I., April 8. He was born in St. Paul Ermitte, P. Q., in 1847, but came to Woonsocket in 1870, where he resided until his death.

**J. C. Gordon**, Superintendent of the Illinois Institution for Deaf and Dumb, at Jacksonville, Ill., died in that city April 12, after an operation for appendicitis.

**William S. Whitwell**, of 37 West Eleventh street, New York City, died April 8, of Bright's disease. He was 57 years old.

**Sheldon Stringer**, one of the most widely known physicians in Florida, died April 7, at Brooksville.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

PNEUMOCOCCUS ARTHRITIS, WITH REPORT OF A CASE AND TABULATION OF SOME ADDITIONAL CASES.

BY  
R. M. SLAUGHTER, M.D.,  
of Theological Seminary, Va.

Member of the Board of Medical Examiners of Virginia.

The subject of pneumococcus arthritis has been so well dealt with in the papers of Leroux,<sup>1</sup> Cave,<sup>2</sup> Cole,<sup>3</sup> and Herrick,<sup>4</sup> that I wish simply to report an interesting case recently seen in my own practice, and to append seven other cases found in recent literature with those already reported or collected by the writers mentioned.

The first of these cases, Meunier's,<sup>5</sup> although reported as far back as 1894, seems to have escaped the notice of all collectors except Pfisterer.<sup>6</sup> This writer has reported two cases and has collected and tabulated a number of others. All of these, however, with the exception of Meunier's case, three of Lexer<sup>7</sup> and his own, are included among those collected by the foregoing authors. Lexer's and Pfisterer's cases were all in

R. H., white, male, aged 15, is a poorly nourished overworked child. Father is living and healthy, mother died of pulmonary tuberculosis and the family has a marked tuberculous diathesis. In the early part of February, 1902, the patient had an attack of pneumonia of the right lung, and was treated by Dr. G. B. Fadeley, of Falls Church, Va. On February 15 I saw him with Dr. Fadeley and found him convalescent, but suffering intense pain in the right knee which showed every sign of an extensive arthritis.

Inquiry elicited the information that for several months past he had had trouble with that leg, which according to his account had been weak, and at times painful, and there was present evident muscular atrophy. We had in fact the cardinal symptoms of incipient joint tuberculosis: pain, weakness, muscular spasm and atrophy, and it was clear that the boy prior to his attack of pneumonia had incipient tuberculosis of the knee-joint. Later this opinion was confirmed by finding tubercle bacilli in pus from the joint. On February 20 he entered the Alexandria Hospital under my care. His general condition was now so bad that I hesitated to do any radical operation, and determined to try simply draining the abscess cavity and to improve his general condition. By this time the pus had escaped from the joint cavity into the popliteal space and burrowed downward beneath the gastrocnemius muscle to a point just above the inner malleolus, and as it was discovered later, upward along the outer hamstring tendon for six inches. On February 21, under chloroform, the joint was punctured with a large trocar and the lower sinus opened at its extremity. An enormous quantity of pus was thus evacuated and the joint and sinus washed out. Following this there was at first marked relief of pain, but no general improvement in spite of daily irrigation of the abscess and tract. Treatment consisted of stimulants and generous diet. The temperature continued

No.	Observer.	Date.	Age.	Sex	Relation to pneumonia.	Seat of arthritis	Nature.	Result.	Complications.	Treatment and remarks.

68	Slaughter.	1902	15	M.	During an attack of pneumonia. Right lung.	Right knee.	Suppurative.	R.	Preexisting tuberculosis of joint. General infection, septicopyemic in nature. Sanguinopurulent stools. Diffuse cellulitis of left lower extremity and stump.	Incision and drainage. Amputation. Pneumococci in pure culture from pus. Tubercle bacilli in pus from joint.

infants. The latest reported case is that of Sireday.<sup>8</sup> These cases I have tabulated with my own, continuing the tabular form adopted by Cave and followed by Cole and Herrick. In Cave's table are 31 cases, 23 of which were collected by Leroux. Cole adds 11 more and Herrick 21, but as 3 cases (those of Nicolaysen, Flament, and Allen and Lull) are included by both of these authors, the whole number previously reported should be 60 instead of 63. I have therefore numbered the cases in my table 61 to 68 inclusive.

It may be of interest to mention two cases described by Bourcey,<sup>9</sup> for these were almost certainly cases of pneumococcus arthritis, but as they occurred prior to the establishment of the etiologic relationship of *Diplococcus lanceolatus* to pneumonia they are not included in the table. One of these was a case of suppurative arthritis of the right shoulder occurring in a man of 25. It began on the seventh day preceding an attack of pneumonia, and was followed by recovery. It is stated that in the pus from the joint there were found diplococci in short chains. In the other, there occurred in a man of 64, on the first day of a pleurisy a serous arthritis of a joint of the right thumb. This case was complicated with nephritis and terminated in death. Diplococci in short chains were found in the fluid from the joint and pleural cavity. The date of Bourcey's paper is 1883.

The following is a detailed report of my case:

high and there was constantly considerable discharge from the sinus. The discharge from the joint soon ceased and the opening closed but there was no return of joint distention. The leg sinus was then opened at its upper extremity just behind the joint and the tract washed out daily. At this time the upper sinus was discovered. Amputation was determined upon as a last resort, and despite the fact that it did not seem possible that the patient could survive the operation, the extremity was removed at about the middle of the thigh in order to avoid the upper sinus. In the operation I was ably assisted by Dr. M. D. Delaney. Dr. A. A. Ritenour administered the ether. To our surprise the boy survived the operation, and after several weeks of hovering between life and death began slowly to improve. During these weeks there was diffuse cellulitis of the stump and of the left leg, considerable sloughing occurring in the stump. There was high temperature at all times, frequently rising as high as 105° in the afternoon, and at one time for several days sanguinopurulent stools were passed. His death was daily expected for many days, but finally inflammation subsided, sloughing ceased, temperature became normal and the boy recovered. The stump, however, did not heal entirely for several months.

In the pus from the joint were found both tubercle bacilli and diplococci. The diplococci were identical in appearance with *Diplococcus lanceolatus* both in the pus and in culture. Some cultures were kindly made for me by Dr. James Carroll, of the U. S. Army, and pneumococci in pure culture were obtained.

Examination of the knee-joint at the time of amputation showed that the articular cartilages were entirely destroyed, and the articular extremity of the tibia deeply eroded, presenting the appearance of advanced tuberculosis.

Many reported cases seem to demonstrate that the pneumococcus has a predilection for joints that are weakened by previous disease or injury, but this case is unique in being the first reported in which it attacked a tuberculous joint. The case is also unique because the boy survived so desperate an illness with such complications and a major operation. The result proved, however, that it would have been far better to have amputated in the beginning, for I feel sure that had this been done recovery would have occurred much earlier and the boy been saved much suffering. My experience in this case and the study of the reported cases incline me strongly to the opinion that immediate amputation is the proper procedure in pneumococcus inflammation of large joints, when the pus has escaped from the joint and sinuses formed, thus giving rise to extensive absorbing surfaces.

Of the 68 now reported cases, 27 patients recovered and 40 died and the result of 1 is unknown, a mortality rate of about 60%.

## FIRST EARLY ELECTIVE OPERATION FOR APPENDICITIS PERFORMED IN WARREN COUNTY, PENNSYLVANIA.

BY

J. NORMAN DAVIES, M.D.,  
of Warren, Pa.

In *American Medicine* for March 14, 1903, in an article by Dr. W. M. Robertson, the author claims that "on January 21, 1902," he performed "the first early elective operation for appendicitis performed in this (Warren) county." Simply to correct the error, I would like to report the following case:

M. F., aged 9, was sent to the Emergency Hospital at Warren, Warren county, by Dr. H. A. Kitchen, and entered the service of my brother, Dr. George A. Davies. A diagnosis of appendicitis made by Dr. Kitchen was confirmed at the hospital. Operation was performed September 14, 1901, by Dr. George A. Davies, assisted by myself; the anesthetic was administered by Dr. F. G. Haines, Dr. John M. Davies in consultation. The appendix was removed, abdominal wound closed with three rows of catgut, and without drainage union took place in nine days—at first dressing. Patient left hospital a few days later, and has remained well.

The foregoing was not the first, nor was it the only "early elective operation for appendicitis performed in Warren county" prior to January 1, 1902.

## EARLY OPERATION IN APPENDICITIS.

BY

THOMAS J. TURPIN, M.D.,  
of Monterey, N. L., Mex.

To the Editor of *American Medicine*:—In the series of five cases of appendicitis reported by Dr. Robertson (*American Medicine*, March 14) the doctor makes a strong plea for early operation based upon the "rapid recovery of all the patients." The following cases from my own experience showing the other side of the shield may be of interest:

During the summer of 1897 I treated five patients for appendicitis. All were first attacks and all were severe cases. In each case I urged operation and in three a consultation of five physicians agreed that operation was imperative. All refused operation and I was given the option of treating them without operation or resigning the case. All were treated expectantly chiefly with calomel, saline cathartics, and ice. All recovered, and now after five years' observation there has been no second attack in any instance.

Surgical cases are much more generally reported than

medical and recoveries much oftener than fatal cases. It follows that a disproportionate number of favorable surgical cases are reported. I am far from thinking that all cases of appendicitis should be treated without operation but I believe that if we could get true statistics of all appendicitis cases we would not find such strong argument for operation as appears from Dr. Robertson's five cases and from hospital reports generally.

Every man who feels himself skillful wants to use the knife whenever he thinks it justifiable, but I believe there are thousands of physicians whose experience will indorse my conclusion that the great majority of patients having appendicitis will recover without operation and that a large proportion who have first attacks never have a second one. As to the exact percentage of recoveries with and without operation we are still a long way from being able to get it owing to the fact as before stated that surgeons report their cases while physicians do not.

## "NEURICITY" NOT IDENTICAL WITH ELECTRICITY.

BY

G. W. DRAKE, M.D.,  
of Hollins, Va.,

To the Editor of *American Medicine*:—Allow me through your valuable journal to express my dissent from the views of Loeb, Matthews, Houghton, O'Brien, and others as to the identity of nerve force and electricity.

Many years ago, in a paper read before the Chattanooga Medical Society on The Parallelism of the Uses of Water in Nature and in the Human Body, referring to Franklin's discovery and demonstration of the identity of lightning and electricity, I incidentally remarked that had he been a neurologist he might have gone further and discovered the identity of nerve force and electricity. Subsequently, I discarded the theory of the identity of nerve force and electricity as untenable.

Among the objections to the theory are the following:

The conductors of electricity are very numerous and vary much in their degrees of conductivity. Electricity may be conducted by long metallic wires over long distances, also by submarine cables, and through the air and ground without wires. It may be evolved by the chemic action of nonliving matter or by the friction of the same.

Nerve force or neuricity (a word coined by me) cannot be conducted by metallic wires, submarine cables, through the air, or through the ground. Neither can it be evolved by the chemic action or the friction of nonliving matter. It is always associated with living matter, and its conductors are the same. It is on account of its constant association with the neuron that the name neuricity was given this energy, to distinguish it from energies which are associated with other forms of matter outside and inside of the animal body. By identifying this energy with a specific name I hope that the study of the problem of its mode of action will receive a new impulse and the explanation of the functions of the nervous system be much simplified.

Electricity is evolved by chemic action, friction, heat, or the action of neuricity (the negative electric current often accompanying the current of neuricity). Neuricity is evolved by chemic, frictional, thermic, or electric stimuli.

The behavior of the two energies is different; conductors of electricity are nonconductors of neuricity.

Franklin demonstrated the identity of lightning and electricity by using a conductor of electricity to conduct lightning. Let those who claim that nerve force and electricity are identical try the experiment of using a conductor of electricity for the conduction of nerve force out of the living body into other substances, and attempt to apply it as a motive power of a non-living machine, or to substitute it for electricity in the electric lights.

The rate of movement of nerve force (neuricity) is 100 feet per second, and that of electricity is 1,000 miles per second.

If nerve force and electricity are identical then nerve force and lightning are identical, and sudden death may be the result of a stroke of neuricity in some vital part. I don't like this theory.

ORIGINAL ARTICLES

A PLEA FOR MORE RADICAL OPERATIONS IN MALIGNANT DISEASE OF THE TESTICLE.<sup>1</sup>

BY  
 CHARLES GREENE CUMSTON, M.D.,  
 of Boston, Mass.,  
 AND  
 WILLIAM A. ROLFE, M.D.,  
 of Boston, Mass.

Although the greater number of surgeons at the present day consider castration as a very simple operation and devoid of any great risk, they are nevertheless unanimous in admitting that in malignant tumors of the testicle its curative action is very far from what it should be, and although it may delay the progress of the growth, this delay is certainly of short duration. Sir James Paget considered removal of the testicle in cases of carcinoma of the organ of such little value that he believed 23 months was the ultimate limit of survival of the patient, and Curling in his classic treatise considers castration in these cases of such little value that he questions whether it is really of any use to submit the patient to it. In the *Traité de Chirurgie* published under the direction of Duplay and Reclus, it is stated that recurrence is sure to take place, and in some cases it is so rapid that it might be believed the operation hastens it. In the *Traité de Chirurgie* edited by LeDentu and Delbet, it is said by Sébileau that he has seen cases which led him to believe that castration

of the testicle has been in no way improved on, the authors only advising an incision of the scrotum and removal of the organ. In their very excellent treatise on "Genitourinary and Venereal Diseases," published in 1902, White and Martin make the following statement on page 907: "When the cord is extensively involved the incision should be extended up along Poupart's ligament as already described. It is deepened to the peritoneum, which is stripped up, allowing access to the glands of the pelvis. When the lymphatic

Fig. 2.—1, muscle. 2, fascial flap. 3, spermatic cord.

involvement extends upward beyond reach it may be attacked through a transperitoneal opening. The glands into which the vessels of the cord pass, completely surround the aorta. There is, moreover, one lying upon the external iliac artery which probably will be involved." We have quoted these authors purposely, because they have given the indications for a radical operation, although the technic is omitted.

In his very excellent monograph on "The Operative Surgery of Malignant Disease" Mr. Butlin comes to the following conclusions regarding castration:

Castration for malignant disease is an operation which may be performed with very small danger to life.

The operation, whether for sarcoma or carcinoma, cannot be said to be attended with large success so far as complete cure of the patient is concerned, but there is a great lack of information on this subject.

There is, however, evidence to show that it may be attended with permanent success, and there is still further evidence to show that the operation may be an excellent palliative measure even if it fails in its primary object—cure.

There is comparatively little fear of recurrence *in situ* unless the cord is thickened or the scrotum adherent at the time of the castration.

There is no prospect of permanent success for operations for recurrent disease unless the recurrence is seated in the scrotum.

Castration may be performed for malignant disease of both testes, if not with a reasonable prospect of permanent yet certainly of temporary relief.

The attention of pathologists and surgeons must now be directed to the extension of the disease to the lymphatic glands with a hope of devising an operation which may help to avert the occurrence of glandular affection and dissemination after the removal of the testis.

The inefficaciousness of castration has certainly nothing to do with the testicle itself, although Monod and Terrillon have put forward the theory that the

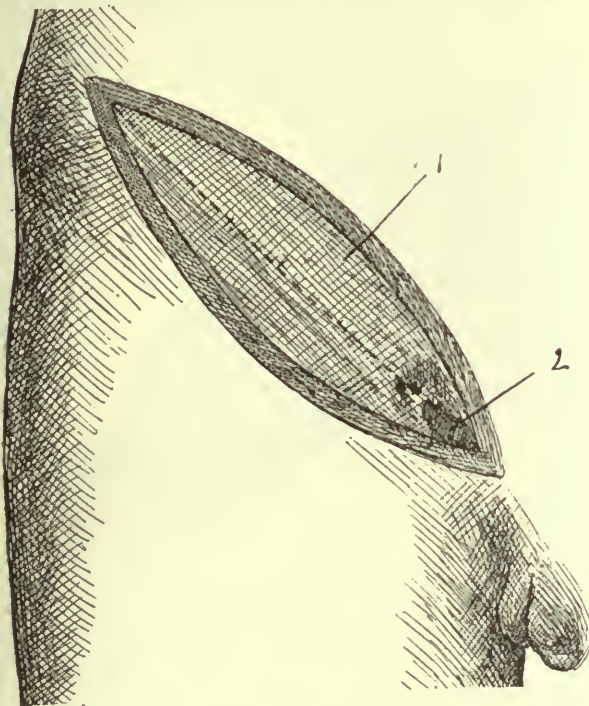

Fig. 1.—1, aponeurosis, showing line of incision. 2, external inguinal ring.

had increased the activity of the metastases in the glands, but he can in no way account for this satisfactorily.

In consulting a number of treatises on surgery which have appeared in the United States within the last five or six years, such as Jacobson's, Fuller's, Park's System of Surgery, a System of Surgery by Dennis, and many others, the technic of the operation for malignant dis-

<sup>1</sup>Read by invitation at the annual meeting of the Manchester, (N. H.) Medical Society, February 18, 1903.

rapidity of recurrence is due to the great abundance of lymphatics in this gland. On the other hand, microscopic researches have proved that carcinoma and sarcoma of the testicle are composed of the same cell elements found in these neoplasms in other organs, and that these elements are always grouped in identically the same way, regardless of the organ in which they arise. The point to be attained when removing a carcinomatous testicle is to avoid a recurrence in the lymphatics, and there is nothing surprising in this, since

Fig. 3.—1, Poupart's ligament. 2, first layer of sutures uniting the muscle to Poupart's ligament.

secondary lymphatic infection is the cause of recurrence in all cases of carcinoma.

According to the classic works on anatomy, the lymphatics of the testicle empty into the lumbar glands; this is certainly an indefinite statement. In a very interesting article published some 18 months ago by Cunéo, the following conclusions are arrived at regarding the lymphatic territory of the testicle: (1) The lymphatics of the testicle empty into the right and left aortic glands; (2) in some subjects there is a lymphatic trunk which empties into a gland situated on the external iliac vein, immediately in front of the point where the ureter crosses this vessel; (3) in a full term fetus were found three small glands along the route followed by the lymphatics of the testicle in their passage into the iliac fossa.

Now, in the everyday surgery of malignant tumors of the breast and uterus, the surgeon is no longer content in simply removing the diseased structure, but large incisions are made in order to remove all the lymphatic glands, whether enlarged or not, which are connected with the lymphatics coming from the diseased organ. It is perfectly logical when operating for a carcinomatous testicle to be guided by the rule governing all operations for carcinoma, and consequently one should endeavor to remove all the lymphatic glands which are susceptible of becoming involved in malignant disease of the seminal gland. It is more than probable that if operators had more generally applied this principle fewer early recurrences would have been recorded. It is evident that at the present day we have not the pretension of radically curing carcinoma by operation in many cases, and it is

also evident that we cannot with impunity remove the enlarged lymph-nodes situated over the aorta, but it is most certain that as regards recurrence a technic may be employed by which the outlook for the patient is certainly better, and we will now describe a technic which we trust may prove of some value. Unfortunately we have only used it once, in the case of a man of 52, afflicted with a carcinoma of the right testicle. The operation was done 20 months ago, and up to date the patient has remained free of recurrence.

In describing the steps of the operation in the first place we would say that we follow Girard's technic for inguinal hernia. The skin incision commences about three centimeters above Poupart's ligament and parallel to it, commencing just a little below the external inguinal ring, and carried from three to four centimeters above the internal ring. It is useless and even bad practice to extend the incision too low, because by pushing the testicle upward it can be easily made to protrude from the lower part of the inguinal incision. So soon as the glistening surface of the external oblique is freely exposed by peeling off the fat it is incised from the external inguinal ring to a little above the internal ring, as is seen in Fig. 1. The fascia is then separated on both sides from the underlying structures to the extent of about four centimeters, so that the internal oblique muscle is freely exposed, and after pushing this aside the inguinal canal with the cord is freely exposed, as shown in Fig. 2. If a hernia is present it naturally should first be treated according to the ordinary rules.

After this incision the cord is easily dissected out of the canal up to the internal ring, and by splitting open the posterior wall of the canal the internal iliac fossa can at once be entered. Since the elements composing

Fig. 4.—1, first layer of sutures uniting muscles to Poupart's ligament. 2, second layer of sutures uniting the internal flap of fascia to Poupart's ligament.

the cord become separated at the internal ring, the vas deferens dipping down toward the small pelvis, while the spermatic vessels pass over the anterior aspect of the psoas muscle to attain the lumbar region, one must naturally attend separately to the vas deferens and the spermatic vessels. After the vas and the vessels have been freely isolated, they should be separately ligated as far down as possible in the pelvis and then severed between two ligatures. The stump of the vas should be

cauterized with pure carbolic acid. The peripheral part of the vas deferens and the spermatic vessels is then isolated in the iliac fossa, and a search should be made for the lymphatic node which is situated on the external iliac vein at a point where the latter is crossed by the ureter, and should this be found enlarged it ought to be removed. The dissection of the cord in the inguinal canal is then continued from above downward, but the cord alone is not to be removed but all its envelopes as well, and if this is done carefully the three small lymphatic nodes described by Cunéo must necessarily be removed along with the rest. When the cord has been dissected out below the external ring of the inguinal canal, the testicle is pushed up out of the scrotum and easily extracted at the lower angle of the cutaneous incision.

It is now simply a question of restoring the parts. First, the internal oblique and transverse muscles are pulled over to Poupart's ligament and sutured there by four or five kangaroo stitches. These should be introduced through the thickness of the muscles and then united as near as possible to Poupart's ligament so that

Fig. 5.—Third layer of sutures uniting external fascial flap overlapped on internal flap. 2, upper layer of fascia. 3, under layer of fascia. 4, the almost closed external inguinal ring.

the muscles completely obliterate the canal, since this can be done as there is no cord. This will be seen in Fig. 3.

At the external inguinal ring a suture is introduced so low down that it practically closes up the opening. After this stitch has been taken, the lower margin of the incised fascia is folded over externally, and the median or upper margin of the fascia is stitched to the under surface of Poupart's ligament, mattress sutures being preferred and placed about one and a half centimeters apart, as can be seen in Fig. 4. These are continued toward the lower part of the incision so as practically to close up the external ring. The external portion of the fascia is drawn over this layer of sutures overlapping them to the extent of about four centimeters, and its free border is sutured down to the underlying surface, here also using mattress sutures as in Fig. 5.

Covering the former inguinal canal, we consequently have three layers, one muscular, and two of fascia, thus giving an exceedingly firm abdominal wall, and we have selected this particular technic, because having no cord to deal with it is certainly under the circumstances

superior to the Bassini operation. We usually close the skin incision by buried catgut sutures in the fat, and the cutaneous line is brought together by intradermic catgut sutures.

## BACTERIOLOGIC STUDIES OF THE SKIN AND THROAT IN CASES OF SCARLATINA.\*

BY

GEORGE H. WEAVER, M.D.,

of Chicago, Ill.

From the Memorial Institute for Infectious Diseases, Chicago.

The material for the studies here recorded was obtained from the wards of the hospital of the Memorial Institute for Infectious Diseases, and from the infectious department of the Cook County Hospital. For courtesies in obtaining this material I am under many obligations to Drs. Frank Billings, J. B. Herrick, and W. L. Baum. I am also greatly indebted to Dr. L. Hektoen for suggestions and encouragement.

Plate cultures of glucose-agar, glycerin-agar, and earth-agar were made from the material upon the surface of the tonsils as early in the disease as possible, and from the skin both before and during desquamation. By inoculation from single colonies in these plates pure cultures were obtained and studied in detail. In each instance efforts were made to obtain pure cultures of all the forms of cocci present, and especially of those which grew in pairs. Single colonies were usually ignored, as were also those which were conspicuously chromogenic. In many instances the material from the tonsil or the cutaneous scales were rubbed over the surface of Loeffler's blood-serum and earth-agar, and when smear preparations from the resulting growth showed cocci, efforts were made to isolate them by means of plate cultures.

Cultures from the skin were made in 15 cases, in several of them repeated cultures being prepared at intervals, beginning with the stage of eruption and ending when desquamation was complete.

Before desquamation had begun the cultures were prepared as follows: The surface of the skin was first washed with alcohol, and after drying, the superficial epithelium was scraped away with a sterile scalpel. The fine scales thus obtained were taken up with a sterile platinum loop, moistened with sterile bouillon and introduced into nutrient media. The cultures from such material often yielded no growth, sometimes *Staphylococcus pyogenes albus* was obtained, and very rarely other varieties of cocci. The scales which were used in these studies were collected with sterile scalpel and forceps, placed in sterile test-tubes, and such as were required for cultures were removed from the tubes by means of a sterile platinum loop moistened with sterile bouillon. From the scales various bacteria were cultivated. Most often *Staphylococcus pyogenes albus* was obtained, being isolated in 10 cases. This was not surprising in view of the fact that the white staphylococcus is "a nearly, if not quite, constant inhabitant of the epidermis, lying both superficially and also deeper than can be reached by present methods of disinfection of the skin," as shown by Welch,<sup>1</sup> who appropriately designated it *Staphylococcus epidermidis albus*. The staphylococci isolated from these 10 cases corresponded in every particular with *Staphylococcus pyogenes albus*, and did not differ from cultures of the same organism isolated from the skin of healthy persons for the purpose of comparison. They turned milk strongly acid, liquefied gelatin, produced a milk-white growth upon agar and potato, and stained by Gram's method. It was not uncommon for the growth on agar to be quite tenacious. As pointed out by Welch, the liquefaction of gelatin and the production of acid in

\* Read before the Chicago Pathological Society, February 9, 1903.

milk are apt to take place rather slowly. *Staphylococcus pyogenes aureus* was obtained in two cases.

Beside the staphylococci mentioned the cultures yielded various cocci and sarcinæ. There were several varieties of sarcinæ, and they were found in about one-fourth of the cases. Several of the cocci corresponded with those previously described, but no variety was found with any constancy. Streptococci were obtained in small numbers from scales taken from the skin of the abdomen in a single case. They could not be found in scales from the same patient at a later time, and it is probable that they had been transferred from the mouth to the skin. Raskin<sup>2</sup> found streptococci in the scales four times in 20 observations, but never in the intact skin. Gordon's<sup>3</sup> examinations of the skin for the streptococcus were negative.

The results of our study agree with those of previous investigators of the bacterial flora of the human skin. Several observers have shown that micrococci of various species, including the pyogenic cocci, are very commonly encountered. That a large proportion of the bacteria are only upon the surface of the skin is shown by the very limited number found in the superficial epidermis after washing with alcohol. The great majority of cocci which can be cultivated from scarlatinal scales are probably derived from dust, clothing, etc.

In plate cultures made from a small amount of material from the surface of the tonsil, colonies of streptococci were always present in enormous numbers in comparison with the relatively few colonies of other bacteria. A series of plate cultures was prepared in the usual manner from the material upon the surface of the tonsils in 18 cases. The second plate of the series frequently contained 100 or 200 colonies of streptococci, and only a few or no colonies of other varieties. Because of the great number of streptococcus colonies it was often necessary to plate a small particle from the other colonies in order to get the bacteria composing them separated from the streptococci, whose minute colonies were contained within the larger ones. This procedure was sometimes repeated two or three times before certainly pure cultures could be obtained, and cultures were sometimes found to contain streptococci after every caution had been taken to eliminate them. In view of the great difficulty sometimes encountered in obtaining cultures free from streptococci one is tempted to believe that J. Seitz<sup>4</sup> did not always have pure cultures when he described such extreme variations in the colonies of streptococci cultivated by him from the throat. In each of the 18 cases the number of streptococci present was enormous. The material in all was obtained early in the disease, usually as soon as the eruption was well developed and sometimes earlier.

These observations of the very frequent presence of streptococci in the throat are in full accord with the findings of former investigators. The earliest observers who noticed streptococci in the throat in cases of scarlatina were Croke, Loeffler, Fränkel and Freudenberg, and Heubner and Bahrdt. Their studies have little more than historic interest since they relate to a very limited number of cases. In 1885 Klein<sup>5</sup> described a streptococcus which he called *Streptococcus scarlatinae* and which he obtained from the teats of cows with an eruptive disease of the udder and also from the blood of persons with scarlatina. He believed this coccus to be the cause of both diseases and thought the infection was carried from cows to man in milk. Wurtz and Bourges in 1890 found streptococci constantly in the throat in scarlatina. In 1891 Kurth<sup>6</sup> described *Streptococcus conglomeratus* which he found constantly present in the throat in cases of scarlatina and which he thought peculiar to the disease. The same year Tangl<sup>7</sup> found streptococci in each of 7 cases. Booker<sup>8</sup> examined 23 cases and found streptococci in all. In 1898 Gordon<sup>9</sup> again brought forward the claims of Klein's streptococcus, which he identified with *Streptococcus conglom-*

*eratus* of Kurth. He obtains the streptococcus both from the throat and from the blood in fatal cases. Chabade (1899) found streptococci in a large number of cases. Charlton<sup>10</sup> found streptococci in cultures from the tonsils in 65 out of 117 cases, and Baginsky and Sommerfeld<sup>11</sup> failed to find streptococci in only 6 out of 701 cases examined.

Hilbert<sup>12</sup> has shown that streptococci are constantly present in the throat, even in health. He used bouillon as a culture medium and his results do not indicate the numbers of streptococci present. In several cultures from the throats of healthy individuals we usually found streptococci, but in relatively small numbers.

The relationship which streptococci bear to scarlatina is still undecided. The majority of investigators have considered the streptococcus dangerous as a frequent cause of complicating secondary infections. A few, as Klein, Gordon, Baginsky, and Moser, are inclined to look upon the streptococci cultivated by themselves as bearing an important etiologic relation to the disease. At present the question must be left open until further study may have furnished a final solution. At some future time we hope to present to the society the results of some detailed studies of streptococci obtained from the throat in cases of scarlatina.

In these 18 cases of scarlatina, 25 pure cultures of cocci other than streptococci were isolated from the throat. In making inoculations from the plate cultures, colonies which exhibited distinct chromogenesis were discarded. Of the 25 cultures, 13 liquefied gelatin, 6 grew in gelatin at room temperature without producing liquefaction and 6 refused to grow in gelatin. Six of the cultures which liquefied gelatin and 9 of those which did not were recognized as sarcinæ. It was not always easy to decide whether certain cultures should be called sarcinæ or micrococci. In the 15 cultures designated as sarcinæ the cocci were arranged in groups of four upon some of the solid media, and in part of them there were regular or irregular bunches of packets in suitable media. In most of the cultures the individuals showed great variability in size. Through differences in their effects upon milk, in their growths upon potato, and in their reaction to Gram's staining method, it was possible to recognize 7 different varieties among these 15 cultures. Of the 6 cultures which did not grow in gelatin, 3 produced no change in milk (1 of them did not stain by Gram's method, while 2 stained). The other 3 which did not grow in gelatin produced acid in milk, 2 causing coagulation (1 stained by Gram's method and 2 did not). Of the remaining 10 cultures, 7 liquefied gelatin and 3 did not. In none of them did the individuals exhibit any special arrangement. Among these 10 cultures only a few were duplicates, there being at least 7 different varieties.

Several times cultures were obtained which possessed the tough properties described by Hlava<sup>13</sup> in his *Leuconostoc hominis*, but they were never in large numbers, nor were they present with any constancy. *Staphylococcus pyogenes albus* was recognized three times and *Staphylococcus pyogenes aureus* twice.

In obtaining material for cultures from the throat, especially in young children who offer resistance, it is very difficult to avoid touching the tongue with the swab. Several cultures were made from the surface of the tongue in cases of scarlatina and in healthy individuals to learn what forms of bacteria were especially liable to gain entrance to cultures from this source. In all such cultures it was found that large diplococci and cocci arranged in groups of four made up the major part of the bacteria which grew.

Observers who have made extensive studies of the bacteria found in the mouth have demonstrated a large number of cocci, including the pyogenic cocci in this location even in health, and the results here related differ in no way from those previously obtained. In the throat large numbers of bacteria may easily gain lodg-

ment from the air and food, and probably most of those observed have such an origin. In a few instances cultures from the skin could be recognized as identical with those from the throat.\*

These observations have led to the following conclusions:

1. The bacteria obtained from cultures from the skin, epidermic scales and the surface of the tonsil in cases of scarlatina are the same as those found in the same locations in health, and no one of them is constantly present except the streptococcus in the throat.

2. Because of the numerous cocci which grow in such cultures, and which appear in groups of two and four or bunches of the same under the microscope, it is impossible to identify them, except by a complete study in pure culture.

3. Cultures made by inexperienced persons or by those who do not fully appreciate the importance of avoiding the tongue are especially apt to contain large diplococci or sarcinae.

4. The streptococcus is present upon the tonsil of scarlatinal patients in enormous numbers in almost all cases.

## THE TREATMENT OF INSOMNIA.

BY

HUBERT RICHARDSON, M.D.,

of Baltimore, Md.

There are several theories as to the causation of natural sleep; the older physiologists endeavored to localize the cause in a particular organ as the thyroid gland or the arachnoid plexus. Purkinje supposed that an afflux of blood to the base of the brain compressed the bundles of the corona radiata, interrupting the communication of the brain with the external world; cerebral congestion was an old theory which no doubt originated by a comparison of coma and sleep. Girondeau argued that the lymphatic spaces of the brain were filled with lymph during sleep compressing the vessels and thus reducing the circulation. Somner believed sleep was the result of reduced oxygen in the brain. Hynsius has shown that absorption is more active during sleep than in the waking state but that the accumulation of reserve albumin is retarded, which he explains by acids arresting the diffusion and exosmosis of albumin, fatigue causing lactic acid and other products of retrogressive metamorphosis, while alkalies accelerate osmosis. Ernera, of Brussels, regards sleep as an auto-intoxication from the accumulation of leukomains in the blood which are retained by the cerebral centers and have a narcotic action producing sleep; the leukomains

formed during activity are oxidized and eliminated during sleep; it is claimed that blood from a fatigued dog injected into a normal one will produce sleep; Bouchard holds that the urine secreted during sleep is more toxic than that secreted during the day. This theory is very attractive, but has received little experimental support, the leukomains with narcotic effect have not yet been isolated and would presumably be ideal hypnotics if admitted to the materia medica. Rabl Y. Ruckardt is responsible for the hypothesis of the neurospongium which advances the theory that the psychic processes are due to the rapid play of the ameboid protoplasmic prolongations of the nerves, sleep being produced by the neurospongium extending between these prolongations and preventing them extending over one another. Lepine and Duval advocate similar theories. Ramón y Cajal believes the neuroglia has ameboid characteristics which enable it to act as an isolator of the nervous current. In relaxation neuroglia pseudopodia extend and intervene between the cells and their protoplasmic processes and the nerve threads so that the nerve currents are intercepted.

The theory generally accepted is that fatigue of the vasomotor center produces arterial dilation with consequent anemia of the brain. Professor Howell, of Johns Hopkins, shows in his experimental work that the immediate cause of sleep is the dilation of the peripheral arteries causing a reduction in the mean arterial pressure, consequently withdrawing blood from the cortex cerebri and at the same time increasing the proportion of venous to arterial blood so that not only the blood-pressure in the brain is reduced but the bulk of arterial blood passing through the organ, thus reducing the metabolism of the brain cells. Leonard Hill is of the opinion, based on experiments, that reduction of blood-pressure is not an actual factor in the condition of sleep, as he found that the mean blood-pressure was the same while in the recumbent position before going to sleep as it was during deep sleep. He considers that the reduced bulk of blood passing through the brain is owing to the increased proportion of venous blood and is the actual factor which produces sleep. Both Hill and Howell agree that the vasomotor system center is the point most concerned in the production of sleep. In his experiments on sensory nerves in curarised animals, Howell has shown that the vasomotor center is capable of fatigue and that consequently the continuous work of the center during waking hours (all our sensations and emotions cause activity of the center) must produce a condition of cell exhaustion which gradually causes dilation of the arterioles with loss of arterial tone, so that on taking the erect position from the recumbent the blood-pressure falls instead of rising 10 mm. to 20 mm. Hg. showing that the power of the vasomotor system to overcome the effect of gravity has been lost.

Sleep is deepest during the first two hours, and then as the center recovers the arterioles gradually contract, reducing the proportion of venous to arterial blood, and increasing the bulk of blood circulating in the brain; when the arteriolar contraction and the proportion of venous to arterial blood are normal, the subject awakes.

The force and rate of the heart-beat is decreased by the reduced quantity of arterial blood passing through the coronary arteries; the heart remaining longer in diastole receives a greater amount of nourishment and does considerably less work, consequently recuperates during sleep. The period of sleep is therefore the result of a systemic loss and resumption of tone of the vasomotor center.

Howell suggests another factor in the production of sleep, viz., the fatigue of the psychic portions of the brain, which are particularly active during the waking state, causing them to lose their reactive power which will be further decreased on the reduction of the blood-supply, when they fall more readily below the standard of consciousness.

\* On May 8, 1899, Class (*Trans. Chicago Pathological Society*, 1897-1899, iii, 525) read a paper before this society upon *Diplococcus scarlatina*, which he considers the specific agent in scarlatina. During our investigations this organism has been kept constantly in mind, and we have been unable to identify any single organism as answering to the entire description of Dr. Class and his associate, Dr. Jaques. It has appeared to us that the remarkable variability of the organism, as it has been described, which makes it "difficult to place it in any class of bacteria," may be explained, in part at least, by impure cultures. The published descriptions, however, leave no doubt that *Diplococcus scarlatina* is not a streptococcus such as has been described by Klein, Gordon, Baginsky, and Sommerfeld and others. Chariton (*Montcal Med. Jour.*, October, 1902) has also been unable to confirm Class's findings, but he gives no details regarding the studies which led him to this result.

During natural sleep the eyelids are closed to exclude light and to avoid visual sensation, the eyeballs are turned upward, the voluntary muscles are relaxed so that the body is in a state of complete repose, respiration becomes slower, the amount of inspired air becomes less, so much so according to Mosso that it may fall to one liter instead of seven as in the waking state. Respiration also changes its character; instead of being abdominal it becomes almost entirely thoracic or costal, the action of the diaphragm is weakened, while inspiration is prolonged, occupying five-sixths of the respiratory period instead of four-fifths, the respiratory pause is absent and the depth is increased.

The gaseous exchange is also modified, there being a decrease in the elimination of  $\text{CO}_2$  from 52% during the day to 42% during sleep, while there is an increase in the absorption of oxygen. The necessity of oxygen for recuperation from fatigue is well shown by the experiments of I. Joteyko in Richet's laboratory. He found that if the isolated gastrocnemius of a dog be fatigued by being alternately tetanised for, say five minutes, and allowed to rest for five minutes, after some time, the intensity of the stimulus remaining constant, the contraction curve begins to fall, until finally the stimulation no longer produces any contraction, and the muscle remains at rest in a slightly contracted condition. If the muscle be left to itself and kept moist for a considerable time, contractions nearly equal to those before the fatigue can be induced anew with stimulus of the same strength. One of the factors in the recovery is the presence of oxygen. Joteyko proved that by excluding oxygen after complete fatigue, the muscle cannot again be put into activity, showing that in fatigue it is absolutely necessary for the muscle to receive oxygen.

During sleep the weakening and slowing of the cardiac action is marked. Berichardt found that in a child 21 days old, during the waking state the pulse was 140, while during sleep it was 121; from 6 to 21 months it was 128 waking, and 112 during sleep. Besides the peripheral arterial dilation there is a fall in temperature of about  $.2^\circ$ . The surface vessels begin to dilate in the evening and reach their maximum during the first hour of sleep. Martin measured the different parts of the body and found that during sleep the chest became three-fourths inch smaller, while after a sleepless night it was enlarged five-sixths inch and the abdomen half inch, showing that during sleep there is continued loss of peripheral arteriolar tonicity. The parts usually resume their waking dimensions after six to seven hours' sleep.

From the dilation of the surface vessels it follows that the sweat and sebaceous glands are more active during sleep, which may account for the peculiar odor of the sleeping-room and for the greasy, moist condition of the skin which exists on waking in the morning. There is a decreased function of the various organs of the body as well as of the brain during sleep. In four cases in which the urine secreted during the sleeping and waking hours was collected separately, I found the following quantities per hour:

	Elimination during sleep.				Elimination during waking.			
	I.	II.	III.	IV.	I.	II.	III.	IV.
Urine, per hour.....	44cc.	31cc.	27cc.	32cc.	66cc.	46cc.	42cc.	52cc.
Nitrogen, per hour.	0.462	0.383	0.587	0.439	0.486	0.452	0.765	0.73
Carbon in organic combination, per hour.....	0.414	0.334	0.32	0.38	0.516	0.35	0.409	0.586
Carbon in inorganic combination, per hour.....	0.0098	0.0049	0.005	0.0042	0.0116	0.0052	0.0097	0.008
Total carbon, per hour.....	0.513	0.339	0.324	0.385	0.528	0.358	0.411	0.594
Carbon } .....	1.2	0.88	0.57	0.87	1.08	0.79	0.58	0.8

Organic carbon } .....	62.7	67.3	63.6	90.8	45.51	42.2	42.1	72.4
Inorganic carbon } .....								

Mendel and Marro claim that more phosphoric acid is eliminated during sleep, especially earthy phosphates, while alkali phosphates are increased during the waking hours owing to brain activity. The elimination of phosphoric acid is influenced by too many causes for these observations to have much weight. Both the nitrogen and carbon elimination is less during sleep, while the factor  $\frac{C}{N}$  shows but little variation. The relation of carbon in organic combination to carbon in inorganic combination is less during sleep by about one-third. This would seem to show that less alkali is eliminated during sleep, and that the alkalinity of the blood is reduced.

Of blood changes we know very little. Keyes found a decrease in the number of red corpuscles after several nights of insomnia, while Byford found that every sleepless night accelerates the blood flow, suggesting it is owing to the decreased oxygen-carrying power of the blood, the increased circulation being compensatory.

In regard to the nervous system, some writers assert that sensibility becomes more intense, others maintain that it is deadened. These differences of opinion are probably due to the methods of investigation, those who find sensibility deadened have observed conscious sensation not sensibility, while those who say sensibility is increased have observed reflex acts. Dr. Noyes, experimenting with a dement, arranged that the knee-tendon be tapped at regular intervals of five seconds. When the patient was asleep and undisturbed the knee-jerk gradually disappeared, but the mere sound of a person walking across the floor was sufficient to stimulate a series of jerks, which gradually subsided, the tap of a pencil again starting the reaction. Reflexes are undoubtedly active during sleep. Upon tickling the foot it is withdrawn; the cremasteric, abdominal, and tendon reflexes, and the pupil reaction are also nearly as active as in the waking state, except in the first hour or two, when sleep is the deepest. Tarchanoff found that the cerebral cortex in puppies ceased to react readily to electric stimuli, but the spinal cord and the sensory nerves were active; sensations of pain were deadened to consciousness. In other words, the nerves transmit the sensations of pain but the sleeping animal does not perceive them.

That the sensory nerves are fully awake during sleep is shown by the increase in the volume of the brain on external stimulation by sound, light or tactile impressions. The voluntary muscles are also awake, as a sleeper will change his position in bed without awaking.

To summarize, there are three main factors in the production of sleep: (1) Diminution of irritability caused by fatigue of portions of the cortical area; (2) voluntary withdrawal of sensory and mental stimuli involved in the preparations for sleep; (3) diminished blood supply to the brain owing to relaxation of tone in the arteries from fatigue of the vasomotor center and the consequent reduction in the pressure and bulk of blood in the brain. If anemia of the brain were the sole cause of sleep syncope would be sleep, but in syncope there is loss of consciousness due to anemia, but there is not sleep.

The nervous theories of sleep are defective because they do not point to a fundamental cause. Creighton Browne's remark, that the arteries were made for the brain and not the brain for the arteries, is very apt, as the amount of blood going to the brain is regulated by the functional activity of the nervous tissue. It is very evident from the foregoing that during sleep consciousness is arrested, so that sleep is the resting time of consciousness, but the arrest of consciousness is not necessarily sleep.

Girondeau declared that sleep was a useless, foolish, harmful practice, but as yet no one has been able to cure himself of the habit, and experiments show that loss of sleep is much more harmful than loss of food. In the

Iowa University, wherein some experiments were made, men were deprived of sleep for about 90 hours; in one case hallucinations occurred, which disappeared after sleep. In all there was a steady increase of weight with a decrease in grip and pull force; acuteness of vision was increased, dropping to below normal after sleep; memory became defective, and power of attention impaired; in one case the temperature fell 3° below normal.

When the ability to sleep is weakened, sleep becomes light and fugitive. As a rule broken sleep occurs in persons with an irritable vasomotor system, who blush easily and in whom the pulse quickens on slight provocation, and also in those of emotional temperament who are easily provoked to grief or laughter. These patients will say that they have not slept a wink all night, that they have heard the clock strike every hour, but if watched it will be found that they sleep lightly at intervals during the night. Complete insomnia rarely occurs, and when it does death takes place in eight or ten days.

Mental overwork produces insomnia probably owing to overdilation of the cerebral vessels, which fail to contract through temporary paralyses. Insomnia the result of physical overwork is probably due in part to the same cause and in part to the increased action of the heart, which fails to subside as rapidly as the pressure. Oliver has shown that under normal conditions the blood-pressure returns to normal much more rapidly than the pulse.

Emotions cause sleeplessness by raising the blood-pressure, the arterioles contracting. In anemia insomnia is due to want of tonicity of the vessels, the blood which gravitates to the lower extremities in the erect position flows to the brain on lying down; these patients may complain that while standing or sitting they are sleepy, but on lying down they become wide awake. In these cases a little food in the stomach with strychnin or digitalis will often give a good night's rest.

In mania and melancholia insomnia is very marked and difficult to treat. In an article on "Blood-pressure and its Relation to Insanity" I showed that in mania there was an increased volume of blood passing through the brain with but slight or no increased intracranial pressure, producing increased mental activity with dilation of the cerebral arteries to such an extent and for such a length of time that they lose their tonicity and are unable to contract even when the heart action is reduced. In simple melancholia there is a decreased volume of blood passing through the brain, but also an increased intracranial pressure; the proportion of venous to arterial blood being increased, lessened mental activity and depression is produced. In melancholia agitata there is an increased volume of blood through the brain with increased pressure, producing mental activity with depression. It is evident that these diseases require different treatment to bring about the conditions necessary to normal sleep.

In order to compare more easily the conditions of normal sleep and the causes of insomnia with the physiologic action of hypnotics the following summary will be of advantage:

The conditions of sleep are: 1. Dilation of the peripheral and abdominal vessels. 2. Increased proportion of venous to arterial blood. 3. Slowing and weakening of the heart's action. 4. Reduced quantity of blood circulating through the brain. 5. Reduced blood-pressure. 6. Decreased elimination of CO<sub>2</sub>. 7. Increased absorption of oxygen. 8. Exclusion of external stimuli which produce activity of the vasomotor center. 9. In sleep consciousness is lost; the vasomotor system recuperates. 10. The spinal cord does not sleep and only portions of the brain, though the reaction to external stimuli is reduced.

The causes of insomnia will naturally be the opposite of the above conditions: 1. Unusual irritability of the vasomotor system. 2. Excessive physical work

which stimulates the heart to such an extent that it fails to subside to normal. 3. Excessive mental work which produces dilation of the cerebral vessels for such a length of time that they become paralyzed, losing their normal tone. 4. Anxiety, worry, intense joy, which stimulate the vasomotor nerves, contracting the arterioles, and which may produce dilation of the right heart. 5. Anemia in which the vessels have lost their tonicity.

The question as to whether hypnotics produce normal sleep is of very great importance considering the liberal manner in which they are prescribed by the physician and used by the laity without supervision.

Opium is probably most used even when there is no pain, and it certainly does not produce the conditions necessary for normal sleep. It has a specially depressing action on the respiratory center. It stimulates the heart causing the heart muscles to dilate more during diastole and to contract more during systole, increasing the amount of blood forced through the circulation. It contracts the arterioles especially in the splanchnic area, and this contraction may be so great as forcibly to dilate the vessels of the skin. The cerebral faculties are at first stimulated by the increased blood supply, it then blunts the perceptive and the sensory centers and impairs the conductivity of the afferent nerves. It is thus evident that instead of producing the conditions for normal sleep opium causes unconsciousness by intoxication which may or may not be followed by sleep; the centers of consciousness are not at rest but poisoned. As the drug is eliminated by the intestines with great rapidity (morphin given hypodermically is found in the stomach two and one-half minutes after injection) the patient may or may not sleep after its effect has worn off. In insomnia from loss of tone of the vessels, opium may produce sleep, but strychnin and digitalis are more certain. An occasional dose of opium is practically harmless, and the beneficial effect of the drug in neurasthenic melancholia is well known, but if it is going to be of value the favorable action is soon evident. The custom in some institutions of keeping patients on opium for months, raising or lowering the dose according to indications, cannot but be harmful, as long-continued use of the drug permanently blunts the perceptive and sensory centers.

Paraldehyd produces a condition resembling sleep and is described as being perfectly harmless. It is said to be antispasmodic, diuretic, but not diaphoretic, consequently it does not dilate the arteries of the skin; it also strengthens, though it slows the heart. I have seen a victim of the paraldehyd habit, who, upon failure to get his dose was thrown into an intensely nervous condition resembling mania. Gradual reduction of the drug was impossible as the patient missed the odor and knew at once when the dose began to get low, finally the drug was stopped altogether and after a week of maniacal excitement he recovered. Another patient took a very large dose with suicidal intent or through ignorance. He lay for two days in a comatose condition and could only be aroused with difficulty; the heart action was very weak and for the first 24 hours it was doubtful if he could survive; he ultimately recovered. A third instance was an alcoholic, who had been taking a nightly dose for some weeks; he developed a mild attack of acute uremia with edema; on stopping the drug without any treatment the elimination of urea rose to 84 grams in 24 hours, and the total quantity of urine to 2,500 cc. In a few days the edema disappeared.

Chloral produces effects which are more likely to produce natural sleep; it depresses the heart, dilates the peripheral vessels, lowers arterial tension, but decreases oxidation and lowers temperature. It seems to have a selective action on the brain cells, producing sopor, which may, however, be due to the cerebral anemia. In some cases, probably of anemia with want of tone of the vessels, it produced headache and insomnia. It is also said to increase the fluidity of the blood and to crenate the red corpuscles. Although its physiologic action

comes near producing the circulatory conditions of normal sleep it must act as a poison, for the chloral habit soon shatters the constitution.

Bromids reduce blood-pressure and diminish the caliber of the vessels, showing that their action must be to reduce the output of the heart and not to dilate the vessels, they also reduce respiration and slow and weaken the heart, being a direct nerve poison, producing sluggish reflexes and defective coordination.

Hyoscin hydrobromate acts upon the spinal and cerebral cortex, having little direct effect upon the circulation. Its prolonged use is apt to derange the mental faculties, and may be responsible for the mental impairment which so often follows the so-called gold-cure for alcoholism.

Sulfonal and trional are probably more used than any other hypnotics, both by the profession and the laity. Potter, quoting Squibb, says that if it were not for the very evident advantage of sulfonal, when used with care and under medical supervision, it would probably either be excluded from practice, or its sale restricted by legislative authority. It produces its hypnotic effect by direct action on the brain cells and upon the red corpuscles by dissolving lecithin. A dose of 1.3 grams (20 grs.) is invariably followed by a large amount of hematoporphyrin in the urine, showing a marked destructive power on the erythrocytes.

The other hypnotics on the market have practically the same effects as those mentioned; that is, they produce sleep by intoxication, and are therefore poisonous. The physiologic action of the bromids, and of chloral, come nearest to producing normal hypnotic conditions, but their toxic effects are well known. I have seen several insane patients slowly succumb whom, if sedatives had not been used so freely, I believe might at least have been saved from death. I have also observed a patient who remained in an active maniacal condition for four months; no sedatives or very few were given, and the patient apparently slept but very little during that time, yet complete recovery ensued.

There are many mechanical and physical methods, which, with attention to details, will obviate the use of hypnotics, or at least enable the patient to sleep with much smaller doses than are usually given. Kraepelin, in discussing some of these methods, says that if the patient does not sleep after their intelligent application it is improbable that he will sleep with drugs.

The hygiene of insomnia is a matter of very great importance, and the following details should be carefully attended to before recourse is had to drugs: The bedroom should be large and well ventilated, as it is necessary to keep up the maximum quantity of oxygen in the inspired air. To attain this the carbonic acid gas eliminated must be removed as rapidly as possible and fresh air admitted. To attain this, it is best, when the bed can be so placed as to prevent draughts, to keep the window open at night; a common expedient in Europe is to remove one or two panes of glass and substitute moderately fine wire gauze. As the object to be attained is to increase the peripheral circulation, the body should be kept warm, in certain cases an extra wrap around the abdomen and hot water bottles to the feet will have a very good effect. The head and neck should be exposed, so as to decrease the circulation, and the temperature of the room should be about 60° F., unless there is some special reason for keeping it higher. In the modern artificially heated bedroom these conditions are rarely observed, with the result that the sleeper rises in the morning with a tired, suffocated feeling.

The influence of light on metabolism is well known. Fabini and Ronchi have shown that much less CO<sub>2</sub> is eliminated in the dark while the patient is awake than in daylight. This has been confirmed by experiments on animals reported by Moleschott, Platen, Seloni, and Piacenti. Platen found further that animals whose eyes

were closed with diachylon plaster eliminated a reduced quantity of carbon dioxide. Light increases external stimuli, therefore the metabolism stimulating consciousness is directly antagonistic to sleep.

Another point of considerable importance is to reduce the mental activity for at least one or two hours before going to bed; the patient should abstain from study, reading, or playing any game which requires mental exertion or excitement, in order to decrease the blood flow through the brain as well as the heart's action. The evening meal should be eaten at least four hours before retiring, and neither tea nor coffee should be taken, chocolate being a good substitute. At bed time a glass of hot milk with a sandwich or a few crackers will, by stimulating the stomach, withdraw the blood from the brain to the abdomen; a glass of hot whisky and water is often a very effective and acceptable hypnotic.

A bath immediately before retiring is often very helpful. The bath-room should be about 65° to 70° F., and the patient should first douche the head and face with water at 100° F., then entering the bath immerse the whole body except the head and neck; the temperature of the bath should be 98° to 100° (if the water is below 96° or above 105°, the peripheral vessels will contract with resultant hyperemia of the brain instead of anemia); five or six pounds of common salt dissolved in the bath is beneficial. The patient should remain in the bath from 10 to 20 minutes, until the pulse-rate falls, and then should be lightly rubbed down and put to bed with as little exertion as possible; a warm bottle to the feet after the patient is in bed or a bandage around the abdomen will often be found of value. A tablet of nitroglycerin, or better, erythrol tetranitrate is a good addition given after the patient is in bed. Sir William Broadbent advises a hot water bottle to the back of the neck as tending to produce local hyperemia; standing in cold water and then rubbing the feet with a rough towel is also recommended. In severe cases the wet or dry pack is of great benefit; the head should be kept cool with a Leiter coil, this being much more satisfactory than the ice-cap, and not so severe.

In cases of neurasthenia in which loss of arterial tone is a marked condition, and in anemic conditions in which the mean and maximum pressure is low and there is a reversed postural change of pressure, small doses of digitalis will often be sufficient to produce natural and quiet sleep; opium in small doses sometimes acts well in these cases.

In acute mania with low mean and maximum blood-pressure, heart stimulants are indicated; but in chronic mania when there is very high mean and maximum pressure, they are useless, and opium is especially counterindicated. In these patients the cerebral vessels are dilated to their utmost capacity, the pulse is rapid and the heart strong, the rapidity of the circulation being enormously increased. Opium in such cases contracts the abdominal vessels, forces more blood through the brain, as it continually flows in the channels of least resistance, while at the same time the heart force is still further increased; Schott baths combined with small doses of bromid, chloral, or nitroglycerin will usually calm the patient and produce sleep. If he can be kept in the bath for any length of time without struggling or exertion, it will usually prove sufficient without drugs; often the administration of 0.6 mg. ( $\frac{1}{100}$  gr.) hyoscin hydrobromate, with the bromid before the bath, will make him amenable. If the bath cannot be given without struggling, it had better be dispensed with; but it is rare that the patient does not appreciate the bath and appear to find comfort while in the tub.

It is not my intention to argue for the abolition of hypnotics; on the contrary, there are some cases in which they are absolutely necessary; but in my opinion it is much more rational and better to endeavor to produce the conditions necessary to natural sleep than to give a poison which produces unconsciousness and not

sleep, and which must be detrimental to the patient. Before prescribing a hypnotic, the physician should make up his mind what is the cause of the insomnia, and not, as is too often done, prescribe without any attempt at diagnosis of the physical cause.

## THE OCULAR COMPLICATIONS OF VARIOLA.<sup>1</sup>

BY

BURTON K. CHANCE, M.D.,  
of Philadelphia.

Assistant Surgeon, Willis Hospital, Philadelphia.

This communication is based upon a series of observations made in the course of the epidemic of variola that visited Philadelphia in the years 1901 and 1902. In addition to the opportunities for study obtained elsewhere on earlier occasions, I was repeatedly called into consultation by Drs. William M. Welch and Jay F. Schamberg at the Municipal Hospital. To the courtesy of these gentlemen I am indebted for the facilities afforded for a personal study of the cases under their care and for other data which have enabled me to present a complete report of the ocular complications found in variola.

Variola is a disease with which the ophthalmic surgeon of the present day only rarely comes in contact, for since Jenner's discovery it is no longer the general scourge it was, and the destructive effects on the ocular tissues are less than in former times. Then, too, early recognition of the disease and therapy of the ocular lesions have been insisted upon in recent years with the result that fewer cases are seen to progress to the degree so commonly noted in past years.

In spite of this, ocular affections are quite usual in variola, attacking almost every portion of the visual apparatus. They appear oftentimes in the acute stages of the disease; again, they may not appear until convalescence, and they are frequently found for the first time as a sequel.

In the analysis of over 2,000 cases at the Municipal Hospital of Philadelphia, there were 36 instances of corneal ulcer, 17 of which were followed by perforation with destruction of one eyeball, and 15 were cured without perforation. Of these cases 15 were in unvaccinated individuals, in 6 others vaccinated at periods more or less remote the lesions were less severe. Pustulation of the lid borders was a common affection; conjunctivitis was frequently found with it and was also found independently; especially to be noted were 10 cases of iritis.

The report of the ocular lesions occurring in variola is necessarily incomplete scientifically, because of the difficulty in studying satisfactorily the eyes of infected persons and the impossibility of keeping track of the individuals after their discharge from the hospital. This incompleteness is increased by the fact that in several cases in which continued observation has found intraocular lesions, it is almost impossible to determine whether the conditions noted are due to the specific variolous infection, or whether they were present prior to the onset of the exanthem.

In taking up the systematic consideration of the action of variola on the parts of the eye, we find that the skin of the lids is commonly a site of the pustular eruption. So much swelling of the tissues may accompany the eruption that the eyes cannot be opened for several days. In such cases severe conjunctivitis is usual and often leads to corneal ulceration. The edges of the lids are liable to ulceration and the subsequent cicatrization distorts them, so that styes, misplaced cilia, eversion of the lids, adhesion of the lids, or occlusion of the meibomian ducts, etc., may result. The lids, like other portions of the skin, may be, after the subsidence of the eruption, the seat of abscesses which produce various

deformities requiring operation later. As to the mucous membrane of the lacrimal passages, pustules may also form there and give rise to acute, and later chronic inflammation of the canal and duct. On the orbital borders periostitis with caries occurs but rarely.

Passing on to the conjunctiva, we find that as in other febrile diseases it is commonly affected. Inflammation develops about the fifth day of the eruption; the conjunctiva appears congested and occasionally presents a catarrhal inflammation which is usually of moderate severity and of brief duration, yielding in a few days to treatment. An exception to this appeared in a young man recently under treatment, in whom severe conjunctivitis began on the seventh day and in spite of careful treatment persisted over a month.

The intensity of the ophthalmia is related directly to that of the pustular eruption in general, and more particularly to that of the eruption on the face and eyelids. On the conjunctiva, pustules form but rarely; among the 2,000 patients with variola examined by us in 1901 to 1902, they were noticed in only two or three instances. When they do occur, these pustules much resemble in appearance and course the phlyctenular eruption observed in strumous children. They are the size of small lentils, elevated but slightly, and usually situated midway between the corneal margin and the inner and outer canthus. They appear sometimes at the limbus, and when there frequently cause ulceration of the cornea. On the tarsal conjunctiva pustules may be found at the inner fold and on the caruncle, but never at the fornix. In these cases the conjunctival inflammation markedly resembles that of gonorrhoeal infection; the inflammation is always severe and is accompanied by profuse secretion and chemosis. Subconjunctival ecchymosis may occur and may produce intense chemosis in hemorrhagic variola. The bacteriologic examination of the conjunctival secretions showed the presence of no specific or hitherto undescribed organisms, but there were present in abundance staphylococci, streptococci, and pneumococci.

The cornea, according to other observers, is not subjected to the specific lesions of variola, and our experience in the treatment of over 7,000 patients leads us to accept this conclusion. Ulceration of the cornea does occur, but it is usually independent of the general process, being rather a consequence of the conjunctival affection. And now, just as in past times, it is the most fruitful cause of blindness as a sequel of variola.

The corneal complications may arise in two ways: First, either without pustules on the conjunctiva or by pustulation, especially when this is at the limbus; second, during the stage of desiccation when the contagion is transmitted from some broken-down pustules—as, for instance, those of the skin of the eyelids.

The corneal inflammation may be only a slight superficial haze confined to the corneal conjunctiva or Bowman's membrane, or it may extend rapidly and involve the entire membrane. Commonly, near the margin of the cornea is seen a small phlyctenular bleb, filled with clear fluid, the thin and delicate covering of which is soon macerated by the increased conjunctival discharge and the vesicle is ruptured, exposing an area of necrotic tissue of greyish color. The symptoms of pain and redness, although usually marked, vary in intensity and duration. As the ulcerated surface spreads the several layers of the cornea are involved until the membrane is perforated, and then the aqueous humor escapes and prolapse of the iris follows. At this time the painful symptoms abate. In bad cases pus forms in the anterior chamber, or the crystalline lens and the vitreous humor may be extruded, panophthalmitis developing from a general suppuration of the eyeball, accompanied by great pain, with marked bulging of the lids. Fortunately, the majority of cases present a milder form of keratitis. In this there is only a circumscribed superficial inflammation, which heals promptly and leaves the

<sup>1</sup> Read before the Philadelphia College of Physicians, February 4, 1903.

eye damaged only by the formation of an opacity as the result of the cicatrization of the necrosed area. These scars cause marked irregular astigmatism, which greatly interferes with the acuteness of sight.

In severe cases of confluent variola rapid destruction of the cornea may take place as early as the eighth day. It is usually a forerunner of fatal collapse. In some instances both eyes are affected. As an example of this, four patients in our own wards sank rapidly after the destruction of both eyes at an early stage of the general disease. In these cases it was noted that the ulceration was preceded by a greyish infiltration of the bulbar subconjunctival tissues; this chemosis rapidly increased, rising above the cornea and surrounding it, choking off its circulation. Immediate destruction of the cornea followed—a true keratomalacia. In certain instances the chemosis is so great as to produce an edema of the subconjunctival and subcutaneous tissues, even to such an extent as to make it almost impossible for the lids to be opened.

It was our experience to find the ulceration of the cornea less extensive in size and degree in the case of those who had been vaccinated; consequently the healing was more prompt and the sequels were less damaging to the integrity of the eyeball.

Parenchymatous keratitis after variola has been reported by but few observers. We observed two cases. The first was in a young man with confluent variola who developed about the seventeenth day a general haziness of the left cornea. This gradually improved, leaving a slight opacity behind it. About two weeks later an ulcer developed upon this site without, however, producing serious complications. The second was in a young woman, aged 19, heretofore of apparent robust health. With her marked corneal haze was noticed in the third week of the general disease. Her convalescence was prompt, yet on discharge from the hospital there was noticed well-defined interstitial infiltration and iridocyclitis associated with it. For two months she has been under treatment and her progress toward recovery has been rapid.

The uveal tract is not so frequently affected as the cornea. In our examinations we noted ten cases of iritis, not plastic in form, but of the serous type; this condition was especially marked in hemorrhagic variola. Other observers have noted iritis developing after the subsidence of the general symptoms. Slight pericorneal injection has been sometimes noticed in the first week, accompanied by lachrimation, photophobia, tenderness, and a small immobile pupil. Although this ciliary irritation may be an independent affection, it is usually a symptom of corneal or iritic disease. It appears to be more frequent in the milder cases, and may persist for a considerable time after the termination of the attack of variola. Choroiditis was revealed only by the presence of opacities in the anterior or posterior part of the vitreous. We have had the opportunity of studying the ocular conditions of a vigorous young man for several weeks after his discharge from the hospital; in each eye were numerous floating vitreous opacities, which rapidly lessened as he regained strength.

In none of the cases examined did we find circumscribed choroidal inflammation, nor did we see posterior polar cataract. We can report no cases of glaucoma due to variola, nor any cases of retinitis or neuroretinitis. But all these have been reported in the literature of variola by other observers.

While renal disease in the course of the variolous attacks was commonly observed, yet it did not progress far enough so that we were able to record any real cases of albuminuric retinitis. And patients with pronounced uremia sank into a coma so rapidly that it was impossible to ascertain whether or not the uremic condition had affected the retinal sheet, although it probably had. In hemorrhagic variola there is no reason to doubt the occurrence of hemorrhages into the retinal sheet and

very probably hemorrhages into the optic nerve may occur. We have not been able to find any such cases reported as actually observed, but Knies is of the opinion that such hemorrhages must have been the cause of some of the affections described as neuritis with and without stasis, and with and without termination in atrophy of the optic nerve.

Meningitis as an undoubted sequel is rarely found, but we have come in contact with cases of meningitis for which no logical cause could be found except a far distant attack of variola.

## ANGIONEUROTIC PURPURA.\*

BY

RAYMOND WALLACE, M.Sc., M.D.,  
of Chattanooga, Tenn.

There still exists considerable confusion in the classification of the various forms of the hemorrhagic diathesis, and this confusion is largely due to the uncertain etiology and pathology of these conditions. The subject has recently been brought to my attention by the difficulty of an exact diagnosis in a somewhat unique case.

The hemorrhagic diathesis may be either congenital or acquired. The congenital form, or hemophilia, is seldom difficult of recognition, for in the majority of cases the history shows a marked hereditary tendency, which, together with persistent bleeding from insufficient causes and occasional joint involvement, form a syndrome which can scarcely be misinterpreted. But the acquired forms, as manifested in the several varieties of purpura, scurvy, and in association with numerous infections and toxic disorders, may give rise to considerable difficulty in diagnosis.

*Etiology.*—The deficient pathologic knowledge of these affections necessitates an unsatisfactory etiology. Johnson<sup>1</sup> divides the causative factors into three general classes: infectious, toxic, and vasomotor. The work of W. Koch, Kolb, Babes, Giovannini, and Gärtner suggests very strongly an infectious origin in many cases as bacilli have been found in those suffering from the diseases, which are pathogenic to animals and cause in them a condition characterized by hemorrhages. It has been further suggested that the hemorrhages are produced by changes in the vessel walls, due to a localization of the bacteria themselves, and the consequent effects of the elaborated toxins.

Breton<sup>2</sup> concludes that in some cases of toxic origin the source is an autointoxication arising from the intestinal tract. Osler is inclined to recognize a relationship between Henoch's purpura and angioneurotic edema. Syers<sup>3</sup> considers the condition allied to scorbutus and due in many cases to poor, unhygienic conditions, and insufficient and improper food. Henoch has suggested the vasomotor origin of purpura in which there is first a paralytic distention of the small vessels, followed by stasis, hemorrhage, or edema. Such an irritation or paralysis of the vasomotor nerves may be either central, peripheral or reflex in origin.

*Pathology.*—The exact pathology of this condition is unknown. Cassel, Riehl, and Wilson have described an endarteritis occurring in the smaller bloodvessels. This is undoubtedly dependent upon some alteration in the blood itself. Cheyne, Martin de Gimaud and others have described emboli and thrombi in some of the grave and undoubtedly infectious cases. However, nothing definite in the form of characteristic pathologic lesions has been described.

The case at hand is one which presents some remarkably unique features and which upon close observation and study has emphasized to me the close relationship between Henoch's purpura and angioneurotic edema—as suggested by Osler—and leads me to suggest a diagnosis,

\* Reported before the Chattanooga and Hamilton County (Tenn.) Medical Society, February 6, 1903.

based upon the apparent etiology in this case, of *angio-neurotic purpura*.

CASE.—Hattie D., aged 15, was admitted to the Orphans' Home five years ago. Her maternal grandmother lived to the age of 72. The history of the other grandparents is unknown. Her mother died at 45 of pulmonary tuberculosis. Father died at 50 of disease of the heart and kidneys. The patient is one of six children, all the others being alive and in good health. She was reared in a desperately poor family. She cannot remember when she did not have profuse hemorrhages from the nose and mouth. During the last five years she has had whoopingcough, scarlet fever and measles with apparently good recovery. Two years ago she had a tooth extracted and the cavity oozed and bled for over two weeks—resisting all efforts to stop it. Other injuries, such as scratches and cuts, do not manifest any excessive hemorrhage. Menses appeared for two days at the age of 9 and then ceased until nine months ago, when they reappeared and she flowed for two days. She has had no periods since that time. There is very faulty sexual development—partial development having occurred only during the past six months.

Since coming to the home five years ago the patient has had several attacks each year, in which the entire body becomes covered with purpuric spots, varying in size from petechiæ to large ecchymoses the size of the palm. These are most abundant over the abdomen and limbs, although no area is exempt. Beneath the eyes a heavy effusion of blood often appears, suggestive of a vicarious menstruation. The limbs and face become edematous.

The last attack began Christmas night, succeeding as a climax the excitement and emotion of the day. For weeks previous to this time the patient had been almost covered with purpuric areas, while the intervening spaces were a pale, creamy white. Just before the external hemorrhages began there was considerable nausea and vomiting with severe colicky pains in the stomach—gastric crises, considerable dizziness, and much bloating of the abdomen. Temperature rose to 104.5°-105°. Pulse and respirations increased and suddenly epistaxis, profuse and intractable, began. Hemorrhage then followed from the lips and mucous membrane of the oral cavity. Fresh blood mixed with a frothy mucus was raised from the lungs and vomited from the stomach. Fresh blood was also passed from the rectum. The spots gradually faded and disappeared completely in four days. Anemic heart murmurs were present and the patient was greatly prostrated. All efforts at feeding were futile and vomiting and retching persisted almost continuously. On January 22, when the patient came under my close observation, the temperature still persisted over 102.5°; pulse 142; respirations 60. Entire body was a cold, creamy white. Spleen was considerably enlarged. There were no purpuric spots or edema present. The mucous membrane of lips showed many hemorrhagic spots. Efforts at nutrition were almost vain, due to continued emesis. Several examinations of the urine revealed no albumin, only a slight excess of urea and uric acid. Blood examination, January 29: Reds, 1,376,000; whites, 8,340; hemoglobin, 20%. Stained specimen showed a moderate poikilocytosis, some endoglobular degeneration, oligochromia, microcytes, macrocytes, few normoblasts, and several megaloblasts in each specimen examined—the picture of a pernicious anemia. The coagulability of the blood was increased, clotting almost immediately upon exposure to the air.

This history undoubtedly suggests purpura hæmorrhagica and Henoch's purpura. The symptom complex, however, is not characteristic. It may, in general, be summarized as follows: (1) Relapses or recurrences extending over several years; (2) cutaneous lesions of a clearly purpuric nature; (3) gastric crises, intestinal crises, pain, vomiting, and diarrhea; (4) marked general hyperesthesia with an angioneurotic edema of extremities and face; (5) hemorrhages from the mucous membranes; (6) the blood picture of a pernicious anemia.

In many ways this case resembles the purpura described by Henoch—but the cutaneous lesions are clearly those of a purpura either simple or hæmorrhagic, and not in the least an erythema multiforme. There has been at no time the slightest symptoms of joint involvement. The marked vasomotor disturbances would in a way remove the case from Henoch's type. It has, too, a marked similarity to purpura hæmorrhagica, yet presents certain marked differences: (a) its recurrent nature over a period of many years; (b) the marked gastrointestinal crises; (c) the pronounced nervous disturbances manifested in the edema and hyperesthesia. Bruce and Galloway<sup>4</sup> have described a form of factitious purpura in which any irritation of the skin, such as might be caused

by drawing the finger-nail over it, produced a white line which almost immediately became pink, and later, intensely purpuric.

To summarize, then, the apparent etiology in this case, there was from earliest childhood the most unhygienic surroundings and poor and improper food, which during the developmental period undoubtedly caused a disturbed metabolism. There was probably some predisposition to a hæmorrhagic diathesis as manifested by the frequent and profuse epistaxis of early childhood. Disturbed nutrition and metabolism affected the composition of the blood and the activities of the blood-forming organs. The altered composition of the blood produced changes in the bloodvessel walls, such as an endarteritis or anemic degeneration. The disturbed metabolism affecting the nervous system, either through malnutrition of the nerve tissue or through autointoxication, produced a vasomotor neurosis. The fact that the various hemorrhages were almost invariably precipitated by intense excitement or emotion points strongly to a vasomotor factor. Whether the blood in the purpuric spots is in a condition of stasis due to a paralysis of the vasomotor nerves, or whether it passes per rhexin or per diapedesin into the surrounding tissues, it is perfectly evident there is present a phase of angioneurosis. The blood changes strongly suggest disease of the blood-forming organs, especially the bone marrow. But whether the condition is idiopathic there or whether it is secondary to the long-continued and excessive loss of blood, and the consequent heroic efforts at regeneration, must needs remain an interesting problem. The factitious edema which may be produced during the periods of purpuric eruption—before the occurrence of hemorrhages—and the transient hyperesthesia, strongly suggest an angioneurosis of a cumulative and temporary character, perhaps due to the cumulative increase of metabolic products leading to an autointoxication.

The angioneurotic character of this condition seems especially apparent in this case, and the fact that the element appears more or less strongly in cases reported by Bruce, Galloway, Couty, and Henoch, leads me to venture a diagnosis of angioneurotic purpura—probably of toxic origin, possibly due to autointoxication.

### LIMITATIONS OF THE DIMETHYLAMIDOAZOBENZOL TEST FOR FREE HCl IN THE STOMACH CONTENTS.

BY

WILBUR F. SKILLMAN, M.D.,

of Baltimore, Md.

Lecturer on Diseases of the Digestive Tract, Woman's Medical College of Baltimore; Assistant, Clinic Diseases of the Stomach, University of Maryland.

The use of dimethylamidoazobenzol as advocated by Topfer as an indicator for the determination of the free hydrochloric acid of the gastric contents has been much criticised as to its accuracy and usefulness in clinical work. Much theorizing has been done and many contradictory statements made by various writers.

Dimethyl is a yellowish powder soluble in alcohol and is used in a 0.5% alcoholic solution or is used in the form of test-papers made by pouring the solution on white filter paper and allowing it to dry. It is ordinarily yellow but turns red in the presence of a free mineral acid. The volumetric test is made by using the dye as an indicator in a measured specimen of gastric filtrate and titrating with a decinormal solution of sodium hydroxid until the color changes. Töpfer claims that

dimethyl reacts only to free mineral acids and acid salts and in this Friedenwald<sup>1</sup> agrees with him. M. I. Knapp<sup>2</sup> and Platt<sup>3</sup> have both recently published articles declaring that dimethyl reacts to other substances than mineral acids. Einhorn<sup>4</sup> has undoubtedly proved that lactic acid, even in the quantities sometimes found in the gastric juice, will give the typical reaction with this indicator. In regard to this, however, Hemmeter<sup>5</sup> says: "It is true that in the presence of lactic acid amounting to 0.2% or more in the gastric juice this test yields a red color resembling that due to inorganic acids; but the objection is more theoretic than real, as the presence of such an amount of organic acid seldom occurs in the stomach, and in the presence of proteids and peptones, mucin, etc., still stronger solutions of the organic acids are required to produce the characteristic reaction." Van Valzah and Nesbit<sup>6</sup> practically arrive at the same conclusion.

That this method is not absolutely accurate I do not deny, but what we want to know is whether it is applicable to clinical work or not; will it serve our purpose for rapid volumetric analysis of the gastric juice, or will we have to look further for some other indicator? Within the limitations defined in the conclusions laid down at the end of this article, dimethylamidoazobenzol will act perfectly satisfactorily as an indicator for free HCl.

Almost all of the writers on the use of dimethyl have left out one of the most important factors in the making of a diagnosis, namely, *the physical examination of the abdomen of the patient*. In every case our conclusions will be modified by the size and location of the stomach, as well as by the tests for its peristaltic function. Knapp<sup>2</sup> says that dimethyl will react to free organic acids. That is so only when they exist in large quantities, and if on examination we find the size and position of the stomach normal and its peristaltic power unimpaired showing no retention of food, certainly we may suppose that very little organic acids are present, and then our dimethyl will answer every requirement.

On the other hand, suppose we find, on examination, the stomach dilated with retention of food beyond the usual time; then we would suspect the presence of organic acids and could use Gunzburg's or Boas' reagents to determine whether our dimethyl reaction was caused by organic or inorganic acids.

The reaction obtained from any chemical test of any kind must be corroborated by the physical examination of the patient. If albumin appears in the urine we should examine our patient for the other symptoms and signs of nephritis, and so we should examine our patient physically in all diseases of the stomach, and not try to make our diagnosis in the laboratory from the gastric analysis alone.

The following conclusions may then be drawn in regard to the use of dimethylamidoazobenzol as an indicator for free hydrochloric acid:

1. If the test for lactic acid is positive, Gunzburg's or Boas' reagents, or some other method, should be used to determine whether our dimethyl reaction is due to lactic acid or to free HCl.

2. If the stomach is normal both as to size and position and the peristaltic function is unimpaired, then dimethyl will give fairly accurate results.

3. If the size and position of the stomach are not normal (gastroectasis or gastropnoia), or if the peristaltic function is delayed, then Gunzburg's or Boas' tests should be first performed to test positively whether free HCl is causing the reaction, or whether it is caused by organic acids, before proceeding to titration with dimethyl.

## SPECIAL ARTICLES

## INFECTION AS A FACTOR IN TUBERCULOSIS.

BY

WOODS HUTCHINSON, A.M., M.D.,  
of Portland, Ore.

Late Professor of Comparative Pathology, University of Buffalo, N. Y.

A most interesting backward swing of the pendulum of medical thought upon the tuberculosis problem has recently become noticeable. Up to the publication of Koch's epoch-making discovery and conviction of the bacillus, we had necessarily concerned ourselves almost solely with but one of the two great factors in any problem of infection—the soil. The discovery impelled us at once toward the other extreme—the almost exclusive study of the seed.

The gain which has ensued can hardly be overestimated, definite conceptions of the disease and its varying processes and distribution in the body, accurateness and promptness in diagnosis, effectiveness in guarding against its spread, all have become for the first time possible. But with all these advances upon the pathologic and botanical side of the problem, the study of the bacillus alone has been singularly barren of therapeutic or even hygienic results. Indeed, it would be hardly too much to say that in our actual treatment of the tuberculous, whether in the private consulting-room or the hospital ward, we practically ignore the bacillus, except as a means of diagnosis and as a possible source of infection to others, reluctantly as we have been driven to do so. And even in these regards its therapeutic value is rapidly declining, for the clinician who waits until he can clinch his diagnosis of tuberculosis by the sputum test has lost the most valuable weeks or months in the whole history of the disease and nearly half his chances of effecting a cure. Enormously valuable though it is as a means of corroboration and of verification with mathematic accuracy, the man who cannot make a diagnosis of tuberculosis without without his microscope is unfit to practise medicine.

The ignominious failure of every germicide from Bergeron's hydrogen disulfid to creasote, the bitter disappointment of fond hopes raised by announcement of every new modification of tuberculin, the "innocuous desuetude" into which the whole family of "antis" and serums has fallen, one after another, have at last started the pendulum upon its return swing, and again the study of the soil is assuming a proper relative, if not a dominant, importance. The more readily since the only method of treatment which has proved of the least permanent value, which will cure alike in the absence or in spite of the presence of drugs, which like charity, both never faileth and covereth a multitude of polypharmaceutical sins, the great elemental open air and overfeeding treatment, owes its victories solely to its effect upon the resisting power of the soil.

A most accelerating tap was given to this return movement of the pendulum by Koch's bold pronouncement of two years ago, the echoes of which are still resounding round the world.

I may perhaps be pardoned for confessing to a special interest in Koch's announcement for the reason that I had been led to a precisely similar conclusion, nearly two years before, from a comparative study of tubercle in the mammals and birds of the London Zoological Society's Gardens, upon grounds described in my monograph<sup>1</sup> on comparative pathology, published late in 1900. It was naturally no small gratification to a mere tyro in the pathologic field to have his tentative conclusions confirmed by the great master of the subject and discoverer of the bacillus in question, but Koch's announcement was far less of a surprise than the storm of protest and shrieks of dismay with which it was received by the medical world. The identity, or even close relationship, of human and bovine tubercle bacilli had been a matter of grave doubt and a debatable ground of research to all pathologists who had had opportunities of observation of both types of the disease, for at least five years past, ever since the masterly and original researches of Theobald Smith, to whom indeed the credit of the discovery of the nonidentity of the two species and of their consequent pathologic processes is really due rather than to Koch. His

second paper, in 1898, is far the ablest and most convincing document upon the subject that has yet appeared.

Indeed, the most astonishing thing about the pronouncement is the calmness with which the great man either ignored or barely referred to all who had anticipated him in his discovery, and the superb *non sequitur* by which he reached his practical conclusion—a conclusion which Adami has justly termed “little less than criminal”—that meat and milk inspection might hereafter be dispensed with.

Both of these show, however, foibles characteristic of the master, a marvel of logic and insight in his pathology, hopelessly at sea in his therapeutics, superbly right as to the bacillus, lamentably mistaken as to tuberculin, right as to the widespread influence of the hematizoon malarie, disastrously at fault as to the quinin-causation of blackwater fever.

I refer purposely to this aspect of the problem at the very outset, as it cannot be made too clear that even those of us who entertain grave doubts as to the communicability of bovine tuberculosis to human beings are utterly at variance with Koch in his astounding practical conclusion from this premise.

Now that the first fiery battle has in a measure abated and nearly all the great guns have been heard, it may not be without interest to sum up very briefly the result of all this artillery.

The responses naturally come from those classes of observers—the pure veterinarians, the pure human pathologists, and the comparative pathologists—who have had practical experience, both clinical and pathologic, among both men and animals. The first class is almost unanimously and hotly opposed to Koch's view; the second in the main opposed, and the third, which, if I may be pardoned for saying so, is alone fully qualified to judge, either in doubt, or in more or less substantial accord with it.

The first and most significant result is that the two observers who alone possess the naturally and necessarily rare distinction of being recognized authorities in both bovine and human tuberculosis, Adami and Theobald Smith, either confess grave doubts as to the communicability of bovine tuberculosis to man, or regard it as a rare and unusual occurrence. I may seem to be too strictly limiting this class of authorities and attaching too much relative weight to their opinions, since all pure human pathologists are of course familiar with the lesions of experimental tuberculosis in several species of animals, and all veterinarians see occasional cases in other than the bovine group. My reasons will be fully explained later, but may be briefly phrased here, in that the human pathologists deal solely with the inoculated and not with the naturally acquired disease in animals, a point of gravest and most fundamental importance in this problem; that they can observe only pathologic and not clinical symptoms, the early stages of “natural” invasion being “short-circuited” and the later aborted by killing the animal just as soon as the lesions are sufficiently advanced to make a sure diagnosis possible.

Veterinarians, on the other hand, are almost as completely restricted to bovine tuberculosis as we are to human, all other domestic animals together furnishing less than 5% of the cases they see, and of course they see nothing professionally of the human disease. They are also almost as seriously handicapped in the study of the complete clinical picture of the disease as are experimental pathologists, since the diagnosis is difficult to make in the early stages and the “patient” is usually promptly slaughtered as soon as the disease is clearly developed.

For instance, I have been trying for years to find out from my numerous and most courteously helpful veterinarian friends what the average duration of the untreated disease would be in cattle, and can get no data adequate to base even a fairly probable estimate upon.

And the problem I respectfully but firmly submit, with all possible recognition of the light which has been and still will be thrown upon it by bacteriology, is *clinical* and not *bacteriologic*: “Is bovine tuberculosis communicated to human beings, and if so, how frequently?”

Now as to the testimony of the pure pathologists, or to speak more accurately, the bacteriologists, the gist of their contributions is, first, that they can, as is well known, inoculate nearly all the animals usually used for experimental pur-

poses with either human or bovine bacilli, and that of the two the bovine appear slightly the more virulent and rapid in their action. In this general result there is substantial agreement, but when we descend to particulars innumerable exceptions crop up at once. Hardly any two species of animals are found to possess the same degree of susceptibility either to the different bacilli or to the same bacillus. Some, like the pig and kitten, can be inoculated by feeding with infectious material from either source (Nocard, Galtier, Peuch, *et al.*), though this is only with viscera or sputum; milk or meat, even in large amounts from condemned carcasses reeking with tuberculosis, being eaten by both these species with impunity. Others like rabbits and calves can be inoculated only with considerable difficulty by feeding. Next come guineapigs, rabbits, calves, and adult cats, which can be inoculated rarely through food, or through filling their cages with sputum-dust, but yield readily (except the last) to subcutaneous or intraperitoneal injections (Nocard, Straus, Gamaleia, *et al.*). Last stand the horse, ass, dog, sheep, goat, and deer, which very rarely contract the disease through food or inhalation, resist subcutaneous, intraperitoneal, and even intraocular injections in 95% of the cases, and yield only to the intravenous injection of huge amounts of infectious material or cultures.

From which one fact, most comforting to us as clinicians and human physicians, stands out clearly, and that is, that while almost any animal can be made tuberculous by flooding its blood-stream with bacilli, a considerable percentage will resist direct inoculation with even large doses and *only a small minority can be infected through their food-supply, or respiratory passages*. Which last, of course, are practically the sole methods of infection to be considered seriously in our own species. Experiments with direct inoculation have no bearing whatever upon this question, for when the bacilli have once penetrated skin or mucous membrane they have broken down an animal's strongest natural barrier. Even the feeble guineapig, which might have been specially created for laboratory purposes, so abjectly susceptible is he to every form and strength of tubercle bacillus,—bar only the avian—never contracts the disease under natural conditions, even in pens under laboratory tables, and is practically impossible of infection through food or sputum dust.

Of direct evidence upon the problem proper they can of course furnish nothing, experimentation upon the actual transference of bovine bacilli to human beings being out of the question upon moral grounds.

For this we are obliged to turn to the third class of observers, the veterinarians. Their testimony is almost unanimously opposed to both the view and the practical conclusions of Koch. In their protest against the latter I cordially and entirely unite, as have also Adami and Smith. First, on account of the glaring *non sequitur* fallacy involved in the position that because human tuberculosis is not communicable to bovines, therefore bovine tuberculosis is not communicable to human beings. Second, because, as I two years ago stated, “We should not tolerate for a moment the use as human food of either the meat or milk of animals suffering from *any* serious disease, nor can we afford to run any risk which is so clearly avoidable.” Indeed, the experiments of Rabinovitsch have since shown that milk from cows with tuberculous udders can produce serious toxic symptoms in both kittens and guineapigs after the complete removal of its contained bacilli by filtration. Third, because the stamping out of tuberculosis in cattle is of almost as great importance and value to agriculturists as the eradication of the disease in our own species would be to the State. Our most rigid and thorough slaughter-house, dairy, and shipping-yards inspections and tests for tuberculosis, with all their apparent loss by condemnation and slaughter, are an abundantly paying investment from a commercial point of view alone, even apart from their sanitary value. This largely accounts for the note of dismay in the veterinarian protest, since inasmuch as nearly all these inspections and safeguards are based upon—and I believe for legal reasons almost necessarily and solely so—the police power of the State, its right to protect human life and health, they see themselves in danger of losing all control of this terrible scourge the moment any serious doubt is thrown upon its danger to human health.

The selfish and unintelligent element among farmers, butchers, and dairymen will of course jump at any chance to have the obnoxious laws repealed or declared unconstitutional, as they certainly would be if Koch's dictum is accepted, not necessarily by scientific men, but by the legislatures and the courts. Of all this Koch must have been perfectly aware, and it is this utter recklessness of the grave dangers to which he was exposing sanitary progress and the public health which justifies Adami's characterization "little less than criminal."

But their testimony as to the actual communicability of bovine tuberculosis to man deserves most careful scrutiny, both on account of its importance and from the fact that it is practically the only evidence which we possess bearing directly upon the question.

This evidence is of three main classes: First, general statements of parallelism, such as Brush's alleged coincidence of tuberculosis with the keeping of dairy cattle, all over the civilized and uncivilized world. The coincidence is surprisingly close and exclusive, and Brush makes out a most plausible defense, but it seems finally to reduce itself mainly to the fact that tuberculosis is rare or unheard of among wild tribes of hunters and nomadic herdsmen, or even civilized ones like the gauchos of the Pampas, who do not milk their cattle, which introduces all the factors of the open-air cure; although there are some cases which cannot be thus explained, as, for instance, its comparative rarity among the Chinese, who use no cow's milk and very little beef. Second and most important, cases in which such communication has actually occurred. Third, the alleged increase of intestinal tuberculosis in children since the wider modern consumptions of cow's milk, while at the same time the disease has been decreasing among adults.

Under the second head quite an array of instances have now been presented by a succession of veterinary authorities headed by Macfadyean, of London (Royal Veterinary College), and Salmon, chief of our Bureau of Animal Industry, and rapidly followed by Ravenel, Repp, Delepine, Holton, Cattle, and others. Each one of these reports from five to twenty cases of alleged transference of the disease by milk.

The first thing which strikes any one who has been watching the literature of comparative pathology for the past decade is that nearly all these cases are old and familiar friends, classic instances which are to be found in all the textbooks; and the more of these recent anti-Kochian reports he peruses the more familiar the case-names become. To make perfectly sure that my memory was not playing me false I have carefully tabulated all the cases reported by the above observers and others since Koch's dictum, cutting out duplicates—or more correctly, triplicates or quintuplicates—and find that the actual total is 37. As this question has been before the medical and veterinary professions for at least 25 years, and several of the most frequently quoted cases date back 20 years, this most inadequate number is really significant. *Thirty-seven* alleged cases in 20 years from the whole civilized world! Granting the validity of every case, human tuberculosis of bovine origin is a rarer disease than leprosy! A disease which numbers but two victims a year is certainly not a serious menace to civilization. It is only fair to add that while of course these figures can by no means be regarded as representing the whole or even the proportional risk of infection from bovine sources, yet in view of the fact that veterinarians have been most alert and watchful for all cases of human disease of this origin, especially since more than half of them have been devoting themselves chiefly to meat and milk inspection—a service of priceless value to the race and which is far from being appreciated as it deserves—and that at least half of these 37 cases are open to most serious doubt of their authenticity,\* when carefully studied they do furnish a rough index of its probable frequency.

I see no reason to anticipate that such cases will become any more frequent in the future, for although on the one hand our own profession will be more keenly alert, yet on the other

\*Since the above was written Koch has reported that on careful reinvestigation of the most striking apparent instance, that of Olivier, in which five girls in one boarding-school died of tuberculosis and one of the school cows was found tuberculous, it was found that *none of the milk of the diseased cow had been given to the pupils, but had been consumed by the servants, none of whom developed tuberculosis.*

the bacilli from such cases will have to undergo the test proposed by Smith and Koch, of inoculation into cattle. This seems to me a fair requirement in cases of such great importance, although as Adami suggests, their failure to infect cattle would not necessarily disprove their bovine origin, as in the adjustment to their human environment they might reasonably be supposed to have lost some of their original virulence for bovines. Yet it does not seem likely that they would have lost it entirely, and they ought to display a greater pathogenicity for cattle than undoubted human cultures. Indeed this requirement has been recently met in a most interesting and important case, ably planned and reported by Ravenel.

In addition to these 37 instances of supposed infection through milk by, so to speak, natural channels, the 10 reports tabulate a total of 17 cases of the communication of bovine tubercle through wounds of the skin, chiefly in veterinarians at autopsies, butchers or milkers. Here, again, the number is exceedingly small, an average of less than one case a year for the past two decades. This danger could of course apply to only a very limited class of our population in any case. And upon careful inspection of the cases this danger shrinks to even infinitesimal proportions. In 12 of these 17 cases only local or cutaneous symptoms resulted. In 9 of them a mere nodule or tuberculous mass at the site of injury, which gave rise to no general infection whatever and was completely cured by excision; in other words, a simple transplantation of foreign bacilli, familiar in all our laboratories. In the other three more or less extensive lupus resulted, which yielded completely to local curetting or excision. In only 4 of the 17 did pulmonary involvement and death result. So that our apparent and only proved fatality from bovine tuberculosis by inoculation is 4 cases in 20 years, or 1 death in 5 years. This comes exceedingly near what the French term *un quantité négligeable*.

The total number of cases thus collected by the believers in communicability is 54 in 20 years, and while, as I have stated, this can by no means be taken as representing the total risk, yet I might add that it stands for not merely all that the ablest opponents of Koch have been able to discover—but also as the outcome of a fairly careful watch which I have kept personally upon both veterinary and human medical literature for seven years past. Other cases have no doubt been reported which have escaped me, and I have gathered reports either through the literature or personally from veterinarian and medical friends of at least as many more, in which the evidence on investigation proved utterly inadequate even to indicate a bovine source, yet the above number represents the sum total of cases from the literature of 20 years in which there was even a reasonable probability of bovine origin. It may also be added that Bovaird, after a careful search through the medical literature of the last 15 years, has been able to find only 22 reasonably authenticated cases of alleged infection through milk. In not one even of these cases, as Adami also points out, could the easy possibility of infection from human sources be excluded on account of isolation or other conditions.

Now, what evidence have we to offer in rebuttal of this gravest section of the indictment against the bovine bacillus?

*First.* In reply to Brush's general charge against the dairy cow we have the broad and consoling fact that while the census returns of every civilized country in the world show an increase in the amounts of meat, milk, butter, and cream consumed per capita of from 200% to 400% in the past 30 years, the mortality from tuberculosis during the same period has declined from 30% to 45%.

*Second.* Every attempt to connect in any definite way tuberculosis with either meat or milk supply, whether by Royal commission, as in England and Denmark, by veterinary inspection boards, as in France and Germany, has failed utterly. Increased use of meat and milk has, on the contrary, in every class, country, age or condition, been found associated with a decreased death-rate from tuberculosis. In fact, as I have elsewhere<sup>3</sup> summed up the evidence, even the leading veterinary authorities, Macfadyean for England, Nocard for France, and Bang for Denmark, admit that the danger from the use of the meat of tuberculous cattle is comparatively small, on account of cooking, immunity of muscle fiber from tuberculous foci, resistance of carnivorous

digestive tract of man, etc. In the words of Nocard,<sup>4</sup> "Although tuberculosis can be transmitted through the digestive tract . . . ingestion only succeeds in giving tuberculosis when the ingested material is very rich in bacilli."

*Third.* Although tuberculosis has been proved to be present in from 2% to 52% (Schleswig-Holstein) of dairy cattle, nowhere (outside of insane asylums and cloisters) does it reach in human beings a prevalence of much more than one-tenth of this degree, viz., from 2 to 5 per 1,000 living. Nor does the highest bovine prevalence coincide in any way with the highest human deathrate.

*Fourth.* We have now on record a large number of instances in which a dairy herd or single cow, on being tested and slaughtered, has been found simply riddled with tuberculosis, without any greater prevalence among the family, institution, or customers consuming the infected milk, and in many cases having consumed it for months or even years, than in the surrounding community. Who of the English royal household was found to be tuberculous when the prize herd of Alderneys at Windsor was slaughtered and shown to be reeking with tuberculosis of years' standing? Clifford Allbutt relates his own acute apprehension when his favorite Alderney, whose milk mixed with that of others had been used by his own family and farm group of 20, including 10 children, for a long period, developed a cough and was found to be in an advanced stage of tuberculosis, with an affected udder and swarms of bacilli in her milk! And yet finally, as he says, "no one was a penny the worse, except myself for the loss of my pedigreed cow." I have had two similar cases in my own experience.

Surely if milk is at all a frequent source of infection we should have found by this time far more striking coincidences between infected herds and infected families. The only such coincidences which I have found reported have been in two insane asylums, but in neither case was the human deathrate above the frightful tuberculous mortality which unfortunately is the rule in the majority of such institutions. The deathrate from tuberculosis among the chronic insane not infrequently reaches 25% and even 60% of all causes.

Lastly, while direct experimentation upon the human subject except with full consent of the victim is inadmissible and we have not yet had time to hear conclusively from the two members of our profession who have pluckily offered themselves as martyrs in this cause, a small but very interesting series of cases, which bear absolutely directly upon the question have recently been furnished by Baumgarten. He reports that nearly 20 years ago, when he was assistant to Rokitsansky, the old master in pathology was led to regard with some favor the theory then under discussion, that there was an antagonism between the cancerous and the tuberculous processes. He accordingly instructed Baumgarten to inject with tuberculous material a number of patients with inoperable and hopelessly advanced carcinoma. To avoid possible complications from other human infections the virus was obtained from bovine sources. Six patients were inoculated with large doses of this virus, by injection, both into the neighborhood of the growth and into other parts of the body, in some cases several times in succession. But as no effect whatever was produced upon the growth of the cancers, the procedure was soon abandoned. Not one of these patients developed any symptoms, either local or general, of tuberculosis. And one could hardly have selected subjects in whom the general powers of resistance to infection would be likely to be more completely broken down than these poor, old, practically moribund victims of advanced carcinoma.

Six cases are, of course, far too few to base any conclusions on, but they are certainly entitled to be balanced against the 17 instances which alone have resulted positively out of the thousands of accidental inoculations, which must have occurred in 20 years among the whole body of veterinarians, butchers and dairymen.

But although both veterinarians and commissions are agreed in the reassuring and cheering conclusion that the actual danger from infected meat is not so serious as was feared, indeed is slight, they are still inclined to regard milk as a source of considerable danger.

The 37 actual reported cases of infection from this source

have already been considered, but there is a further basis for their contention, and this brings us to the last class of evidences adduced in favor of human infection from bovine sources. This is the alleged increased mortality from intestinal tuberculosis in children under 1 year of age, viz., at the chief milk-drinking period.

This contention was first raised by the distinguished sanitarian, Sir Richard Thorne-Thorne in his Harben Lectures for 1899. His statement was a striking one and attracted wide attention, but not, I fear, of character likely to be very gratifying to its author. It was that while the deathrate per 1,000 from tuberculosis had decreased in England and Wales 39.1% in 45 years among all ages, that among children under 5 years had decreased only 3%, while under 1 year it had increased 27.7%, and that this increase was in the form of intestinal tuberculosis. The statement was simply riddled to a shell within a month.

In the first place, Sir Richard, with a sad lack of pathologic information, had taken *tabes mesenterica* of the Registrar's returns as intestinal tuberculosis. As Still, Donkin, and Carr, the leading pediatricists of London, showed in rapid succession, *tabes mesenterica* is an ancient name made to cover chiefly a chronic mucoenteritis with enlargement of the mesenteric glands and typical "pot-belly," which has a fearful fatality among the children of the London poor, but of which we see most mercifully little in this land of cheap and abundant food and good wages, and is not tuberculosis at all. Furthermore, these gentlemen, supported by Sherman, of Edinburgh; Coleman, Guthrie, and other pediatricists, reported an aggregate of nearly 700 autopsies upon the bodies of children dead of tuberculosis, which showed less than 20% of cases of the intestinal form, nor could they find any evidence of an increase in tuberculosis mortality among children at any age.

But worse was to follow. American, French and German observers took up the question, and their results have been recently collected and analyzed with great industry and skill by Bovaird, of New York,<sup>5</sup> with the following showings as to the frequency of intestinal tuberculosis in children:

	Total cases of tuberculosis in children (autopsies).	Percent of intestinal form.
German (Kossel, Haushalter, etc.).....	236	4%
French (Comby, d'Espine).....	128	.....
American (Northrup, Holt, Bovaird).....	369	1%
English.....	748	18%

That is to say, in every country in the world, except England, intestinal tuberculosis is one of the rarest forms of the disease in children, and even in England it occurs in less than one-fifth of all cases.

The extraordinary discrepancy between the English and all other statistics cannot be entered into here; suffice it to say that I believe it chiefly depends upon the meaning attached to the term "intestinal tuberculosis," the English observers applying it to every case in which the intestine or its lymph nodes are seriously involved, and the American and Continental observers more justly restricting it to those cases in which the primary infection has apparently occurred through the food-tube.

However, even at that reported level, if the frequency of milk infection is to be proved by the frequency of intestinal tuberculosis in children, as Thorne asserted, and Salmon, Repp, and veterinarian observers generally, except Macfadyean, have eagerly echoed, the argument not only collapses but becomes a positive boomerang.

On the other hand, it must be said that the mere occurrence of the chief theater of infection in a particular organ or region of the body is by no means conclusive evidence of its entry by that port. No matter by what channel tubercle bacilli enter the body they will make their chief and fatal lodgment in the lung in the vast majority of cases. The lung is a point of least resistance in the entire body, as my experience both among domestic animals and in the London Zoological Gardens convinced me years ago. As shown five years ago by Theobald Smith, and by many observers since, animals are definitely

infected through food or by peritoneal inoculation will ultimately die of pulmonary tuberculosis, with no appreciable trace of intestinal infection except a few infected glands. So the fact that 65% to 75% of fatal tuberculosis in children is in the lung by no means proves that the infection did not in many cases enter in the food.

However, although the original lesion in the mucous membranes has entirely disappeared there will nearly always upon careful search be found one or more infected foci along the mesenteric lymph chain through which the bacilli reached the general circulation and the lung. And cases in which there are isolated foci of this sort, in the intestinal lymph nodes, are very rare, outside of England at least.

With the contention that human tuberculosis can be communicated to cattle I have no quarrel, first, because it is universally admitted by bacteriologists and veterinarians, even by Ravenel, the warmest and one of the ablest champions of intercommunicability, to be both difficult and probably rare; and second, because I hold that the question of the possibility of infection of any particular species by any particular bacillus stands absolutely upon its own merits and must be settled by actual evidence as to that special fact. *A priori* reasoning and analogy are of no weight whatever, and cannot even establish a reasonable probability.

Who, for instance, on *a priori* grounds would have imagined that the feeble sheep, with their low resisting powers and a mortality so high that "to die like sheep" has passed into a proverb, would absolutely resist inoculation with every form of the bacillus, except in rare exceptions by intravenous injection? Or that the most generally susceptible of known animals, the guineapig, would resist the avian bacillus, while his near relative, the rabbit, succumbed to it. And a germ which has been passed through 10 generations of rabbits has no more effect upon a bird than one which has lived an equal length of time in the tissues of guineapigs.

If the human germ be practically innocuous to cattle, as Koch maintains, this proves absolutely nothing, and throws no light upon the virulence of the bovine bacillus for human beings. If, on the other hand, infection of cattle by the human germ is, as claimed by the veterinarians, difficult, but reasonably possible, this is equally inadequate to prove or even suggest a reasonable probability of the infection of man by the cattle germ.

In fine, a careful consideration of the evidence bearing upon the actual communication, which has and can occur of bovine tuberculosis to the human subject, leads us to the same general conclusion as the laboratory results of the inoculation of various animals with the three type forms—human, avian, and bovine, viz., that tubercle bacilli which have become specifically adjusted to the tissues of a particular host have, as a rule, lost practically all their virulence for other species through the natural channels of infection.

Nor, it must be remembered, is the tubercle bacillus alone or singular in this respect. On the contrary in fact, were it as universally communicable as we have been led to suppose, it would be the great and striking exception among parasites, both vegetable and animal. Physicians, who are not working naturalists, have often little idea of how strictly exclusive in their habits most parasites are. Even among the animal forms and such high and independent types as the insects they die if transferred to the bodies of even closely allied species. The flea of the dog will not live for more than a few hours or days upon man, nor will the flea of the hen survive long on either the human or canine skin. It was one of the old cherished proofs of the multiple origin of the human race that the fleas and bedbugs of certain South American tribes would not live upon the skins of Europeans.

Almost any domestic animal and every wild one which has been studied "helminthologically" has its own private species of tapeworm or roundworm which can live in no other species of host.

I have prepared a list of the (23) infectious diseases most common among domestic animals and man. Of these only 1 (rabies) is readily communicable to 3 or more species, only 3 (anthrax, tetanus, and foot-and-mouth disease) are readily communicable to 2 species and with difficulty to several others, 1 (diphtheria) is rarely communicable to the cat and dog, 4

(smallpox, glanders, influenza, actinomycosis) rage furiously through 1 species, and in isolated instances infect one or more others, while 19 practically never attack any member of a species other than the one they originate in, although this class includes such deadly and active infections as yellow fever, cholera, typhoid, pleuropneumonia, and syphilis.

If tuberculosis be readily communicable among seven different species of mammals, as is claimed, it is a most striking and surprising anomaly among diseases.

So far as the three so-called species of tubercle bacilli—the human, the bovine, and the avian—are concerned it is now pretty generally agreed among bacteriologists that they are all three varieties or modifications of one common form, although there are some who still hold out for the specificity of the avian. Bird tuberculosis is much more difficult to inoculate upon mammals than either of the mammalian varieties, while birds are almost absolutely immune to either of these latter. And yet, as Nocard's ingenious experiments showed several years ago, mammalian bacilli can be raised to a pitch making them virulent for birds, by introducing them into the peritoneal cavity of the latter enclosed in a collodion capsule so as to be affected by the temperature and fluids of the body, but protected from the leukocytes. A stay of six months, or passage thus protected through four or five successive hosts, will render them capable of finding a foothold in the tissues and infecting the whole body when inoculated naked.

The question simply is whether their differentiation and adjustment to the conditions present in certain hosts has not rendered them practically harmless for all others. This is certainly true and admitted as regards the avian bacillus, collodion capsules not being found in a state of nature, and in my judgment the overwhelming balance of such evidence as we possess points in the same direction as regards the bovine for human beings. Infection by the natural and ordinary channels is possible, but requiring the cooperation of so many favoring conditions as to be highly improbable and exceedingly rare. At least this is as far as the evidence hitherto adduced would justify us in holding. Adami and Smith arrive at practically the same conclusion. Further data may carry us further, and we must await their accumulation by the slow process of time, lacking the power to make the direct test. Even negative results upon single volunteer subjects would prove little either way.

This brings us to the interesting question, Which one, if any, of these three is to be regarded as nearest to the type of the common ancestor? As no one of them has any substantial advantage over the other two, either as to wider prevalence, greater virulence, or greater range of culture media or temperature viability, neither form has any valid claim to more primitive qualities, still less to being the ancestral form, as some veterinary pathologists have claimed for the bovine.

The little that we know of tubercle bacilli in cold-blooded animals is either negative or of an exceedingly limited character, at most indicating a modified, attenuated form of some avian or human germ.

In short, our search for the primitive ancestor of the tubercle bacillus would appear to be directing itself outside of the animal body, and possibly toward some organisms widely different from the bacillary form. This is the most interesting, and to my mind, the most important problem before bacteriologists today, and is exciting wide attention.

Investigators seem to be grouping themselves along two main lines of research. One, headed by Metchnikoff, Fischel, and Hueppe, regard the tubercle bacillus as not a bacillus at all in the strict sense, but one of the stages in the development of a pleomorphic mold. The name of Metchnikoff alone is enough to command respectful attention for this view, which is based upon the curious branching tendency, approaching the formation of a mycelium, seen in cultures of the bacillus under certain conditions, its remarkable "shyness" of growth and narrowness of limitation to certain mediums and within extremely narrow ranges of temperature, making its existence, except in spore form, outside of the body, a practical impossibility; and the remarkable association of the disease with dampness of subsoil, dark and ill-ventilated rooms, and overconfinement.

The other group, represented by Möller, Lubarsch, Petri, Rabinovitch, and Kenyon, are trying to trace a possible connection between *B. tuberculosis* and certain acid-resisting bacilli of almost identical shape and growth-habits, which swarm upon timothy and other forms of meadow-grasses (*Phleum*, *Bromus*, and *Alopecurus*), and hence are known as the "grass bacilli." These are so strikingly similar to the tubercle bacillus in shape, reaction to stains, methods of growth on culture-mediums that the latest work upon them by most competent critics (Abbott and Gildersleeve<sup>6</sup>) can discover only three means of distinguishing them: that they can be decolorized by slightly weaker acids, can grow at a lower temperature and do not produce typical tuberculous infection upon inoculation into animals. The first distinction is probably simply a question of a larger or smaller percentage of fatty matters in the outer layers of the organisms. The second, it must be remembered, is but little more than can be said of the injection of any foreign bacillus, *e. g.*, an avian tubercle germ into a mammal, or vice versa.

All observers find that these grass-bacilli and dung-bacilli, on injection into animals, produce nodules which are sometimes difficult to distinguish from tuberculosis, but that general infection seldom occurs. The organisms can be recovered from the nodules, and Möller and Kenyon are reported to be now engaged in determining whether any increase in virulence can be produced by passing them through a series of animals, and to have already obtained some interesting results.

Their presence upon cultivated grasses gives them, of course, a very wide opportunity of distribution and Abbott and Gildersleeve found no less than 30 or more forms in stable manure, in the intestinal contents and smegma about the vulva and anus of normal man, horses, cows, dogs, guinea-pigs, and white rats; in the saliva of nontuberculous individuals, and in butter. If inoculated in pure culture into the peritoneal cavity only a few scattered nodules resulted, but if accompanied by a little sterilized butter a fibropurulent peritonitis follows. Intravenous inoculation is usually followed by a free formation of nodules, histologically resembling true tubercles, in the viscera. In short, the only important character they seem to lack is that of producing a general infection, and even this is forthcoming if some of the media in which they are found be injected with them.

Their action is a curiously close parallel to that of the human bacillus when injected into bovines, which also in pure cultures produces only scattered nodules or purely local reactions, more extensive results if pus or caseous matter accompany it, but genuine generalized infection rarely in any combination. The only apparent difference between the grass bacillus in mammals and the avian or human bacillus in bovines appears to be one of degree of virulence.

Abbott and Gildersleeve agree with Möller in regarding the botanical relationship of the acid-resisting bacilli—which probably all fall under two species—with *B. tuberculosis* and the ray-fungi of actinomycosis as unquestionable, and that the term "bacillus" is not a correct designation for any of them, but that the whole group should be called actinomyces. It will at once be evident, if prolonged "saturating," repeated infections, with successive generations of grass bacilli might possibly give rise in susceptible individuals to tuberculosis, what an interesting light is at once thrown upon Brush's contention as to the dairy. Wherever the dairy cow goes tame grasses follow. Also if *B. tuberculosis* passes through an intermediate stage on grasses before it can again infect, this ought to be a factor in the puzzle of the immunity of high altitudes and deserts, in neither of which tame grasses will grow. With settlement and irrigation immunity is lost.

What makes the study of the grass and butter bacilli of such interest and importance is, that our knowledge of the precise process and paths of infection in human tuberculosis is so imperfect and unsatisfactory.

We know certainly that introduction of one case into a community, institution, or family, is likely to be followed by others, but as to the period of incubation, the vehicle of contagion, the process or port of entry of the invasion of the body of the next victim, we are completely in the dark. In no case do more than a small percentage of those exposed to infection

contract the disease, and the period of incubation is often so prolonged—in some cases covering many years—that the question is already raised from several quarters, whether the bacillus may not require some intermediate host, like the mosquito in malaria and yellow fever, and the rat in bubonic plague, or have to pass through a saprophytic stage outside of any animal body before it can again attack a human subject.

In this connection it is interesting to note that Straus, Nocard, and Theobald Smith have all called attention to the fact that certain cultures of fully virulent tubercle bacilli readily adapt themselves to a saprophytic habit of growth, and in a number of generations come to be able to grow on media and at temperatures which they were quite incapable of when first isolated. And as the last observer has shown, bacilli isolated from different cases of tuberculosis, especially "scrofulous" glands and skin lesions, show marked variations in virulence.

On the one hand we have the classic series of cases of alleged transmission from husband to wife and wife to husband, collected by the Collective Investigation Committees of the British Medical Association in 1883, 158 instances; by the Berlin Medical Society, 40 cases; and by the Medical Society of the Paris Hospitals, 107 instances—a total of 305.

These figures certainly establish the danger of communication under these circumstances, but they have two grave defects. They give us no information as to the total number of persons who had lost a husband or wife by tuberculosis from among whom these cases were selected, nor do they give the length of time elapsing between the primary case and the death of the survivor.

When we remember that these figures represent the total number of coincidences of this sort occurring in the experience of, at moderate estimates, from 500 to 1,000 physicians—the British list was based upon 267 affirmative replies—making less than one instance to each physician interrogated, and that nearly any physician can number from 5 to 25 patients who have lost a husband or wife by tuberculosis, the probable percentage of infection in such cases is not shown to be very large. Lists which do not give the total number of patients exposed to such contact-infection are of no value whatever as a basis for conclusions.

In the only series of cases which I have been able to discover in which this was done, that of Prevost, the actual mortality by tubercle among the total number of survivors of such marriages was found to be no higher than that of the rest of the community. The whole question is in urgent need of further investigation upon broader lines.

Again, we have the wellknown and statistically abundantly attested fact that tuberculosis tends to "run in families," which at one time was attributed solely to heredity, now chiefly to contagion. But even here our knowledge is of the vaguest and most confused description. So many other possible factors enter into the problem. First, there is the possibility of the common inheritance of a weak constitution and vulnerable organization, not specially so toward tuberculosis, but of low powers of resistance to any unfavorable influence. Then we have the exceedingly potent influences of housing, of food, of bodily habits, and occupation all in common.

Lastly, the data so far collected are imperfect and incomplete. They are usually concerned solely with positive instances, or consist of a list of tuberculous individuals with the percentage of "family history" of the disease, without any statement as to the total size of the family groups under consideration in each case. When one in seven of the entire community die of the disease, it is obvious that any family group of seven or over is liable to contain one case of tuberculosis. Statements of total number of cases observed, or of descendants of tuberculous couples, are as urgently needed here as in the conjugal infections.

Next, we hear loudly trumpeted from time to time, usually in the public press, or by health officers and politicians, the warning that tuberculosis is rapidly increasing and spreading among the previously healthy inhabitants of some of the great health resorts or in the neighborhood of some sanatoriums. I have taken some pains to investigate reports of this description, and have not succeeded in finding one yet which was supported

by facts. The facts have been carefully gone into and the statements utterly disproved by Gordinier, for Colorado Springs; Aeby, for Davos; Trudeau and Baldwin, for Saranac Lake; Detweiler, for Falkenstein, and a physician of the English colony for Mentone.

Lastly, since the report of Cornet in 1874 it has been repeatedly alleged that the deathrate among nurses from this disease is extremely high. Nurses in the Paris hospitals and nursing sisterhoods were shown to have a mortality by tuberculosis of from 30% to 63% of all deaths. But such reports fail to state what has since been discovered, that the deathrate by tuberculosis is equally high in the nonnursing sisterhoods, nor will any one who has seen the scandalous conditions as to light, ventilation and dirt which prevailed even 15 years ago in the Parisian hospitals—one of the most famous being a converted warehouse—wonder at any deathrate which might prevail among the nurses.

On the other hand we have the fact that not a single death from tuberculosis has occurred among the nurses or internes of the great Brompton Hospital for Consumptives in 60 years. Not one in the famous sanatoriums at Falkenstein and Goerbersdorf, nor one in the 15 years of the Saranac Lake Sanitarium of Trudeau. Where nurses are allowed to live under civilized and clean conditions they are in no danger of infection.

The same may be said of the high mortality in prisons and insane asylums, both of which reach as high levels as the nursing sisterhoods; infection is necessary, but confinement and overcrowding are the really effective factors in its success.

In fine, the general balance of such evidence as we possess up to this date upon the role of infection in tuberculosis seems to me to point clearly toward the view, that while the introduction of infectious material is necessary, the most potent factors in determining the question of the development of the disease are those of the soil, *viz.*, *resisting power and environment*.

The three chief environmental factors are now well known, housing—including lighting, ventilation and overcrowding—food and occupation. Upon these three factors is based our only known or successful treatment of the disease.

Upon the side of the resisting power of the subject our chief desideratum is a group of criterions for its early detection before a bacteriologic diagnosis is possible, to apply our open air treatment at a stage when it will cure 90%.

There was a considerable amount of truth in the old views as to the habitus phthisicalis, as Galton and Mahomed have confirmed by composite photography, only unfortunately many of the "warning" features were signs of the actual presence of the disease.

What we need are characters which can if possible be relied upon to indicate low powers of resistance, in advance of actual disease. There are of course many of these, but some include the entire physiognomy and most are too vague for accurate description or appreciation.

One, however, I believe we have which is definite, significant and congenital. This is a high Chest Index. By chest index I mean the relation between the anteroposterior and transverse diameters of the chest at the level of the nipples.

Contrary to general impression, I believe this to be high in tuberculosis, in other words, that the chest of the consumptive is not flat, but round or deep. Since calling the attention of the profession to this fact five years ago I have accumulated measurements of nearly 400 tuberculous chests on both sides of the Atlantic, with the result that 85% show a higher index or rounder chest than normal. The average for the entire series is 80, while the normal index is 70 to 72.

This shape of chest is simply the persistence of the fetal—Index 100—and child (85 to 90) forms of chest. The chest of a patient over 16 years which does not show a flattening of at least 80, ought to be regarded as suspicious, and the patient put to an open air life at once.

I am also finding it a valuable and reliable sign in very early stages of the disease: if the index is above 77, give the patient the benefit of the doubt and send him to the woods.

Guard against infection by every possible means. Meat and milk inspection, tuberculin tests, destruction of sputum, notification of cases, prevention of expectoration in public, all are

of highest value and worth to the public health and well ten times their cost and trouble. But at least twice as potent, in my judgment, in the eradication of tuberculosis will be light and airy rooms, good food, short hours of indoor work, and above all a reversion to our vigorous, happy, ancestral life in the open air and for children in the tree-tops, flattening and expanding the chest, reddening the blood, hardening the muscles, and making life once more really worth living.

### CIVIL SANITARIUM AT BAGUIO, BENGUET.

From the report of the Secretary of the Interior of the Philippine Islands to the commission we extract the following details:

During the past year it has been possible to conduct some practical experiments as to the effect of the Benguet climate upon sick or debilitated persons. The opportunity presented itself to acquire a considerable tract of land with two houses upon it, owned by Mr. Otto Scheerer. The position of this land with reference to the probable future site of government buildings at Baguio was such as to make it seem desirable that the government should purchase it before further improvements were made upon it. One of the houses was assigned to the Governor of the province as his official residence. The other, containing a dining-room, a kitchen, and three bedrooms, with a total capacity of eight beds, was taken for a hospital. With considerable difficulty the necessary furniture and hospital supplies were sent up over the Naguillian trail, and the institution was opened with a personnel consisting of an

acting superintendent, a nurse, a hospital steward, and the necessary servants. Later another nurse was added.

Plans were prepared for a new building to accommodate 60 beds, and to be constructed in such a way that the old building would form a part of it. The construction of six cottages, to be occupied by the families of civil officers and employes in need of recuperation, was also provided for. Work upon the projected improvements was begun immediately. Progress has necessarily been slow, as lumber could be had only by felling pine trees and sawing them up by hand, while it was necessary to take other supplies in over the Naguillian trail.

Very sick persons could not have endured the long, rough trip over the trail, but it has been possible to send a limited number of malaria patients and persons convalescing from dysentery and other wasting diseases. Thus far 43 persons have been admitted to the sanatorium. A few of these were in good health and were members of the families of the real patients. Approximately four-fifths of those admitted sought relief from general debility, induced by the tropic climate or by wasting diseases, and in nearly every instance they reacted promptly to the bracing air and rapidly improved. We now know positively what we had every theoretic reason to believe would prove true: that convalescents gain rapidly in weight, strength, and color at Baguio, and are soon restored to vigorous health. In some instances slight discomfort is felt during the

first few days owing to the change in altitude, but this soon passes away.

The first estimate of the time required to complete the cottages and the addition to the sanatorium building proved inaccurate. Owing to strikes among the workmen, cholera, bad transportation, the extraordinary rainfall during the month of August (54 inches), and scarcity of labor, progress was much slower than had been anticipated. The force of nurses and hospital attendants, based on this estimate, proved unnecessarily large, and it became evident that if patients, even when convalescent, were to be sent to Baguio there must be a physician and surgeon there to attend them. Act No. 429 was accordingly adopted, reducing the original force to one nurse, one hospital steward, one cook, and two native servants, and providing for the appointment of an attending physician and surgeon.

Many of the persons who have been at Baguio are anxious to secure building lots there in order that they may erect cot-

tages and send their families to Benguet during the hot season. The establishment of homes where the families of civil officers and employes can at any time, and at small expense, get the beneficial effects of a bracing climate will greatly add to the stability of the civil service, and I urge the surveying of a town site on government land and the sale of building lots in the near future, in order that it may be possible for those who desire to do so to build at Baguio. When this can be done many persons who now hesitate to bring their families to the Philippines will feel perfectly safe in sending for them.

For further details in regard to the work of the Civil Sanitarium, reference is made to the first annual report of the attending physician and surgeon.

**Sanatorium for Consumptives.**—The *Baltimore News* says that the trustees of the Hospital for Consumptives at Towson are making plans for the establishment of a branch of the hospital at some place in the Blue Ridge Mountains, and a friend of the hospital has promised to give \$25,000 toward the project if a like sum can be raised by the trustees. The plan will probably take definite shape within the near future, and a small farmhouse will be rented for this summer for use as a kitchen and dining-room, while the patients will sleep in tents. The site has not been decided upon as yet. The trustees of the hospital have secured the cooperation of the Quarter Club in the movement, and that organization has raised about \$3,000, which will be devoted to the furthering of the plans for the mountain hospital. It is believed that this sum can be raised, and plans are being formulated accordingly.

**Yellow Fever and Mosquitos.**—Assistant Surgeon Grubbs, in charge of the Gulf quarantine station, has settled the question as to what extent and under what circumstances mosquitos infected with yellow fever germs can be carried by vessels. From June to November last he inspected vessels arriving from ports where the presence of the stegomyia render them liable to infection. Of the 82 vessels from possibly yellow fever ports, 65 had no mosquitos on board at any time during the voyage, 5 had the insects on board at port of departure, 9 reported the appearance en route of culex or harmless mosquitos, and 3 brought stegomyia to the station. All 3 of the last group were from Vera Cruz, a yellow fever port, and the voyages lasted on an average 17 days. Surgeon Grubbs gives the mosquito history of each of the 3 and reaches these conclusions: First, that mosquitos can come aboard a vessel under favorable conditions when the vessel is not over 15 miles from shore; second, that stegomyia can be carried from Mexican or West Indian ports to those of our Gulf States; third, that they can board a vessel lying at anchor a half mile or less from shore, being conveyed by the open lighters used or flying aboard, and, finally, that a vessel moored a short distance from land may become infected with yellow fever, our old beliefs to the contrary notwithstanding.

## THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

[April 11, 1903. Vol. XL, No. 15.]

1. A Modification of Panas' Operation for Ptosis. FRANK ALLPORT.
2. The External Preparations and Their Therapy. CARL S. N. HALLBERG.

12. The Treatment of Traumatic Gangrene of the Extremities. VAN BUREN KNOTT.
13. Poisoned Wounds by the Implements of Warfare. LOUIS A. LA GARDE.

**1.—Operation for Ptosis.**—F. Allport gives a schematic drawing which demonstrates the steps in Panas' operation more clearly than the original drawings. The latter show the double threads in the eyebrow coming out of the same hole whereas they should emerge from separate holes. The outermost of the five sutures should be inserted in the spaces between the skin flaps, including the tissues of the lid, except the skin and tarsal cartilage, the loop being on the conjunctival surface. He makes his incision straighter than those shown in Panas' lines, and scarifies and denudes the lower middle flap before dissecting it and drawing it up under the upper flap, which he calls the bridge flap, in order that the surfaces may adhere, leaving no pocket to collect debris. The lumpy appearance usually left by the operation is minimized by making the bridge flap as narrow and as thin as possible. Puckering at the corners of the lid is remedied by trimming the side flaps to a point. [H.M.]

**2.—External Preparations.**—C. S. N. Hallberg points out that fats are the best vehicle for rectal suppositories, because of the alkalinity of the secretions, but water-soluble substances should be used in the urethra and vagina, as their secretions are normally acid. Glycerogelatin probably answers best. Commercial rubber plasters lack penetrative properties in any considerable degree, and should not be used with drugs like belladonna when endermatic effects are sought. The oleates, as represented by lead plaster, penetrate into but not through the skin, and thus do not produce any systemic results. For diadermatic or systemic effects the vehicle for plasters should be animal fat, as lard or suet with waxes, or preferably mixtures of these with lanolin, like the plaster-mulls of Unna. While the natural oleates, oleopalmitates and stearates in which the acids are linked with glycerol, penetrate through the skin, the artificial compounds with metal and alkali bases are not absorbed through external use. Agents such as belladonna, camphor, etc., in volatile liquids, are more effective when applied by means of an occlusive dressing than in oil or soap solutions. Collodion is indicated when lasting effects are desired over small areas. Mulls permit evaporation, thus preventing maceration of the skin, which usually occurs from more occlusive dressings. A 1% water solution of the alkaloidal salts permit germ growth, while 10% solutions are easily kept sterile. The U. S. P. should contain a formula for sterilization of hypodermic and other injections, collyria, etc., which the physician could specify in prescribing. It should also give directions for the purification of commercial gauze. [H.M.]

**3.—Intraabdominal Irrigations in Puerperal Septicemia.**—J. H. Burtenshaw uses the normal saline solution of Locke containing sodium, calcium, and potassium chloride, and kept at 110° F. In the case reported the kidneys began to functionate immediately after the irrigation was begun, or he would have discontinued it at once. Intravenous infusions would have influenced the general systemic infection as favorably, but with regard to the attendant peritonitis it was the local action which cut short the inflammatory process and prevented

adhesion formation. The streptococcal infection spreading from the uterus by means of the lymphatics and the solution being absorbed by the latter the toxin was attenuated almost at its origin. The heat caused contraction of the arteries and disappearance of the inflammation. On account of its action in laking the corpuscles and its toxicity toward cellular activities the 0.6% salt solution commonly regarded as normal should not be employed. [H.M.]

#### 4.—Fistula Between the Gallbladder and Stomach.—

A. B. Snively finds only four operative cases reported in literature, but many unrecognized cases have probably existed since in general there are no symptoms except those of cholecystitis or cholelithiasis. Small stones might pass through the pylorus to the stomach. Vomiting of a large stone justifies the suspicion of fistula. He reports a new case. [H.M.]

#### 5.—Light Treatment in Lupus.—

J. W. Kime uses a modification of the ray filter employed in photography with an 18-inch focus. At the focal point it is intensely hot, but in some cases nothing short of this will arouse reparative action. With a beam of sunshine one foot in diameter falling through the office window the instrument is ready for use. The surface is freed from crusts and washed with water without antiseptics. The light is moved over the surface coagulating the albumin in the tissues until it is of a smoky white color. This takes but a few minutes and should be done by the physician, who can then turn the treatment over to the nurse, who seats the patient so that the true focal point is avoided and continues the application 20 minutes longer. A wet dressing is applied and removed by the nurse the following morning when she gives another 20 minutes' treatment, repeating it on the second day and on the third the physician again applies the strong light to any part which seems to be lagging behind in its response to the irritation. The parts should be thoroughly cleansed twice daily. A solution of copper is used to absorb the nonchemic rays. [H.M.]

6.—Therapy of Dysentery.—W. Roberts writes to reemphasize the value of ipecac in large doses in dysentery, and to recommend its use in the form of pills dipped in liquid salol, which does not dissolve until the bowel is reached, thus avoiding nausea and vomiting. It is probably more of a specific than any other remedy. Its advantages are its simplicity, safety, certainty, and rapidity with conservatism of the constitutional powers and abbreviation of convalescence, decrease in frequency of recurrence and of abscess of the liver, and diminution in mortality. [H.M.]

7.—Postoperative Pulmonary Complications.—R. Peterson reports two cases of pneumonia, three of pleurisy, and one of bronchitis occurring in 14 months' service. Such pneumonia may be infectious or due to inhalation. Bronchopneumonia is apt to follow operations on the pharynx or larynx, and the administration of an anesthetic in the extremes of life. The writer's experience does not agree with Prescott's as to the relative infrequency of lobar pneumonia. He uses the best Squibb's ether, and takes particular care to avoid chilling the patient during operation, and he modifies the Trendelenburg position by partially elevating the head of the table after the intestines have been removed from and held away from the pelvis by packs. Pneumonia is more apt to occur after abdominal than other operations, especially if ether is employed. There is undoubtedly a hypostatic form of pneumonia which develops usually at the base of the lungs of a patient with peritonitis or other forms of sepsis. Pleurisy has often been overlooked on account of the pain having been ascribed to a reflex from below. Since at certain times of the year the grip germ is present, the writer avoids operation in the presence of even a slight cold. [H.M.]

8.—Iodoform Dermatitis.—W. A. Bryan describes a local toxic action appearing on surfaces surrounding the wound to which it has been applied. The redness produced is obscured by numerous small vesicles increasing in area, sometimes extending several inches from the focus. The vesicles nearest the focus are the largest. When broken the liberation of serum is more profuse than in any other lesions ever seen by the writer. On removal of the cuticle the true skin appears red, raw, edematous, uneven, and filled with pockets of serum. The chief symptom is intolerable itching. It is incessant and

described as a burning pain, with tenderness and irritability, and great care must be used in removing the dressings. Iodoform seems to produce its effect by spreading through the cellular tissues of the skin; iodine by acting only on the surface. Aristol produces the same lesion. Peroxid of hydrogen should be used to remove every particle of the iodoform. After daily cleansing 5% carbolized vaselin or an aqueous solution should be applied. It is well to immerse the part in an astringent solution in hot water from 10 to 30 minutes at each dressing. Dry dressings, if used, must be frequently renewed. Duration under treatment is from one to four weeks. [H.M.]

9.—See *American Medicine*, Vol. III, No. 25, p. 1063.

#### 10.—Typhoid Perforation with Peritoneal Infection.—

General suppurative peritonitis is not necessarily fatal. In streptococcus infection denudation and consequently toxic absorption occurs earlier than with infection from the staphylococcus or colon bacillus. In the past diagnosis was based on collapse. At present it is based on pain, nausea, vomiting, localized tenderness, circumscribed flatness on piano percussion, elevation of temperature and hyperleukocytosis, in the order mentioned. Operation should be performed as soon as these are manifest. If postponed until collapse occurs the case will end fatally. If done early the "peritoneal shingles" will be found intact, thus preventing absorption. Reduction of pressure lessens absorption, as is shown after draining an abscess while not entirely emptying it. The upper half of the peritoneal cavity absorbs more rapidly than the lower, hence the writer, J. B. Murphy, keeps patients in a semisitting position in order that the pus may settle in the pelvis. He administers antistreptococcal serum and unguentum crede and sometimes gives saline transfusions. Excessive manipulation, sponging and irrigation are responsible for many fatalities. [H.M.]

11.—See *American Medicine*, Vol. III, No. 25, p. 1059.

#### 12.—Treatment of Traumatic Gangrene of the Extremities.—

V. B. Knott refers to the frequency with which gangrene continues after amputation, making a second operation necessary. The dissection of the soft parts into suitable flaps interferes with the blood supply in parts the vitality of which is already low. The suture tension also interferes with the flap nutrition. He therefore makes a circular amputation, cutting through soft tissues and bone at the same level, ligating all the vessels carefully, and including no perivascular tissue in the bite of either forceps or ligature. The wound should be dressed two to four times daily with gauze saturated in salt solution. After 7 to 10 days, if the wound is clean and the patient's condition favorable, the classical circular amputation may be made by dissecting up the flap already outlined, and sawing the bone at the proper level. By this method the source of infection is removed and we may be able to amputate at a lower level than by the old method. The freest possible drainage is provided for a sufficiently long time, and there is less shock to an enfeebled patient. [H.M.]

### Boston Medical and Surgical Journal.

April 9, 1908. [Vol. CXLVIII, No. 15.]

1. Dry Hot Air as a Therapeutic Agent, with Demonstration of the Body Treatment. CLARENCE EDWARD SKINNER.
2. The Role of Atmospheric Pressure in the Hip-Joint. SEABURY W. ALLEN.
3. The Doctor in the Navy. A. J. NUTE.

1.—Dry Hot Air as a Therapeutic Agent.—C. E. Skinner notes that in judging of the efficiency of hot air in rheumatism the error of diagnosing as rheumatism conditions of an entirely different nature must be remembered. He advises the use of some salicyl compound with the heat. The application of the latter results in immediate relief of pain, shortening of the duration, lessening liability of cardiac involvement, lessening amount of drug ingestion required. When properly applied there are no vicious after effects. Sprains treated within 4 or 5 hours of their occurrence are entirely relieved in from 2 to 4 days. Heat should be reapplied as often as the pain returns. Hot air alone will cure many cases of arthritis deformans and in conjunction with other remedies restore the majority to useful and comfortable lives. From 6 to 12 months is usually required for a cure. Hot air will relieve pleuritis at once and

pneumonic consolidation in 2 to 5 days. Local septic infection responds most kindly in nephritis, dropsy, respiratory oppression, mental somnolence, and cardiac disturbance diminish during the first treatment. In some cases perfect health has been restored. The writer lists many other diseases in which its value has been demonstrated. Local treatment acts by stimulating cell metabolism through increased temperature and by reflex acceleration of nutrition through the nerve endings in the skin. In local bacterial disease its action is inhibitive, the germs becoming more susceptible to attack by stimulated leukocytosis. The copious perspiration induced aids in eliminating the toxin. Sometimes reflexes in distant parts result from local treatment. The action of body or general treatment is reflex through the spinal sympathetic. White corpuscles are increased from 15% to 50%, red from 10% to 20%, the urine from 25% to 100%, urea from 15% to 60%. Its administration is agreeable to the patient. Its action is in line with that of the Turkish bath, electricity, massage, etc. The writer describes the technic of application. [H.M.]

**2.—Atmospheric Pressure in the Hip-joint.**—S. W. Allen quotes various authorities who subscribe to the opinion of the Brothers Weber, who in 1836 demonstrated to their own satisfaction that atmospheric pressure plays an important and distinct role in maintaining the head of the femur in the acetabulum. The author, not satisfied with the accepted correctness of this view, performed experiments on seven suspended cadavers. Three pins were driven into the bones adjacent to the hip-joint—one into the anterior superior spine, one into the iliac crest vertically above the trochanter, and one into the great trochanter, thus making a triangle, two legs of which should show variation in length with any separation of the bones entering into the articulation. Trephining the innominate within the pelvis and thus letting air into the joint caused no separation of the bones. Then the muscles about the joint were severed with a like result. Cutting the posterior half of the capsular ligament caused slight separation and a consequent lengthening of the legs of the triangle; still more so on cutting the anterior half of the capsule. But by far the most pronounced separation occurred on severing the cotyloid ligament. The author's conclusions are that atmospheric pressure is of no appreciable influence in maintaining the bones in contact, but that it is accomplished primarily by the cotyloid ligament, and secondarily by the capsular ligament. Of course, complete separation cannot take place until the ligamentum teres is severed. [A.B.C.]

**3.—Medical Men in the United States Navy.**—A. J. Nute gives a general summary of the requirements for medical men entering the United States Navy. Examinations are now held at Washington instead of at Brooklyn, as formerly. About 10 days are devoted to the examination, which begins with a rather rigid physical examination. The theoretical examination is partly written and partly oral and the examining board can use its full discretion as to the extent of the medical subjects covered, number of questions, time consumed, etc. Receiving his certificate of appointment the young officer is ordered to report at the Navy Medical School at Washington for a six months' course preparatory to active duty. He has no positive rank, but is ranked as a staff officer. He starts in at a salary of from \$1,400 to \$1,650, and his pay is gradually increased. Should he continue in the service he is retired at the age of 62 on three-fourths pay for the remainder of his life. The service is easy, the pay far better than in many European countries, and the medical officer is always well supplied with medical literature, apparatus, etc. [A.B.C.]

#### Medical Record.

April 11, 1903. [Vol. 63, No. 15.]

1. The Technic of Nephropexy, with Special Reference to a Method of Attaching the Kidney as Nearly as Possible in Its Normal Position. RAMÓN GUITÉRAS.
2. Intranasal Obstruction and Its Treatment. H. HOYLE BUTTS.
3. Cases of Morphinism in Which the Drug was Immediately Withdrawn. MARGARET S. HALLECK.
4. Bronchopneumonia. JOSEPH N. STUDY.
5. The X-ray and the Finsen Light in the Treatment of Lupus. A. D. ROCKWELL.
6. The Treatment of Ring-worm. GEORGE THOMAS JACKSON.

**1.—The Technic of Nephropexy.**—Ramón Guitéras contributes a valuable article, its subdivisions being: The incision, the part of the kidney used in the fixation, the material used in the fixation, the part of the parietes used in the fixation, the author's technic, and the principles of nephropexy. Under the latter he says: 1. The kidney should be fixed in as nearly its normal position as possible. 2. It should be fixed in such a manner that it subsequently does not (a) sink in the vertical plane, and (b) rotate on the vertical axis. 3. The kidney may, however, be allowed to turn to a certain extent on its horizontal axis, such a rotation being normal with each respiratory act, according to Küster. 4. The permanence of the fixation should not be made dependent on sutures, no matter what suture material be employed, but upon firm adhesions between the kidney parenchyma and the lumbar wall. 5. The material used for suture should be one that holds long enough to allow adhesions to form and yet is ultimately absorbed without injury to the parts. (Chromicized gut is the only material that corresponds to these requirements.) 6. The operation should be as simple as possible; should include as few stitches as possible, and should take the least possible amount of time. [A.B.C.]

**2.—Intranasal Obstruction and Its Treatment.**—H. H. Butts, under this heading, discusses acute passive hyperemia, foreign bodies, rhinitis hypertrophica, echondrosis and exostosis of the nasal septum, deflections of the cartilaginous septum, irregularities of the bony septum, abscess of the septum, nasal myxomata, etc. Under the subject of treatment for nasal spurs he says: For the guidance of those who, through inexperience, are in doubt as to when they should operate, the following rules are laid down: (1) When a septal spur seriously impairs the respiratory function of a nasal fossa, it should be removed; (2) when a septal spur impedes the drainage from an accessory sinus or a nasal fossa, it should be removed; (3) when a septal spur is in contact with opposing structures, it should be removed. [A.B.C.]

**3.—Morphinism.**—M. S. Halleck reports five cases of immediate withdrawal of the drug in which only strychnin, hyoscin, and codein with laxatives were administered with quick and practically painless recovery. The strychnin stimulates all the functions depressed by the morphin, and nausea, restlessness, insomnia, and pain are cared for by the hyoscin and codein. [H.M.]

**5.—Röntgen Rays and Finsen Light in the Treatment of Lupus.**—A. D. Rockwell says that the actinic rays, which are the only efficient rays of light in the treatment of malignant or tuberculous skin affections, possess one great advantage over the Röntgen ray: they are more benign in action. On the other hand, there seems to be no question that the curative effects of the Röntgen ray in lupus and other skin affections follow more rapidly than those of light, while with improved technic Röntgen ray burns may in time become an almost negligible quantity. The Röntgen rays and the actinic rays of light do not differ so much in kind as in degree—in the frequency and intensity of their vibrations. Their therapeutic effects are therefore very much the same. They cure the same diseases. The author makes reference to a case of lupus vulgaris successfully treated up to a certain limit with the Finsen light. Further treatment resulting in no improvement, a change was made to the Röntgen rays, when complete recovery took place. He suggests that there may be many instances in which this would prove true, and *vice versa*. [A.B.C.]

**6.—Treatment of Ring-worm.**—G. T. Jackson has found an ointment of 1 dram or more of iodine crystals in 1 ounce of goose grease a most effective remedy in ring-worm of the hairy regions. It must be applied twice daily until a little swelling occurs, and then once daily. In two or three weeks the hair falls out. Epilation is not necessary. If there is too much reaction it should be suspended for a few days and a 3% salicylated oil used. A cure requires only three weeks. The goose grease must be genuine, and this is expensive. In obstinate cases the writer has had good results from half a dram to a dram of croton oil to an ounce of sulfur ointment. [H.M.]

## New York Medical Journal.

April 4, 1903. [VOL. LXXVII, No. 14.]

1. Terminal Coma in Diabetes. ARTHUR R. ELLIOTT.
2. Syphilitic Pseudotabes: Report of a Case; the Differential Diagnosis of Tabes. JOSEPH COLLINS. (Concluded.)
3. Practical Points on Intubation of the Larynx for Croup, with a Report of Thirty-six Cases. FIELDING LEWIS TAYLOR. (To be continued.)
4. The Practical Recognition of the Tubercle Bacillus in the Sputum. CHARLES B. FITZPATRICK.
5. The Jews as Immigrants—from a Medical Standpoint. MAURICE FISHBERG.

**1.—Terminal Coma in Diabetes.**—A. R. Elliott reports four fatal cases of diabetes, which illustrate in an interesting manner some of the different varieties of the terminal coma in this disease. The first was a well-marked case of diabetic collapse, the diabetic heart coma of Von Schmitz, induced by myocardial degenerative change, probably fatty in character, under the influence of the depraved diabetic nutrition. In the second case a nephritis complicated the diabetes. After a few days' treatment the patient neglected the dietetic and other hygienic precautions, the kidneys later became thoroughly irritated, starting into activity the latent nephritis, which, under the influence of further congestion gave rise to profound uremia. The third case was that of a man, aged 76, who became diabetic at the age of 55. The glycosuria proved amenable to dietetic treatment for years, when it gradually became less controllable, and signs of nephritis increased. Diabetic coma followed. This gradually improved until the diabetic toxemia entirely disappeared. A few days later he died of uremic toxemia. In the fourth case an injury to the central nervous system served to aggravate the diabetes and converted a previously mild disease into a fatal one. Prophylaxis is of the first importance in the treatment of diabetic coma. The author believes that the rigidity of the diet should be relaxed, that he should have as much bread, green vegetables, and potatoes as he likes, providing his wants be not too immoderate. He should be protected against all disturbing nervous influences, from fatigue and cold, and elimination should be stimulated. Sodium bicarbonate in doses which do not interfere with gastric digestion should be administered at this stage. When the prodromes of coma appear, the patient must be put to bed, stimulants given, and the bowels thoroughly evacuated. Alkalies should then be given in enormous doses, and normal salt solution charged with sodium bicarbonate may be used freely by bowel and subcutaneously. Oxygen may be administered. [C.A.O.]

**2.—Syphilitic Pseudotabes.**—A case is reported by Joseph Collins in which the symptoms and signs of tabes were typical but in which the pathologic lesions of the cord and meninges were characteristic of syphilis. The facts of the case are given in detail, as are also the pathologic changes made out in microscopic examination. He also considers the differential diagnosis of genuine tabes and syphilitic pseudotabes and multiple neuritis, tabes and flat feet, tabes and multiple sclerosis, and tabes and paresis. [C.A.O.]

**4.—Sputum Examination.**—C. B. Fitzpatrick outlines the following method: Spread a moderately thin layer of sputum on the slide or cover glass. The smear is allowed to dry in the air or in an oven at a temperature of about 50° C. It is then passed three times through the flame. The preparation is next placed in a fresh solution of the Ehrlich aniline-fuchsin. If the smear has been made upon a cover glass, a watch glass full of the aniline-fuchsin solution is taken, and the preparation is floated upon it with the smeared surface facing downward. The watch glass is then held over a flame until the solution begins to boil. It is then allowed to stand for one minute. If the preparation is upon a glass slide, the slide should be covered as a whole with the solution and the smeared surface should be separated from direct contact with the bottom of the receptacle by a layer of the coloring solution. The solution when used in this way is also heated until it begins to boil, and is then allowed to stand for one minute. The smear is next removed from the fuchsin solution and washed off in running water; then placed for about one minute in a decolorizing solution made up of three parts of hydrochloric acid and 97 parts of 70% alcohol. The smear is then washed off in running water and covered with the Loeffler alkaline solution of methylene-blue.

This contrast stain is allowed to remain on the smear one or two minutes, or until the preparation becomes a distinct blue. It is then washed off and the smear dried with filter paper and passed rapidly through the flame several times. The examination of this preparation will show the tubercle bacillus, when it is present, as a minute red or pink rod. [C.A.O.]

## Medical News.

April 11, 1903. [Vol. 82, No. 15.]

1. Some Problems in the Major Surgery of the Kidneys, with a Report of Cases. JOSEPH A. BLAKE.
2. An Operation for Paronychia, or "Run-round." SINCLAIR TOUSEY.
3. The Geographic Distribution of Uncinariasis in the United States. WILLIAM RIDGELY STONE.
4. Lung Surgery: Historical and Experimental. BENJAMIN MERRILL RICKETS.
5. Report of a Case of One-sided Dislocation of the Mandible: Reduced by a Novel Manipulation. FRANK WOODBURY.
6. Eye Affections Complicating and Resulting from Rheumatism. RALPH OPDYKE.

**1.—Surgery of the Kidneys.**—J. A. Blake confines himself to the treatment of surgical conditions of the kidney, dwelling for the most part on the relative merits of nephrectomy and nephrotomy in suppurative conditions and in advanced calculous diseases of the kidney. He enumerates as coming under this classification pyonephrosis, infected hydronephrosis, pyelonephritis, and calculous disease with suppuration. On the whole the author agrees with Johnson, whose conclusions are that primary nephrectomy, in any of these conditions, is the safest, and that nephrotomy gives a much higher mortality. Isreal's statistics agree in the main with the experience of the author and Johnson. The writer reports a series of nine cases: Four were cases of pyonephrosis, all treated by nephrectomy, with one death; three were cases of infected hydronephrosis, nephrectomy being performed in two cases with resulting cures, and nephrotomy in one case with a permanent resulting urinary sinus; one was a case of acute pyelonephritis with puerperal sepsis, a nephrectomy effecting a cure; and one was a case of multiple renal calculi with suppuration, a nephrectomy resulting in recovery. [A.B.C.]

**2.—Treatment of Paronychia.**—S. Tousey asserts that it is radically wrong to make an incision through the flesh of the finger into the pus sac at the root of the nail. The infection and pus are in the groove in which the root of the nail is lodged, and the proper route for reaching it is by merely separating the attachment of the cuticle from the dorsal surface of the nail to permit the escape of pus, and a proper disinfection of the pus sac. It may be necessary to cut across and remove the root of the nail. By this method the only instrument needed is a small knife to push back the adherent cuticle. No anesthetic is necessary, and no blood should be drawn. In cases of long standing, in which pus has burrowed under the nail, it may be necessary to remove entirely that appendage. [A.B.C.]

**3.—Uncinariasis.**—W. R. Stone thinks the literature of the disease will soon increase, since these parasites abound in our new insular possessions. The disease is found in our Southern States, where whites and blacks indulge in clay eating. It is to be looked for in the new subways, in which so many Italian laborers are employed. But 38 undoubted cases have been reported in this country, and 18 were infected outside. Building of the Isthmian canal will swell the numbers. The writer describes the two varieties infesting man. Great care should be exercised in identifying them. [H.M.]

**4.—Lung Surgery: Historical and Experimental.**—B. M. Ricketts deals almost exclusively with the literature of the subject, and the article, while valuable from a historical standpoint, contributes but little from a clinical standpoint. Some of the writer's conclusions with reference to surgery of the lung, apparently based upon the experimental work of others, are: Hermetically closing the chest is irrational, unscientific and dangerous; hemorrhage when due to pulmonary tuberculosis should not be allowed to become fatal without opening the chest wall and control measures inaugurated; bleeding of the lung from any cause will in many cases cease when the lung is allowed to contract upon itself with an open chest wall; abscess of any character and at any location in the lung should be found and opened; any portion of or a complete lung may be

removed surgically; puncture of a lung from any cause resulting in hemorrhage should be treated by opening the chest wall and by suture-ligature, forceps or compression controlled. [A.B.C.]

**5.—Unilateral Dislocation of the Mandible Reduced by a New Method.**—Frank Woodbury reports the case. A girl of 20, in an effort to bite an apple produced a unilateral dislocation of the mandible. The author tried the usual methods of reduction and failed in every instance. He then seized the ramus and angle of the bone in his left hand, placing his thumb in front of the coronoid process. While pressing the bone downward and backward he instructed the patient to gently open and close the mouth several times. Then at a time when the mouth was nearly closed he struck the chin a sudden gentle blow with the knuckles of the half-closed right hand. The dislocated condyle instantly went into place with an audible "click." The author is of opinion that in unilateral dislocation this is a method which will usually prove effective, but it is probably of less value in bilateral dislocation. [A.B.C.]

**6.—Eye Affections from Rheumatism.**—R. Oplyke shows that an inflammation of almost any of the tissues in and about the eye may result from an attack of acute articular rheumatism, these structures frequently exhibiting a peculiar susceptibility and quickly responding to rheumatic remedies. He discusses the manifestations in conjunctivitis, chalazia, hordeola, lacrimal disease, lithiasis conjunctiva, keratitis, scleral disease, iritis, cyclitis, neuritis, and involvement of the external muscles. [H.M.]

#### Philadelphia Medical Journal.

April 11, 1903. [Vol. xi, No. 15.]

1. Some Remarks on the Treatment of Croupous Pneumonia. C. S. BRADFUTE.
2. The Diagnosis and Treatment of Incipient Pulmonary Tuberculosis. H. EDWIN LEWIS.
3. A Plea for the Use of Less Drugs in the Treatment of Typhoid Fever. J. K. P. BOWEN.
4. The Postorbital Limbus: A Formation Occasionally Met With at the Base of the Human Brain. EDWARD ANTHONY SPITZKA.

**1.—The Treatment of Croupous Pneumonia.**—C. S. Bradfute expresses the following conclusions regarding pneumonia, each of which is detailed: Pneumonia is a self-limited disease, and tends to recovery without medication; it has been observed in common with other infectious diseases; that the virulence of the pneumococcus appears to vary at different times and under different circumstances; pneumonia is rare in normal individuals; inflammation of the pulmonary structures, answering to the clinical condition of pneumonia is not always produced by the pneumococcus alone; pneumonia is not a systemic disease, but a localized infection characterized by secondary systemic disturbances, the general systemic involvement being due, primarily, to exaggerated reflex influences, and secondarily to toxemia; while the morbid condition to be met is similar, simple and free from obscurity, the indications for therapeutic measures are complex; in the present state of our knowledge the therapy of pneumonia is purely symptomatic, but not in the old sense. The treatment is based upon these views. Free purgation should be obtained in the beginning of the attack with calomel. Cocain, strychnia, ammonium, and alcohol are the principal drugs to be employed during the attack. The control of the temperature is imperative, the best means of accomplishing reduction being by the means of cold compresses after the method of Baruch, of New York. Alcohol is to be employed as a food, and not as a stimulant. [F.C.H.]

**2.—The Diagnosis and Treatment of Incipient Tuberculosis.**—Edwin Lewis predicts that in the near future there will be a law enacted, declaring a physician negligent who neglects to use due care and vigilance in determining tuberculosis. The early diagnosis of incipient tuberculosis cannot be made from one symptom alone, the principal facts are obtained by a careful inquiry in regard to the temperature, pulse, cough, weight, digestion, physical condition of the chest and the repeated examinations of the sputum. Interrogation of the temperature is one of the most valuable aids to diagnosis. Not that its absence precludes tuberculosis, but that an unaccountable rise of temperature, 1° to 3°, some time during each 24

hours is pretty certain to indicate the presence of a tuberculous process. Two minor symptoms of value are a more or less marked and extreme dilation of the pupil, and a tendency to horseness without apparent cause, ranging from slight huskiness to complete aphonia. The treatment consists in fresh air; attention to the diet; strychnin in doses larger than ordinarily administered is the most valuable drug; arsenic comes next, in the form of Fowler's solution; atropin, agaricin and picrotoxin are each efficient in relieving night-sweats, but the average patient is markedly improved by an alcohol bath and rub down at bedtime. [F.C.H.]

**3.—A Plea for the Use of Fewer Drugs in Typhoid Fever.**—J. K. P. Bowen concludes the treatment of typhoid fever as follows: Rest; cleanliness; one to three pints of buttermilk daily; no drugs as a routine, except for external antiseptics and for mouth and nose and some complications; calomel in the beginning; castor-oil for meteorism, necrosis and ulceration; diluted hydrochloric acid if the tongue is soft and flabby; morphin and atropin for sleeplessness in some cases, and strychnin may be indicated especially in convalescence. [F.C.H.]

### CLINICAL MEDICINE

DAVID RIESMAN                      A. O. J. KELLY

#### EDITORIAL COMMENT

**Carcinomatous Gastrocolic Fistula.**—While perforation of the stomach in cancer is not uncommon, it rarely occurs into the free peritoneal cavity since prior to the perforation the stomach usually becomes adherent to one of the neighboring viscera, such as the liver, the spleen, the pancreas, the gallbladder, or the transverse colon. If the perforation takes place into the colon a gastrocolic fistula is formed. Two interesting cases of such fistulas, verified at autopsy, are reported by Ph. Koch.<sup>1</sup> The diagnosis is, as a rule, comparatively easy; but other conditions may, at times, closely simulate it. The fistula may exist without characteristic signs, but this is rare. The most frequent symptom is fecal vomiting. Another symptom, which, however, is not mentioned in many of the reports of cases of gastrocolic fistula, is lientery. It is possible that the absence of reference to the presence of undigested food in the stools is in some instances due to an insufficient study of the feces. Diarrhea is the rule, and the vomitus and dejecta are identical. Symptoms of minor importance are thirst, a fecal odor to the breath, and fecal-smelling eructations. The sudden cessation of vomiting is also significant. Various objective signs may aid in the diagnosis. Among these are: (1) A chemical examination of the stools for hydrochloric acid; (2) insufflation of the stomach, which leads to the prompt discharge of flatus per rectum; (3) insufflation of the rectum, which causes distention of the sigmoid flexure, then of the descending colon, next of the stomach, and last of the cecum; (4) the introduction under high pressure of colored fluids into the rectum, which will be followed by their rapid evacuation through the mouth; (5) the passage of water in a cool state from the rectum, after lavage, the coolness of the fluid being appreciable to the patient. In the differential diagnosis a number of conditions must be considered: 1. Intestinal obstruction. In this there is usually meteorism, visible and palpable peristalsis, profound collapse, and obstinate constipation, with fecal vomiting; while in gastrocolic fistula the abdomen is soft and presents no visible peristalsis; the profound collapse is generally absent, and diarrhea persists. 2. Acute peritonitis. The pains in this are very severe. The abdominal walls are hard, distended, and tender. The vomit is usually bilious, and the temperature is elevated. 3. Carcinoma of the pylorus, converting the latter into a stiff, unclosable tube of uniform caliber. This may, in a very marked degree, simulate gastrocolic

<sup>1</sup> Arch. f. Verdauungskrankheiten, Bd. ix, Hft. 1, 1903.

fistula. The writer has seen such a case. At the autopsy a large cancerous growth was found encircling the pylorus, converting it into a patulous canal. A similar case was recently reported to the Pathological Society of Philadelphia by Dr. D. L. Edsall. 4. Hysteria may simulate a gastrocolic fistula. The treatment of the condition is entirely palliative, and consists in the use of morphin. In exceptional instances the establishment of an artificial anus and the partial resection of the stomach and colon may be indicated.

#### REVIEW OF LITERATURE

**Microorganisms in the Water of Public Swimming Baths.**—E. E. Glynn<sup>1</sup> gives the results of a series of observations on the microorganisms present in the water of the various Liverpool swimming baths at different periods of the day. Experiments showed that the multiplication of bacteria in the water during the day is slight and that practically all the increase is obtained from the bodies of the bathers. Taking the average of five observations on separate days and the number of bathers as a basis it was found that from each person there had been removed approximately the colossal sum of 4,000,000,000 germs. These figures are for first-class baths frequented by the better class of people. For the second-class baths the number is about one-half more. Streptococci were never found; *Staphylococcus albus*, three varieties, were present in large numbers; *B. coli* was present in the bath at the end of the day, being always absent in clean water. Glynn gives reasons for concluding that danger of contracting typhoid fever from the baths is very slight. He suggests a method by which to avoid the introduction of many organisms that are carried into the water by the bathers, who first walk in the corridor where people wearing shoes are allowed. The ideal bath would have two corridors, an inner one between the bath and the boxes and a second one outside the boxes, the latter being open back and front. In the inner corridor only barefooted people would be allowed and in the outer only those wearing shoes. [A.G.E.]

**Concerning Biologic Overexertion of the Organism in the Artificial Nourishment of Nurslings as Compared with the Nourishment with Mother's Milk.**—A. Wasserman's<sup>2</sup> article proves that if two children are given equal amounts, one of artificial the other of mother's milk, the one which is breastfed will thrive more and quicker than the other. This is due to the difference in albumens. The albumens of the artificial food must be changed first into homologous albumens, and to do this certain ferments are necessary, the production of which uses up some of the calories of the milk. The production of these ferments he proves by the following experiments: Two guineapigs are injected intraabdominally, one with goat's milk, the other with guineapig milk, in each case this is followed with an injection of typhoid fever bacilli. In the former case ferments (Ehrlich's complements, Buchner's alexins) to convert goat albumens into homologous albumens are secreted; they destroy the typhoid bacilli, but in producing this ferment considerable energy is wasted. In the latter case the albumen is already homologous, no ferment is needed, and the animal dies of typhoid infection. The older the child grows the less energy is necessary to produce the ferments, and the better the child will thrive on artificial food. He also states that the blood-serum of breastfed children possesses more bactericidal power than that of artificially fed children. [E.L.]

**The Action of Adrenalin on the Animal Organism.**—P. P. Belaventz<sup>3</sup> has studied the physiologic action of adrenalin on animals, chiefly dogs and rabbits. The hydrochlorid of adrenalin was employed. The drug was given by intravenous injections, in doses varying from a total of 2 decimilligrams up to 1 milligram for every kilogram of the animal's weight. The former dose, when injected into the aural vein of a rabbit, causes in a few seconds severe vascular spasm, both ears becoming extremely pale and cold. This spasm lasts on the average 1 to 2 hours, and is more pronounced on the injected

side. No general effects are produced by such small dosage. By increasing the dose up to  $\frac{1}{2}$  milligram for each kilo of weight other symptoms were observed: dyspnea, dilated pupils, and paresis. One milligram per kilo produced extreme dyspnea, convulsions, incontinence of urine and feces, maximal dilation of the pupils, and death. The same results followed the injection of adrenalin beneath the skin, the fatal dose being about 10 times larger. The influence exerted by adrenalin on blood-pressure and on respiration was also studied, and the conclusions are summarized as follow: 1. Adrenalin raises blood-pressure by stimulating the heart and constricting the vessels. 2. The vascular spasm is due to a direct action on the vessel-walls. 3. Adrenalin at first irritates and then paralyzes the vagus center, without affecting the peripheral ends. 4. In small quantities adrenalin increases gaseous metabolism, i. e., the amount of oxygen absorbed and the amount of carbonic acid thrown off are both increased. Large quantities of the drug bring about a markedly diminished gaseous metabolism, accompanied by fall of temperature. 5. Adrenalin causes death by paralysis of the respiratory center. 6. The nervous system is depressed by the drug. 7. Caution is imperative in employing adrenalin intravenously or subcutaneously, a frequent pulse being a contraindication to further injections. [L.J.]

**Complications and Results of Dental Infections.**—The paper by C. A. Hamann<sup>1</sup> sets forth some of the results of infections starting in or about the teeth, only the surgical complications of dental caries being considered. Among the frequent complications is pyorrhea alveolaris, a chronic suppurative condition that can hardly be other than injurious to the general health. Hamann has seen intense ulcerative stomatitis, diffuse submaxillary suppuration, and thrombosis of the cavernous sinus originate from this affection. He believes many cases of so-called cryptogenetic septicemia are to be attributed to it. The occurrence of diabetes mellitus with pyorrhea is believed to be only a coincidence. Three cases of thrombosis of the cavernous sinus have been seen by Hamann. The venous connection between the teeth and peridental structures and this sinus is traced. One case of osteomyelitis of the jaw following dental caries has been observed by the writer. The main consequences of infection from the teeth are stated in conclusion as: (1) Tuberculosis of the cervical glands; (2) general septicemia; (3) Ludwig's angina; (4) thrombosis of the cavernous sinus; (5) osteomyelitis of the maxillary bones. [A.G.E.]

**Transmission of Bovine Tuberculosis to Man Through Accidental Inoculation; Reinoculation to Calf.**—C. Spronk and K. Hoefnagel<sup>2</sup> report the case of a flayer of 63, who accidentally injured the little finger of his right hand 20 months before while skinning a tuberculous cow. The wound healed but remained tender, and later became inflamed and cracked open. Examination now shows the presence of a cutaneous tubercle with corresponding infiltrations; the glands at the elbow are enlarged and painful, there is slight dulness over the back part of the right upper lobe, and moist rales. No tubercle bacilli can be found in sputum; the tuberculous nodule and glands were excised; guineapigs inoculated with parts of these developed general tuberculosis, the foci of which contained numerous tubercle bacilli; but few of these were found in the nodule and gland. An emulsion of spleen from the guineapig was injected into the neck of a healthy calf. A granuloma formed at the point of injection; at the autopsy, two months later, in addition to the local tuberculosis, general infection of the pleura and lungs, bronchial and mediastinal glands were found, thus proving that the man was infected with tubercle bacilli of bovine origin. The authors express it as their opinion that it takes several passages through the human body before the bovine bacillus becomes identical with the human, and that infection, the result of tuberculous milk, meat, etc., is much more common than Koch and Baumgarten are willing to admit. [E.L.]

**Xylol in the Treatment of Smallpox.**—T. K. Wisniewski,<sup>3</sup> discouraged by the failure of vaccinations with cowpox to influence favorably the course of smallpox, resorted to

<sup>1</sup> Pediatrics, March, 1903.

<sup>2</sup> Deutsche medicinische Wochenschrift, January 1, 1903.

<sup>3</sup> Russki Vrach, February 15, 1903.

<sup>1</sup> Wisconsin Medical Journal, March, 1903.

<sup>2</sup> La Semaine Médicale, 1902, Vol. xxii, p. 341.

<sup>3</sup> Russki Vrach, February 8, 1903.

xylo given by the mouth. The results surpassed all expectations. Six cases were treated, beginning on the second, third, or even fourth day after the eruption, and in all six suppuration did not take place. Where discrete vesicles had already begun to turn into pustules the process was promptly arrested. As a result, no scars remained in any case. Furthermore, the disease either ran a completely afebrile course or the fever was irregular and short in duration, never lasting longer than four days after the treatment had been inaugurated. Xylo was administered in 15-drop doses, 4 to 6 times daily, in claret. It was readily taken and produced no undesirable collateral effects. [L.J.]

**Paratyphoid Fever.**—Paratyphoid fever, according to L. F. Jermain,<sup>1</sup> does not constitute a clinical entity. Three cases lately under his care are believed to have been this affection. All were in young adults, and all recovered. The average duration of the febrile stage was 16 days. No complications appeared, but in one there was a distinct relapse. In each case three serum tests with typhoid bacilli were made at different stages, but in no instance was a positive reaction obtained. In two of them no cultures of paratyphoid or paracolon bacilli were at hand to demonstrate the serum reaction, but in the last one a positive reaction to Gwyn's paracolon bacillus was obtained. No cultures of the bacillus could be obtained from the blood, but this was probably due to the fact that the temperature of the patient had been normal for several days when the inoculation was made. The symptoms were marked malaise, headache, anorexia, chills with fever, prostration, and in two cases mild bronchitis. General abdominal tenderness and pain were marked in all three cases. The spleen was palpable in all, and quite tender in one. A rash that resembled that of typhoid fever was present in one. The temperature was irregularly remittent and disappeared by lysis. The pulse never exceeded 100 per minute, even with a temperature of 104.5°. No albumin was found in the urine. [A.G.E.]

**The Etiology and Terminology of Septic Diseases; with Reference to the Value of Bacteriologic Blood Examinations in Surgery.**—Canon<sup>2</sup> advises bacteriologic blood examinations in all cases of surgical infection, especially in cases in which amputations seem indicated, in puerperal septicemia, cholelithiasis, and instances where biologic remedies are to be used; only by knowing the infecting microorganism can we be certain which serum to inject. The picture of a general infection is brought about in the following manner: Pus organisms and their toxins enter the blood from the local focus. The blood possessing bactericidal power kills the organisms. This continues for a variable length of time, but as the bactericidal power is weakened, the organisms live longer and longer until at last they are even able to thrive in the blood. The weaker the germicidal power of the blood, the more likely the success of cultivating organisms from the blood, and the more likely the appearance of metastatic foci. If the toxins are very powerful death may occur before bacteria are demonstrable in the blood; it must be remembered, however, that the proliferation of the cocci and their destruction are more important in producing septic conditions than the toxins. The separation of sepsis into bacteremia and toxemia is therefore in the main incorrect. The latter may hold in cases of strangulated hernia, intestinal obstruction, etc., but as a rule the word sepsis expresses the condition much better. The term pyemia may be used in conditions where metastases exist. [E.L.]

**Embolism of Aorta in Typhoid Fever.**—Among the numerous and varied conditions complicating typhoid fever embolism of the aorta is an extremely rare occurrence. Z. F. Orloffsky<sup>3</sup> records an example in a man of 22, who was seized on the fifteenth day of typhoid fever with chilliness and deep cyanosis, accompanied by a frequent pulse (150). Subcutaneous camphor injections restored the failing heart action, but a relapse took place, and was followed by the sudden appearance of pain and paresthesia in both legs. The next day brought complete flaccid paralysis of the legs, with complete loss of all reflexes and anesthesia. Both legs, excepting the toes, were cyanosed, and on the left ecchymoses marked the course of the

saphenous vein. The femoral artery could not be felt to beat in either groin. Abdomen bloated and painful, especially below the navel, along the linea alba near the promontory. Spleen painful. Heart-sounds muffled but not arrhythmic. Two days later death supervened. The autopsy revealed thrombi in the lower aorta, in both iliac, the left common pudic, left femoral, left profunda femoris, and left renal arteries. Infarctions of spleen and left kidney. Mural thrombus in left ventricle. The author proposes the following explanation: The patient having shown signs of myocarditis and possibly also aortitis, it is reasonable to surmise that during the collapse thrombi were formed in the diseased heart; when the organ recovered its energy, one of these thrombi was swept down by the blood-stream and became firmly lodged in the aorta. The condition had been diagnosed *intra vitam*. [L.J.]

**Disturbances in Health Produced by Atmospheric and Technical Electricity.**—Jellinek<sup>1</sup> discusses the conditions which make an electric current more or less dangerous, laying especial emphasis on the strength of the current, and the resistance offered it by the injured individual. A current of 500 volts is usually dangerous to life, but one of 95 has proved fatal, while other individuals have not been injured by 4,000 volts. The harder and dryer the skin the more resistance to the current. If the current is strong, even a unipolar contact is injurious to health. The local symptoms of electric injuries are burns, singeing of hair, ecchymoses and extravasations, perforation, and separation of superficial tissues, and "lightning figures" on the skin. The latter are absent after technical electric injuries. A number of illustrations of the latter are given. Lightning burns, in his opinion, are not due so much to the action of the lightning flame as to the effect of the electricity, which diffuses itself through the tissues. Occasionally no local symptoms are noted; not even at the immediate point of contact. The general symptoms depend on the amount of psychic disturbances and organic changes produced by the electric shock. Thus paralyzes may be purely functional and disappear within a short time, or due to lesions of the central nervous system and become permanent. Death due to electric shocks are explained fully by anatomic changes in brain and spinal cord; they consist of extravasations of blood into gray matter of brain or cord, or into central canal, of destruction of ganglion cells of the anterior horns, of laceration of the finest capillaries, of cell changes, etc. Histologic examinations of other organs have thus far been without result. Diagnosis of electric shock being the cause of death can be made only in recent cases. [E.L.]

## GENERAL SURGERY

A. B. CRAIG                      MARTIN B. TINKER                      C. A. ORR

### REVIEW OF LITERATURE

**Taste Fibers and Their Independence of the Trigeminal Nerve.**—The article on this subject by Harvey Cushing<sup>2</sup> is based on deductions from 13 cases of Gasserian ganglion extirpation and details taste experiments made before and after operation on the patients. The object of the communication is to negate the possibility of taste transmission by way of the trigeminal nerve rather than to advocate any other course for such fibers. Cushing says, however, that the generally accepted statement to the effect that an intracranial lesion of the facial nerve is unaccompanied by loss of taste seems to be made on rather slight evidence and should be given the further confirmation, if possible, of experimental observations. The conclusions reached by Cushing are: (1) The perception of taste is unaffected on the posterior portion of the tongue and never permanently or completely lost on its anterior two-thirds after removal of the Gasserian ganglion; (2) a temporary abolition or lessening of the acuity of taste may be found to exist over the anterior and anesthetic portion of the tongue for some days after the operation; (3) this temporary loss of function may possibly be occasioned by some interference with chorda transmission brought about by a mechanical or toxic disturbance

<sup>1</sup> Wisconsin Medical Journal, March, 1903.

<sup>2</sup> Deutsche Zeitschrift für Chirurgie, Vol. Ixj, p. 93.

<sup>3</sup> Russki Vrach, February 8, 1903.

<sup>2</sup> Johns Hopkins Hospital Bulletin, March-April, 1903.

due to degeneration of the N. lingualis; (4) a lesion of the trigeminal nerve may be associated with disturbance of taste over the chorda territory without the necessary inference that the nerve is a path for gustatory impulses; (5) the N. trigeminus in all probability does not convey taste fibers to the brain either from the anterior or posterior portion of the tongue. [A.G.E.]

**Prolapse of the Bowel Treated by Injection of Paraffin.**—Stephen Paget<sup>1</sup> reports the case. A man of 65 years eight years ago had undergone excision of the rectum for carcinoma. Since then there was prolapse of the bowel. The author tried the submucous injection of paraffin around the prolapsed bowel. Two rather large masses some  $\frac{3}{4}$  inches in height were skilfully placed immediately beneath the mucous membrane and had the effect of preventing subsequent prolapse. Numerous punctures were not made for fear of injuring the veins. The prolapsed bowel with the nodules of paraffin in its submucous layer must be replaced and retained. The bowel must be kept inactive for several days after the operation. The patient should remain in bed for ten days or more until the tissues are thoroughly contracted. [A.B.C.]

**Injurious Renal Mobility ("Nephrospasis").**—W. F. V. Bonney<sup>2</sup> considers Glenard's method described as "palpation nephroleptique" as the only one giving reliable results. He divides abnormal mobility into three classes: (1) Those due to exaggerated diaphragmatic movement; (2) those in which the diaphragmatic attachments are relaxed with failure of respiratory return but with support from the fat below; (3) those without either upper or lower supports, evidenced by inward rotation about the pedicle. These cases are always accompanied by symptoms from the drag or strain, suggesting the term "nephrospasis" to describe them. Diseases of all the abdominal organs have been simulated by these symptoms, but the similitude is closest in the case of the pelvic organs. His statistics show that child-bearing and advancing age do not materially increase liability to abnormal mobility. He has never encountered general enteroptosis as an accompaniment of movable kidney. There is a tendency to ventral displacement, constant when rotation is present. This becomes manifest in the erect posture in which Bonney examines all his cases. The location of pain corresponds to the upper lumbar vertebra, radiating *transversely* around the waist and sometimes along the outer half of the front of the abdomen and thigh. There is complete relief on assuming recumbency. Treatment consists in encouraging obesity and in a well-fitting belt, which should be put on while lying down. The belt should fasten in front like corsets, with a lace in the back for permanent adjustment. If the belt fails to give relief operate. [H.M.]

**Gastric Tetany.**—B. G. A. Moynihan<sup>3</sup> in a brief note emphasizes the point that gastric tetany is not the rare or serious disease that has been described by Frankl Hochwart and others. The five cases reported by him were all in males, all were due to simple diseases, and gastroenterostomy cured each of them. Moynihan states that it is probably not too much to say that the extreme form of gastric tetany is a preventable disease. The timely performance of gastroenterostomy would remove the cause, whatever that may be, of the affection. [A.G.E.]

**Three Cases of Acute Intussusception in the Same Family.**—Riddall<sup>4</sup> reports the cases, one ending fatally and two being relieved by operation. The youngest was a child of five months, who had the ordinary symptoms of intussusception and died on the third day without operation. The second was seven months of age when the intussusception occurred. At operation intussusception was found and reduced without difficulty, the child recovering. The next patient was also about seven months of age when the attack occurred. The elongated mass could be felt in the upper part of the right abdominal region. Operation revealed an intussusception, which was reduced, the child making a good recovery. [A.B.C.]

**Pancreatic Disease Simulating Cholelithiasis.**—Between the liver and the pancreas there exists a well-recognized

physiologic and embryologic relationship. An equally intimate pathologic nexus, although it has been repeatedly suspected, has not heretofore, according to Worobjew,<sup>1</sup> received the attention it deserves. The pancreas frequently participates in diseases of the liver, and what is more important to know, it may closely simulate hepatic disease, particularly cholelithiasis. A complete clinical picture of gallstones may thus be present, due exclusively to chronic disease of the pancreas. Infrequently, also, both organs are affected, and we have reason to surmise that the classical symptoms of biliary calculi are only in part due to the latter, the pancreatic component entering largely into the clinical picture. For the physician, and still more so for the surgeon, these facts carry the greatest weight. It has occurred that an operation was performed for "gallstones," and stones were removed from the gallbladder, yet no improvement resulted, and at the autopsy calculi were discovered in the pancreas. Symptoms pointing to pancreatic involvement (chronic inflammations, calculi, etc.) are: 1, colicky pains in the left hypochondrium, unaccompanied by jaundice; 2, diabetic manifestations, chiefly rapid emaciation; 3, fatty evacuations; 4, salivation; 5, tumefaction and resistance in the region of the pancreas, and 6, the appearance of calculi in the stools following attacks of colicky pains, the calculi consisting of carbonates and phosphates of lime. As to treatment, narcotics are of small value in pancreatic colic. Pilocarpin hypodermically and pancreatin internally deserve a trial, but in the event of failure recourse should be had to surgical measures. [L.J.]

**Metastatic Goiter.**—This unusual case is reported by M. Jaboulay.<sup>2</sup> The patient was aged 65 and had had for three months a tumor growing from the supero-internal wall of the left orbit. The growth of the tumor had been rapid and painful. Running across it were large vessels, it was pulsatile and expansile and was projected slightly forward synchronously with each pulse beat. Two severe nasal hemorrhages had occurred. The diagnosis of osteosarcoma was made. Removal of the tumor revealed a perforation of the frontal bone, the forward movement of the tumor having been communicated to it by the brain. Histologic examination showed the tumor to be a malignant goiter. The thyroid gland was somewhat hypertrophied and increased in density but had remained in that condition for 30 years without any sign of malignancy. It was movable and painless and there was none of the occipital pain so characteristic of the degeneration of old goiters. The tumor of the thyroid must then be regarded as clinically benign and the tumor of the orbit as clinically malignant. Attention is called to the fact that secondary tumors of other varieties are in certain instances more malignant than the original growth. [A.G.E.]

**Constriction of Small Intestine by Gangrenous Appendix.**—Guilland and Wallace<sup>3</sup> report the case. The patient was a boy of 11 who had previously enjoyed good health. He was suddenly seized with pain in the right iliac fossa after some indiscretions in diet and vomiting soon supervened. Medical treatment was unavailing, the vomiting became constant and stercoraceous. There was a good deal of gastric pain. The temperature was never high and the pulse range was low. A diagnosis of appendicitis was made. On opening the abdomen it was found that the appendix was  $3\frac{1}{2}$  inches long, was gangrenous in all but the proximal  $\frac{1}{2}$  inch. It was not perforated. It had been twisted on itself and the distal tip was adherent to the mesentery close to the base of the appendix, and through the ring thus formed there was a loop of small intestine 10 inches in length. Its base was constricted. It was much distended and congested, forming an internal hernia. The appendix was removed, the constriction relieved, but the patient died. Necropsy threw no new light on the subject. [A.B.C.]

**Lateral Retroperitoneal Tumors.**—R. Goebell<sup>4</sup> reports three of these tumors from Hefelrich's clinic, and has endeavored to collect all the cases belonging to this group and recorded in literature. He found 101 such cases. Pathologically they are classed as follows: Thirty sarcomas, 10 myxolipomas, 9

<sup>1</sup> British Medical Journal, February 14, 1903.

<sup>2</sup> Edinburgh Medical Journal, December, 1903.

<sup>3</sup> The Practitioner, March, 1903.

<sup>4</sup> British Medical Journal, January 10, 1903.

<sup>4</sup> Deutsche Zeitschrift für Chirurgie, Vol. lxi, p. 1.

lipomas, 6 each fibromas and serous cysts, 5 dermoid cysts, 4 each fibrolipomas, tumors of accessory adrenals and teratomas; 3 each chylous and blood cysts, 2 each myxomas, myofibromas, myomas, neuromas, ovarian cysts, carcinomas, and 1 cyst of unknown nature. Symptoms of importance in these cases are the pressure signs—edema of lower extremities, stasis of the venous circulation, pains radiating along the course of nerves, paresthesia and intermittent hydronephrosis. Through inflation the colon can always be found to be in front of the tumor. The prognosis is good in the cases of the cystic tumors, in all others, unless operation is performed very early, it is very bad. No operation, however, should ever be performed unless the kidney of the opposite side has through ureteral catheterization been found to be functionally in good condition. [E.L.]

**Remote Anatomic Results of Bottini's Operation.**—F. Arloing<sup>1</sup> details the autopsy findings in two patients upon whom had been performed the Bottini operation for hypertrophy of the prostate. One was a man of 83 in whom all the symptoms of obstruction disappeared, or were markedly relieved, after operation. One year later symptoms again appeared and in three months the man died from retention and ascending infection of the urinary passages. The second patient was a man of 66, with a history practically the same as the first except that the symptoms recurred earlier and death soon followed. Autopsy on both, one 15, the other 7 months after operation, showed the cut made by the cautery still open. One had been bridged over by fibrous tissue, but this was old and had no part in the later obstruction, this being caused in both instances by increase in the remaining parts of the prostate. The cases are cited to prove the possibility of the long persistence of the incision made in the Bottini operation. [A.G.E.]

**Scirrhous Carcinoma of the Male Breast.**—W. Blair Bell<sup>2</sup> reports the case. The patient was a man of 56. Four and one-half years previously he had noticed a small hard lump the size of a pea in the region of the left nipple. This gradually enlarged to the size of a hen's egg. Local treatment was unavailing. Two and one-half years after the initial onset the growth began to ulcerate, and when seen by the author there was a large ulcer, four by three inches, involving the right breast. The discharge was foul, the edges of the ulcer were hard, raised and everted. The entire growth was excised, the underlying fascia and muscles being removed, together with the glands in the axilla, which were apparently unaffected. The patient's recovery was uneventful. Microscopic examination showed the tumor to be a scirrhous carcinoma of the breast. [A.B.C.]

**Syphilis and Life Assurance.**—It seems to B. Bramwell<sup>3</sup> entirely illogical that most medical advisers refuse to accept cases of primary and secondary syphilis and bad cases in which tertiary symptoms have appeared while they accept at ordinary rates cases which have been effectively treated and in which a sufficient time has elapsed to render the further appearance of symptoms unlikely, since they leave out of account the possibility of late nervous symptoms developing. He believes that syphilis shortens life by about ten years and a person who has had it should not be accepted as first class. Life is shortened by the typical tertiary symptoms, particularly those affecting the nervous system, and by parasymphilitic lesions like tabes, general paresis and aneurysm. These diseases occur most frequently during the first ten years of the infection. During this period the greatest extra premium might be required, during the second decade a less one, while during the third very little extra might be demanded. Deaths due directly to syphilis are caused by tertiary manifestations. Tertiary lesions occur in 10% of all cases. [H.M.]

**Hypernephroma.**—A. P. Ohlmacher<sup>4</sup> says that it is now far from permissible to call hypernephroma a rare form of renal tumor. During a limited autopsy service in Chicago the past winter he encountered two cases and received two more from surgical clinics. At one meeting of the Chicago Pathologic Society three new cases were presented. Notes on Ohl-

macher's four cases are given. Macroscopically hypernephromas are characterized by a peculiar sulfur-yellow color and a granular cut surface. Foci of softening, of necrosis, and of gelatinous disintegration with occasional hemorrhagic discolorations often mar the uniform appearance of the proper tumor substance. Pathologically these tumors may be benign or malignant. Aside from the discovery of the tumor in the region of the kidney the most significant symptom is periodic hematuria. The liver, lungs, and bones are the most frequent sites of metastases. Incursion of the renal vein is not uncommon. In the operative removal of primary hypernephroma the possibility of venous invasion should be kept prominently in mind, so that precautions like the ligation of the renal and other large veins may be practiced before the tumor mass is manipulated or disturbed. [A.G.E.]

**Primary Carcinoma of the Lung.**—H. D. Rolleston and R. S. Trevor<sup>1</sup> report the case. The patient was a girl of 13 who was apparently suffering from bronchitis. Pain was most marked on the right side of the chest. After rest in bed there was considerable improvement and after three weeks she was able to be about, when the symptoms again grew worse. The case now appeared to be one of empyema. The whole of the right side of the chest was dull on percussion and the intercostal spaces bulged. There was edema in the right axilla. The subcutaneous veins were dilated. Measurement of the right side was more than that of the left. The heart's apex was displaced outward to the anterior axillary line in the fifth space. The liver was displaced downward. There were no enlarged glands. An exploring needle introduced in two different places failed to find fluid. A rib was resected and the solid growth found. The patient lived three months, weakness and dyspnea being especially marked toward the termination. Necropsy showed that the whole of the right lung, except the apex, was replaced by a soft growth of the consistency of gruel. It was mottled, hemorrhagic and variegated in color. It was markedly adherent to the ninth and tenth ribs. There was no growth elsewhere in the body. Examination of the cervical glands showed that they were not involved. Microscopic examination showed the growth to be a small spindle-celled sarcoma. Pässler's records show that in 9,246 necropsies there were 1,000 cases of malignant disease, only four of which were primary carcinoma of the lung. [A.B.C.]

**The Means of Combating Surgical Tuberculosis.**—According to A. A. Bobrow<sup>2</sup> surgical or local tuberculosis may be grouped under two forms, showing certain dissimilarities in their course: the one is a chronic process, characterized by infiltration and formation of new connective tissue; the other is also chronic at times, though oftener subacute, and consists in a cellular infiltration which forms tubercles and through their necrosis leads to cheesy degeneration. In either instance the advent of pus cocci transforms the sluggish process into an acute inflammation. In the absence of a specific remedy our therapeutic efforts must aim at increasing the patient's resisting powers and thus aiding him to overcome the microbic invaders. All hope of salvation by removing the diseased part is distinctly illusory, since surgical tuberculosis must be considered as the local manifestation of a general infection. We combat the chronic nonsuppurating variety with local rest and contrairritating measures, like hot applications, iodine, or the cautery, which all act beneficially by attracting leukocytes and phagocytes to the affected tissues, as well as by stimulating the local circulation. A similar result is obtained by incising and packing with gauze-strips, in order to direct the current of tissue-fluids outward. These measures, however, are inadequate when we come to deal with necrotic and suppurating forms of local tuberculosis. Here active interference is called for, and operative removal of dead or diseased tissue advisable, to be followed by iodine or iodoform locally. It is to be understood that such operations are merely palliative measures, as complete removal of affected areas is impossible in view of the persisting general source of infection. Since this truth has gained recognition surgeons are no longer so anxious to operate as of old, but rather seek to strengthen their patients and pave

<sup>1</sup> Gazette Médicale de Paris, March 14 and 21, 1903.

<sup>3</sup> Medical Press and Circular, December 10, 1902.

<sup>4</sup> Cleveland Medical Journal, March, 1903.

<sup>1</sup> British Medical Journal, February 14, 1903.

<sup>2</sup> Russki Vrach, January 18, 1903.

the way for nature's own cure. In this connection climatic influences deserve all confidence. Prolonged stay (one to one and a half years) at the seashore exerts a markedly salutary effect, especially in the case of children; the sea-air, the bathing, and not least, the sunlight, contribute their respective share to the final result. Solar rays play a highly important role in the treatment of local tuberculosis, and patients should be instructed to expose their diseased parts to the sunlight. [L.J.]

**Fractures of the Lower Extremity Produced by Indirect Violence.**—An article elaborately illustrated by skiagraphs to show the position of the fragments and the results of treatment in fractures of the lower extremity is contributed by W. Arbuthnot Lane.<sup>1</sup> He again emphasizes the misleading statements of standard anatomic textbooks regarding the anatomy and physiology of the foot and ankle. The mechanics of Pott's fracture is fully described and the deformities of different types illustrated. Lane urges open operation with coaptation of the fragments by wiring or other means in fractures of the tibia and fibula and also of the femur. [A.G.E.]

**Enterectomy for Malignant Disease.**—Walter L. Woolcomb<sup>2</sup> reports two cases, the first being a man 35 years of age who suffered from the ordinary symptoms of intestinal obstruction. On opening the abdomen a growth was found involving the entire circumference of the transverse colon. Resection was done, the bowel united with Robson's bone bobbin. The patient recovered, but died a year after from recurrence of the malignant disease in the dorsal vertebra. The second case was a man of 55. The growth was found completely inserted in the bowel in the sigmoid region. The growth with five inches of the bowel was removed. An uninterrupted recovery followed. Microscopic examination showed the tumor to be a typical glandular carcinoma. The operative treatment in the last case consisted of delivery and fixation of the growth and contiguous bowel outside the abdomen; opening and drainage of the gut above the growth; freeing and uniting the ends of the bowel and repair of the abdominal wall. [A.B.C.]

**Operation for Perforation in Typhoid Fever.**—A. Depage<sup>3</sup> reports a case of typhoid fever with perforation of the intestines on the twelfth to the fifteenth day. The patient was operated upon these days later, at a time when there was a general infection, and made a good recovery. The wound was washed with artificial serum. [J.H.W.R.]

**Surgical Interference in Lesions Involving Motor Areas of the Brain.**—W. F. Verdi<sup>4</sup> states that the most important symptom in localizing the seat of motor lesion of the brain is the localized spasm. The exact preoperative localization of the Rolandic fissure, since the exposure of large areas of the brain by the osteoplastic flap, is not so important as formerly. Verdi recommends the use of the rubber band, with pads in front of the ears, to prevent hemorrhage. This expedient saves blood and saves time that would be spent in arresting its flow—both vital points. The technic of operation is minutely detailed. The dangers are three—sepsis, hemorrhage and acute edema of the brain. Three operated cases are reported, two being for traumatic epilepsy and one for tumor. In one of the former cure has apparently followed operation, as two critical periods, June and November, have been passed by the patient without signs of convulsions. In the second case the general health is improved and the number of convulsions diminished. The third patient, operated two months ago, is now practically well, but the recurrence of the tumor, a telangiectatic glioma that had undergone cystic change, is expected, as all of it could not be removed. [A.G.E.]

**Radical Cure of Hernia in Young Children.**—D. Kennedy<sup>5</sup> believes it is exceptional for hernia in children to be cured by a truss. Operation is far less dangerous because it prevents all possibility of strangulation. The truss often causes irritation and eczema, and is objectionable on account of becoming soiled with the discharges. The pressure also prevents the development of the adjoining muscles, and finally,

the truss is rarely effectual in keeping up the hernia. He advises operation from the fourth month onward. Points essential to success in operating are prevention of hemorrhage, quickness and thoroughness of anesthetization to prevent shock. He ligatures and resects the sac, but does not fix it to the abdominal wall. He invariably circumcises the child. In congenital hernia he has always found complete union of the elements of the cord with the posterior wall of the sac, and has given up attempts to isolate the latter. He draws it down, transfixes it, passes a ligature in front of the cord as high up as possible, and divides the sac transversely above the scrotum, leaving the lower part to form a tunica vaginalis, dissecting away all he can of the part lying in the inguinal canal below the ligature. [H.M.]

**Duodenal Ulcer Perforating Acutely.**—Power<sup>1</sup> details four cases of perforating duodenal ulcer, which according to his deductions teach the following lessons: (1) Duodenal ulcers occur more often in men than in women; (2) the extravasated fluid trickles into the iliac fossa, and causes a local peritonitis which may be mistaken for an acute appendicitis; (3) the transparent or bile-stained succus entericus found in the peritoneal cavity is diagnostic of a perforated duodenal ulcer. It is quite different from the gastric contents escaping at a perforated ulcer of the stomach; (4) the prognosis of a duodenal ulcer is worse than that of a perforated gastric ulcer on account of the greater difficulty in closing it satisfactorily; (5) the prognosis should not be too sanguine until after the lapse of the eighth day, and it is always bad, however well the patient may appear, if the pulse-rate continues rapid. The pulse is a much better guide than the temperature; (6) free drainage is imperative, both iliac fossas, the rectovesical pouch, and the space below the liver more particularly need tubes; it is better that the patient should recover with a scarred belly than that he should die with an abdomen full of pus; (7) the feeding of the patient is a matter of great importance. Small quantities of food should be given frequently, and if the patient feels sick the amount must be reduced at once. It is better to give nutrient enemata for some days after the operation than to administer food by the mouth. [A.B.C.]

**Operative Asepsis.**—Depage<sup>2</sup> states that neither he nor his assistants touch a septic case or assist at an autopsy before operating. Nevertheless, inoculations from the subungual spaces of those who have made autopsies or dressed infected wounds have convinced him that the following will completely disinfect the hands of such persons: washing from 10 to 15 minutes in soap and water, 5 minutes in alcohol, and 5 minutes in corrosive sublimate solution. He does not believe that a general bath by the surgeon just before operating is a necessary procedure. To disinfect his hands before operating he employs the above method, using soap and water (after cutting and cleaning finger-nails) for 5 to 10 minutes, alcohol and corrosive sublimate 3 to 5 minutes each. The first two are sufficient for disinfection, but the sublimate is used as a supplementary precaution which is well to observe in hospitals. [A.G.E.]

**A Rare Case of Cephaloma.**—Recent researches have led to a recognition of two fundamental groups of cerebral hernia. The one represents a hernia proper—that is, a prolapse of brain or meninges—while the other is a genuine teratoid growth, which has been named "cephaloma." Tatarinow<sup>3</sup> reports such a case in a boy 2 months old. The enormous tumor, occupying the occipital region, measured 27 centimeters across, and showed fluctuation. Under general anesthesia the mass was removed. In the occipital bone an aperture 2 centimeters in diameter was found, through which a small portion of the brain protruded, covered with pia mater. The prolapse was reduced without difficulty, the opening closed by uniting two flaps of periosteum, and the child made a good recovery. Microscopic examination showed the tumor to be a genuine newgrowth, consisting of fat and connective tissue, with areas of neuroglia interspersed. The cutis was very thin, rich in sebaceous and sweat-glands, and abundantly infiltrated with round cellular elements. [L.J.]

<sup>3</sup> Chirurgia, January, 1903.

**Successful Removal of 265 cm. (8 ft., 9 in.) of Gangrenous Intestine.**—This case is reported by Roswell Park,<sup>1</sup> the patient being a man of 21, operated on five days after the onset of abdominal pain and intestinal obstruction. Incision made in the middle line revealed adherent coils of intestine and a collection of seropurulent fluid. Search showed that the primary fault was a gangrenous appendix, about which three or four coils of small intestine had united themselves and adhered to the cecum, and that all these adherent surfaces were in a gangrenous condition with threatening perforation at numerous points. By a Murphy button the ascending colon was connected with a loop of intestine above the uppermost gangrenous area, and the involved intestine, together with a part of the cecum, removed. Both ends of the bowel were turned in and sutured. The removed intestine measured 265 cm. (8 feet, 9 inches). Drainage was followed by a fecal fistula lasting some months, this healing rapidly after the Murphy button came away, nearly four months after its insertion. The patient is now in the best of health. Park emphasizes the point he made some years ago, that most cases of general peritonitis not plainly due to some ordinarily easily recognized lesion take their origin from an inflamed appendix. In many of these cases it is wise to operate, unless the patient be already moribund. Park agrees with Price that symptoms of obstruction call for incision in the middle line. The location of pain as described by the patient in cases of appendiceal general peritonitis is not always a safe and is often a misleading sign. In the case reported the first complaint of pain pointed to the general peritoneal cavity rather than to the appendix. Frequently the pain is referred to the left instead of the right side. Park appends a table of 17 cases, including his own, in which more than 200 cm. of bowel have been removed. Of these but three died. [A.G.E.]

**Resection of Large Intestine for Carcinoma.**—James Swain<sup>2</sup> reports three cases which exhibited the usual symptoms of obstruction. His method of operation in each is detailed. All the patients recovered so far as the operation was concerned. His postoperative treatment in these cases consists in combating shock by the administration of nutritive enemata of brandy and peptonized milk every four hours. Hot water is allowed by the mouth from the first, and so soon as vomiting has ceased water gruel and such substances are permitted. Bread and butter may be given on the third day, and solid food thereafter regularly increased. [A.B.C.]

**Enterostomy in Cancer of the Stomach.**—Napalkow<sup>3</sup> cites his personal experience in favor of enterostomy in certain cases of gastric carcinoma. The general opinion is against this operation, the majority of surgeons being in favor of noninterference with extensive carcinomatous involvement of the stomach. Such a neutral attitude is to be strongly condemned. Life can be prolonged and rendered tolerable by performing an enterostomy, provided, of course, that a gastroenterostomy is contraindicated, as in widespread growths which either leave no healthy space for an artificial outlet or else threaten to involve the latter within a short time. The operation entirely eliminates the stomach from the digestive process, which can be quite efficiently carried on by the intestinal tube alone. Care should only be taken to ensure a free flow of bile and pancreatic juice from the upper segment of the intestine into the lower, and to prevent the gut from discharging its contents through the fistula. In feeding the patient small quantities are to be introduced, otherwise distention of the bowel will be very apt to cause pain. As to pains originating in the stomach, which were due in a great measure to the ingestion of food, they are done away with after enterostomy, and the patient may thus enjoy a comparatively comfortable existence. [L.J.]

**Carcinomatous Gastrocolic Fistula.**—P. Koch<sup>4</sup> reports two cases of gastrocolic fistula resulting from carcinoma of the stomach. He also gives a critical review of the subject of gastrocolic fistula, and tabulates the cases previously reported. These fistulas form when pathologic processes in the abdomen lead to adhesions between the stomach and colon,

followed by a perforation. The causes are: Carcinoma of the stomach, 35 cases; ulcer of stomach, 12 cases; tuberculosis of stomach, 1 case; carcinoma of colon, 8 cases; abscess of peritoneal cavity, 5 cases; congenital, 1 case. A gastrocolic fistula may pursue a latent course, but this occurs very rarely. The commonest symptom is fecal vomiting. A second characteristic symptom is lentyery. These two symptoms rarely occur together since the conditions that favor lentyery, namely, pyloric stenosis with large fistulous opening, are just those which diminish the tendency to fecal vomiting. Diarrhea usually accompanies the fecal vomiting, and a third characteristic symptom consists in the identity of the vomitus with the stools. The diagnosis may be affirmed by three tests: (1) Chemical examination of the stools for free hydrochloric acid; (2) insufflation of the stomach or of the rectum whereby the air passes at once into the rectum or stomach, as the case may be; (3) injection of colored fluids into the rectum, with recovery of the same almost immediately by the mouth or vice versa. [B.K.]

**The Tuning-fork and Stethoscope in the Diagnosis of Fractures.**—The value of these simple instruments in the diagnosis of lesions other than those of the middle and internal ear is emphasized by A. H. Andrew.<sup>1</sup> The test for fractures, especially of long bones, is made by placing the stethoscope in close proximity to the bone near one end and the handle of a vibrating tuning-fork as close as possible to the bone beyond the seat of fracture. When the bone is intact the sound of the fork will be heard with great distinctness. If there is a solution of continuity the sound will be heard faintly or not at all. The variety of instruments giving the best results and the technic is detailed. Several cases are mentioned, among them being three fractures of the neck of the femur. In one of five weeks' duration the sound was heard with almost equal distinctness on both sides, showing that union had occurred. Experiments with the same means in the diagnosis of dislocations are under way. [A.G.E.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Mortality from Cancer.**—Charles Templeman<sup>2</sup> gives certain statistics with reference to the mortality of cancer during the past 25 years: The deathrate from cancer as a whole during the 25 years under review has more than doubled, having increased from 7.27 to 16.92 per 10,000 of the population over the age of 20. This increase is greatest at ages over 45, is common to both sexes, but more marked in the male sex, though the actual mortality is higher among females. In females this is chiefly due to an increase in malignant affections of the abdominal viscera. Uterine cancer and cancer of the breast in females have increased, though not in any marked degree. Cancer of the rectum also show a slight increase in both sexes. In males the highest mortality is from cancer of the abdominal viscera. In males cancer of the mouth and upper digestive tract has also greatly increased. Therefore cancer of regions which may be described as "accessible" has increased, as well as that of parts which are not so accessible and where the diagnosis is more difficult, but the increase in the latter is out of all proportion to that in the former class. During the same period there has been a great improvement both in clinical and pathologic diagnosis, as well as in death certification, and consequently a considerable diminution in returns from such indefinite conditions as "old age" and "disease" of the various organs (without any specification of its nature). This must to a considerable extent have helped to swell the returns of death from "cancer." The author is of opinion, however, that this is by no means sufficient to account for the great increase in cancer mortality, and that this increase is a real and substantial one, though by no means so great or so alarming as the general public believe or as a superficial glance at statistics would seem to indicate. [A.B.C.]

**Shall We Curet After Abortion or Not?**—A patient of

<sup>1</sup> Buffalo Medical Journal, April, 1903.

<sup>2</sup> British Medical Journal, January 10, 1903.

<sup>3</sup> Chirurgia, January, 1903.

<sup>4</sup> Archiv für Verdauungs-Krankheiten, Bd. ix, Heft 1.

<sup>1</sup> Chicago Medical Recorder, March 15, 1903.

<sup>2</sup> British Medical Journal, February 14, 1903.

Michelet's<sup>1</sup> was passing through her third abortion, and as she bled profusely he was forced to dilate the inner os and curet; three days later, on account of renewed hemorrhage, this had to be repeated. The finger was called to the assistance of the curet, and pulled away several large pieces of membrane. The patient recovered and was delivered of a healthy child a year later. In Michelet's opinion the habitual abortion was due to chronic endometritis. The curetment, by removing the mucous membrane, not only stopped the bleeding, but gave the uterine mucosa a chance to regenerate. Curetment therefore seems to him the proper procedure after abortion. [E.L.]

**Vaginal Cesarean Section.**—W. Ruhl<sup>2</sup> recommends the anterior uterovaginal incision for obstructed delivery after vaginal fixation, and for those cases in which the posterior cervical wall cannot be reached. But when the cervix is completely accessible the Dührssen procedure, the simultaneous splitting of anterior and posterior cervical walls is to be preferred, as it will undoubtedly give the needed room and avoid the splitting of the lower uterine segment. This Dührssen method is also indicated by a premature loosening of a normally situated placenta. [w.k.]

**Recurrent Chorea of Pregnancy.**—This rare complication of pregnancy is the subject of a report by Rosenblum.<sup>3</sup> Immediately following her first labor, which was premature, the young woman (24 years) was seized with convulsions, accompanied by loss of consciousness (eclampsia). She had never before suffered from chorea. Some four months after confinement choreiform twitchings appeared in the face and hands. The entire body soon became involved in the involuntary, incoordinate, rapid movements. Examination per vaginam led to the diagnosis of pregnancy in the second month. The choreic attacks gained continually in violence, sleeplessness was superimposed, and the condition of affairs justified artificial abortion at the seventh month. She remained in the hospital about two months and was discharged cured. Chorea had disappeared. Two months later a new pregnancy could be diagnosed, which led to a recurrence of the chorea (fifth month). She carried her child to term, however, was confined while suffering from her chorea, and then gradually improved again. At the time of writing the twitchings were almost gone.

**Primary Carcinoma of Ovary.**—May Thorne<sup>4</sup> reports the case. The patient was a female of 46. She had suffered from pain in the region of the left ovary for several weeks, which had been developed rather suddenly after muscular examination. Nothing had given relief. On examination the left ovary was found enlarged, the size of a small orange and was tender. A week later the enlargement was more marked, pain was more intense. On opening the abdomen a mass with enormous small cysts on its surface lay to the left of the uterus. It was hard and densely adherent to the pelvic wall. The uterus was apparently normal. It consisted of an enlarged malignant condition of the left ovary. This was removed and the patient made an uneventful recovery and for two months was apparently well, but the growth recurred in the abdomen wall in the angle of the scar, where drainage had been originally placed. The growth was rapid, death occurring four months after operation. Microscopic examination showed the original condition to be carcinoma of the left ovary. [A.B.C.]

**Postoperative Hematemesis.**—K. Winslow<sup>5</sup> reports a fatal case of this obscure surgical complication. The patient was a short, stout woman of 65, operated on for strangulated umbilical hernia. The operation lasted an hour and the patient had taken such a small quantity of ether that she talked to the etherizer while the dressing was being applied. The after-progress of the case was at first fairly satisfactory, but on the evening of the third day the patient began to vomit a dark fluid that was brought up in small quantities without retching. At midnight she suddenly vomited an enormous quantity of dark blood and immediately expired. Autopsy revealed considerable dark, clotted blood in the stomach and intestines, but no lesion of the mucous membrane was discovered. There

was no evidence of infection, the wound having healed by first intention. The intestines were apparently normal and there was no sign of tension on the stitches uniting the wound. [A.G.E.]

**Periurethral Infiltrations and Abscesses in the Female: Chronic Gonorrhoeal Induration of the Female Urethra.**—Just as in man so in woman does the acute gonorrhoeal process spread to the depressions and glands of the urethral mucous membrane. In most of the cases the infiltration stays limited to the follicles, but in cases where the mouth of the follicle becomes obstructed retention of pus follows, and miliary abscesses form in the tissues of the urethra; but if this does not occur, or incision is not performed, the cavernous infiltration will spread along the urethra; and this becomes very much thickened and hardened. Perforation may take place into the urethra or vagina. Matzenauer<sup>1</sup> has seen nine such abscesses during a period of six years, thus illustrating their rarity; five were incised through the anterior vaginal wall. The pus of three contained gonococci in pure culture, two contained gonococci and staphylococci. The other four cases perforated spontaneously, twice into urethra, once through anterior vaginal wall, and once in both directions. Three presented the picture of a mixed infection; one contained only staphylococci. In some of the observed cases the swelling, thickening and induration of the urethra did not disappear, a state of chronic gonorrhoeal induration of the urethra forming, which brought with them urinary disturbances, as difficulty and frequency in micturition. [E.L.]

## TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

## REVIEW OF LITERATURE

**The Form of Hypnotic Sleep in Its Therapeutic Relations.**—Rybakow<sup>2</sup> divides the hypnotic sleeps into four groups which are not, strictly speaking, stages. In the first, which is the lightest form of hypnosis, the condition is very similar to that which occurs sometimes in awaking from a sound sleep. In this form the patient is conscious of his surroundings, and may with difficulty resist the will of the hypnotizer, and on awaking there is a distinct recollection of what has occurred. In the second form the eyes are closed, and the patient is unable to resist the will of the operator, although sometimes he attempts to do so. The muscles are in a condition of catalepsy, so that he remains in the position in which placed. On awaking there is at least partial recollection of what has occurred. In the third form the patient's will is entirely subsidiary to that of the hypnotizer, and on awaking there is no recollection of what has occurred during the sleep. In the deepest form of the sleep there is somnambulism or automatism, so that the actions of the hypnotized may be independent of the will of the operator. It is generally taught that the degree of suggestibility of the patient's mind depends upon the depth of the sleep; while in a general way this is true, the personal idiosyncrasies of the patient and the peculiarities of his disease are also important factors. Every healthy mind is more or less open to suggestion, and it is no evidence of mental or moral weakness when the suggestibility is strong, for this function is the groundwork of the psychic life of mankind. The reception of suggestion depends upon two psychic factors, the capability of taking up foreign thought (suggestibility in its narrow sense), and the capability of making such thoughts the part of one's own ego (psychic assimilation). For therapeutic results both of these processes are necessary; that is, the patient shall not only adopt a suggestion as it is given, but shall make it such a part of his mentality that it shall influence his future actions. Hypnotic sleep is simply a condition in which the interfering activities of the brain as well as the will of the patient are done away with, so that the mind is open to the reception of suggestions. There is, in other words, a temporary increase of the normal suggestibility of the man, but

<sup>1</sup> Deutsche medizinische Wochenschrift, January 1, 1903.

<sup>2</sup> Zentralblatt für Gynäkologie, March 7, 1903.

<sup>3</sup> Medizinische Obozrevie, lix, No. 3.

<sup>4</sup> British Medical Journal, February 14, 1903.

<sup>5</sup> Northwest Medicine, March, 1903.

<sup>1</sup> Wiener klinische Wochenschrift, November 6, 1902.

<sup>2</sup> Die medizinische Woch., 1902, p. 418.

not of necessity any increase in the psychic assimilation of suggestions. If the natural suggestibility is small, the consciousness of the patient is not able to take up the thought during hypnosis and use it after awaking. Under these circumstances sometimes repeated suggestions fix themselves more firmly on the patient's mentality. If the natural suggestibility of the patient is large, a mild degree of hypnotic sleep does not seriously affect, but deep sleep may increase; if, on the other hand, the natural suggestibility is small, hypnotic sleep may often considerably augment. [H.C.W.]

**The Relations of Calcium Excretions to Tuberculosis.**—According to Croftan<sup>1</sup> the fever-producing power of tuberculin depends upon a peculiar proteid body allied to pepsin. This substance has a very close chemie affinity for calcium. Kühne found that the injection of deutoalbumose produced a febrile reaction in tuberculous cattle. Croftan discovered that if this substance was saturated with calcium it failed to produce any reaction. Moreover, he found that in tuberculosis there is a very high calcium content in the urine, so much that he regards the increased lime in the urine as a suspicious sign of tuberculous infection. On these grounds he believes that calcium salts should be of benefit in the treatment of tuberculosis. [H.C.W.]

**Protulin.**—It has long been known that certain phosphorus-holding proteids act particularly upon cell nutrition,<sup>2</sup> as an example of which may be mentioned the effect of nucleins. In these bodies phosphorus appears to exist in the form of anhydrous phosphoric acid. Protulin is a new synthetic, containing 2.7% of phosphorus in the form of the anhydroides combined with natural albumin. It is a white, tasteless powder, insoluble in water, and forms a gelatinous mixture with alkalies. It resists the digestive action of pepsin but not that of the pancreatic secretions. Kocher<sup>3</sup> has found it useful in cases of goiter and the beginning of Graves' disease, even when the ordinary forms of phosphorus had failed. He believes it even surpasses in power the newly recommended lecithin. It may be used in osteomalacia, rachitis, neurasthenia, etc., in doses of 2 to 4 coffeespoonfuls. [H.C.W.]

**Theocin.**—Meinertz<sup>4</sup> reports the results of clinical trials of this new diuretic, which, as we have noted in a recent abstract, is an artificially made theophyllin, an alkaloid found in tea leaves, and is isomeric with theobromin. Meinertz employed it in dropsy due to heart failure, kidney diseases, serous and pleural effusions and the like. In the great majority of cases there was immediate increase in the amount of urine, sometimes the secretion being augmented four or five times. The effect, however, was usually transitory, so that after several days' experiment the quantity gradually fell again to normal. If under these circumstances the drug was withdrawn several days a second course brought about a renewed diuresis. In one case, for example, after seven treatments, each lasting from four to nine days, and spread over 19 weeks, the seventh trial of theocin produced as large an increase in the flow of urine as did the first. Meinertz was not able to see that the drug had any direct influence upon the circulation. He believes, however, to the contrary, too low blood-pressure prevents its action. Among its undesirable effects are noted disturbances of the digestion with nausea, loss of appetite and in some cases vomiting. It appeared that it was less likely to disturb digestion if given in tablets than if given in powders. The dose is  $\frac{1}{2}$  gram (5 grains) three times a day. [H.C.W.]

**Therapeutic Use of the X-ray.**—Ross and Wibert<sup>5</sup> believe that although experience with the x-ray as a therapeutic agent is not sufficient to place it definitely among practical methods of treatment, it seems certain of a valuable future. They have found it useful as an analgesic in cases of inoperable tumors, as sarcoma and carcinoma, or any recurrence of these tumors. Besides alleviating the pain associated with these growths, they believe it has some effect in deterring the growth of the tumors. In epithelioma they have found that it exercises a definite curative action. They report one case in which

there had been no return of the growth seven months after its disappearance. They have also found it useful in lupus. In this disease there is apt to be a very marked reaction to the treatment, so that x-ray burns are quite common unless the method is employed with much care. [H.C.W.]

**Treatment of Burns.**—According to Bjorkmann,<sup>1</sup> in burns of the first degree in which there is merely hyperemia, disinfection of the injury with aseptic protection is usually all that is needed. If the lesion is very painful, Stahls' liniment frequently acts very happily in relieving the pain.

Lime water.  
 Linseed oil . . . . . āā 120 cc. (4 ounces)  
 Sodium bicarbonate . . . . . 60 grams (2 ounces)  
 Thymol . . . . . 0.5 gram (8 grains)

Cover the injured part with a liberal amount of the liniment; then apply borated gauze and a bandage. Shake well before using. The dressing may be renewed as soon as pain returns. (The thymol has sufficient antiseptic properties to keep the lesions sterile and to prevent the bad odor often produced by the liniment itself.)

In burns of the second degree the hypodermic injection of morphin relieves the pain and lessens the danger of constitutional effects. More than one injection is rarely necessary because the first injection allows time for the use of topical applications; injections of camphor and ether are indicated. When the lesion is so extensive that a fatal result is feared, Bjorkmann advises placing the patient in a warm bath of weak sodium bicarbonate. After this the affected area should be thoroughly cleansed with antiseptic solution and the blebs evacuated, allowing, however, the epidermis to remain. In burns of the third degree involving the deeper layers morphin should be freely used to lessen the pain, and stimulants, as ammonium carbonate and strychnin, administered hypodermically, to prevent shock. In severe cases he has frequently resorted to anesthesia, which prevents unnecessary suffering and allows the physician to make a thorough investigation of the extent of the damage. If the lesions are deep and important vessels are scorched or laid open, they should be ligated or tamponed as soon as possible. After this an antiseptic occlusive dressing should be applied and the part elevated. In burns not of a severe degree, Bjorkmann recommends picric acid as being analgesic, antiseptic and reconstructive. The manner of

Picric acid . . . . . 4 (1 dr.)  
 Rectified spirits . . . . . 60 (2½ oz.)  
 Distilled water, sufficient to make . . . 800 (27 oz.)

Externally.

application is, after opening the blister, to place a strip of sterilized gauze soaked in the picric acid solution over the wound, and over this an occlusive dressing. In burns of the second and third degree the dry treatment sometimes gives good results. For this purpose he recommends the various antiseptic powders, especially aïrol, nosophen, and aristol. These may be applied in the form of an ointment, as in the following prescriptions:

Aïrol . . . . . 4 (1 dr.)  
 Woolfat (anhydrous),  
 Petrolatum . . . . . āā 15 (4 dr.)

Sterilize. Apply freely to the burned parts, and cover with gauze and absorbent cotton, and bandage. Leave the dressing intact for several days.

Ichthyol . . . . . 3 (45 grs.)  
 Olive oil (sterilized) . . . . . 10 (2½ dr.)  
 Woolfat,  
 Petrolatum . . . . . āā 40 (10 dr.)

Sterilize. Apply freely on sterilized gauze in burns of second and third degrees. [H.C.W.]

**Nicolicin, a Professed Cure for Chronic Morphinism.**—B. Fischer and B. Wagner<sup>2</sup> have made analyses of nicolicin, a drug claimed by its manufacturers to cure the morphin habit. They found its base to be morphin, pure and simple. It contained 3% of this alkaloid by actual weight. [E.L.]

**Treatment of Membranous Enteritis.**—Bjorkmann<sup>3</sup> considers colitis mucosa a neurosis and the treatment therefore should be largely along the line of suggestion. The patient should be discouraged in studying his own symptoms and

<sup>1</sup> Journal of Tuberculosis, Vol. v, 1903, p. 22.

<sup>2</sup> Klinische therapeutische Wochenschrift, Vol. x, p. 107.

<sup>3</sup> Archiv für klin. Chirurgie, 1901, S. 469.

<sup>4</sup> Therapeutische Monatshefte, 1903, 17, p. 59.

<sup>5</sup> Therapeutic Gazette, 1903, No. 23, p. 79.

<sup>1</sup> Merck's Archives, March, 1903, Vol. v, p. 82.

<sup>2</sup> Münchener medizinische Wochenschrift, December 23, 1902.

<sup>3</sup> Merck's Archives, March, 1903, Vol. v, p. 82.

impressed with the fact that his disease is neither uncommon nor incurable. Exercise, hydrotherapy and massage are beneficial. The only medical treatment he recommends is the occasional use of a mild laxative, such as saline, cascara, or an occasional course of calomel. In general he believes local medication more harmful than beneficial, but he has occasionally seen high injections of silver nitrate give good results. [H.C.W.]

**FORMULAS, ORIGINAL AND SELECTED.**

For cardiac weakness associated with hepatic congestion:<sup>1</sup>

- Powdered digitalis . . . . . 0.05 gm. (1 grain)
- Powdered squills . . . . . 0.05 gm. (1 grain)
- Resin scammony . . . . . 0.05 gm. (1 grain)
- Calomel . . . . . 0.01 gm. (1/3 grain)

Five such pills daily for three days. [H.C.W.]

Bernard<sup>2</sup> recommends in sciatica and other neuralgias the injection of a solution composed of:

- Sodium chlorid . . . . . .65 gram (10 grains)
- Sodium sulfate . . . . . 1.3 grams (20 grains)
- Distilled water . . . . . 1 liter (1 quart)

This is warmed to bodily temperature and about 5 cc. injected in the neighborhood of each painful point. Several injections may be given at one sitting. [H.C.W.]

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 11, 1903:

**Changes in the Medical Corps of the U. S. Army for the week ended April 11, 1903:**

WEIRICK, SAMUEL T., contract surgeon, in addition to his present duties at Fort Mason, will make the physical examination of recruits at the recruiting station in San Francisco, Cal.

CHASE, ALPHA M., contract surgeon, is granted leave for one month from about April 15.

The operation of so much of orders of March 27 as relate to Major Guy L. Edle, surgeon, is suspended until July 1.

WINTER, Captain FRANCIS A., assistant surgeon, in addition to his present duties, will report by letter to Major-General John C. Bates, commanding the department of the Missouri, for such duty as may be assigned to him in connection with the assembling of troops at St. Louis, Mo.

HENDERSON, First Lieutenant ALBERT H., assistant surgeon, is granted leave for one month and twelve days from about April 20.

HUSSEY, SAMUEL W., contract dental surgeon, now at San Francisco, Cal., is relieved from further duty in the division of the Philippines, and will report to the commanding general, department of California, for assignment to duty.

CARPENTER, ALDEN, contract dental surgeon, now at San Francisco, Cal., is relieved from further duty in the division of the Philippines, and will proceed to Vancouver Barracks and report to the commanding general, department of the Columbia, for assignment to duty.

WATSON, HARRY J., contract surgeon, is relieved from duty at the Presidio and assigned to duty as transport surgeon of the army transport Sumner now in this port.

ROBINS, ROBERT P., contract surgeon, now casually at Fort Porter, from detached service, is assigned to temporary duty at that post until further orders.

ROBERTS, First Lieutenant WILLIAM, assistant surgeon, will proceed to Hot Springs, Ark., and report at the Army and Navy Hospital at that place for treatment.

WELLS, Captain GEORGE M., is granted leave for seven days.

So much of orders of March 27 as direct First Lieutenant Willard F. Truby, assistant surgeon, to proceed to Columbus Barracks, is amended so as to direct him to proceed to Fort Ethan Allen for temporary duty.

**Changes in the Medical Corps of the U. S. Navy for the week ended April 11, 1903:**

BIDDLE, C., surgeon, detached from the Navy Yard, League Island, Pa., and ordered to the Minneapolis—April 3.

SMITH, G. T., surgeon, detached from the Puritan and ordered home to await orders—April 3.

NORTON, O. D., surgeon, detached from the Minneapolis and ordered to the Navy Yard, League Island, Pa.—April 3.

HALLOWAY, J. H., assistant surgeon, detached from the Naval Museum of Hygiene and ordered to the Franklin—April 4.

BROWN, E. M., assistant surgeon, detached from the Naval Museum of Hygiene and ordered to the Naval Hospital, Norfolk, Va.—April 4.

MCCORD, D. P., acting assistant surgeon, appointment revoked to take effect April 4, 1903—April 4.

BOGERT, E. S., surgeon, ordered to the Naval Academy, Annapolis—April 8.

LIPPITT, T. M., assistant surgeon, retired, detached from the Naval Hospital, New York, and ordered home—April 9.

ELY, C. F., assistant surgeon, ordered to the Naval Hospital, New York—April 9.

**Changes in the Public Health and Marine-Hospital Service for the week ended April 9, 1903:**

MURRAY, R. D., surgeon, granted leave of absence for fourteen days from May 1—April 6, 1903.

MCINTOSH, W. P., surgeon, to proceed to Lumpkin, Georgia, for special temporary duty—April 5, 1903.

PIERCE, C. C., assistant surgeon, detailed to represent the service at the meeting of the Florida State Medical Association, to be held at St. Augustine, Florida, April 8-10—April 3, 1903.

ALTREE, G. H., acting assistant surgeon, granted leave of absence for five days from April 8—April 7, 1903.

RODMAN, J. C., acting assistant surgeon, granted five days' leave of absence from April 8—April 7, 1903.

WALKLEY, W. S., acting assistant surgeon, granted leave of absence for two days—April 5, 1903.

HOLT, E. M., pharmacist of the third class, promoted to be pharmacist of the second class, effective March 2, 1903—April 3, 1903.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. V, No. 17.

APRIL 25, 1903.

\$5.00 YEARLY.

“Two industrious baby-killers,” such is the way Dr. Spalding, of Chicago, designates measles and whoopingcough. In seconding and emphasizing the protest against popular and even professional carelessness as to the seriousness of these two diseases the Chicago Bulletin of the Health Department is right. An impression is too widespread that measles and whoopingcough are necessary children’s diseases and the younger the having the disease the better. In other words the more ill-prepared and tender the organism the more resistant it is to disease. Since January 1, says the Bulletin, there have been 129 deaths from measles against 49 for the same period one year ago; 60% of all deaths from measles are among children less than two years of age. And the after-effects are also severe, only less than those of scarlet fever. Physicians should therefore aid in instructing parents that it is not “better to have it now and get through with it,” but on the contrary, it is best to postpone the disease as long as possible. Conditions in England are indicated by this excerpt from the *Medical Press*:

Our two most deadly complaints at present are measles and whoopingcough, both highly infectious and altogether preventable maladies. What is the moral of it all? Why, clearly, that we must prevent the preventable and not rest content until we have weeded these deadly germ-diseases from our midst. The Metropolitan sanitary authorities have only recently commenced to attack measles in earnest. If measles cannot be eradicated without isolation in hospital, then in the name of humanity let the Asylums Board provide the necessary accommodation. To the honor of Londoners be it said that no money has ever been stinted in that direction. Both measles and whoopingcough can be abolished by strenuous notification, isolation, and disinfection.

**The Sale of Poisons, the Sales of the Patent Medicine Trust, and the Sale of the People.**—According to the *Boston Medical and Surgical Journal*, a parliamentary committee in England has reported upon a revision of the lists of poisons that may be sold, and the conditions under which the sale may take place. To the old lists the committee recommend that a third be added, of such poisons as are used by farmers and gardeners. Similar laws were enacted by the Massachusetts Legislature in 1887–1888, but in 1896 the patent medicine trust found that these laws restricted their sales, and according to their wishes “patent and proprietary medicines” were exempted. During the present

session the State Board of Health has advised that such articles as complexion-bleaches, many of which contain dangerous quantities of corrosive sublimate and lead, should have the poison label required by law of 1896. The recommendation should be accepted, of course, and the exemption brought about by the patent medicine trust should be repealed. The English parliamentary committee found that deaths had occurred from a number of patent medicines containing poisonous substances, *e. g.*, Chlorodyne, Winslow’s Soothing Syrup, Martin’s Pectoral Balsam, Hooper’s Whoopingcough Mixture, Holt’s Whoopingcough Specific, Indian Tincture, etc. Medical societies, local, State, and national, should use their influence to put an end to the free sale of poisons, and especially to those of the patent medicine concerns.

**Meat-eating and Alcoholism.**—Of the two extremes we believe that vegetarianism is worse than overindulgence in meats. This opinion is also reflected in the new movement called “semivegetarianism,” which, while not wholly foregoing meat, advocates a decided and salutary restriction in that article of diet. Careful observers are convinced that the excessive eating of animal food is one of the causes of a similar excess in alcoholism. The customs and statistics of England are striking in proof. According to an English physician, 55% of the children of the working classes die before the age of 5, as against 18% of the upper classes; \$200,000 a year is spent by the Society for the Prevention of Cruelty to Children. Recent cases of cruelty to children by parents under the influence of drink include a burning stick applied to a child’s leg; a baby half eaten alive by maggots; a 2-year-old child fallen from the lap of a drunken mother against a burning grate, and raw rum poured in sheer devilry down the throat of a babe. There is military necessity behind the agitation in England as to diet and alcoholism. The late war in Africa opened the eyes of the authorities to the physical deterioration of the masses, and bad diet, bad housing, immorality, and alcoholism were seen to be responsible for the incapacity and scarcity of the volunteer soldier.

**The Ill-tempered Doctor.**—There is one good result of “an overcrowded profession,” and of the sharp competition that exists among doctors in the rivalry for popular favor. This is the disappearance of

the old-time spirit of harshness and lordliness which sometimes degenerated into positive brutality. These characteristics were the natural products of an original boorishness, increased by success and a comparative monopoly of practice. It takes a gentlemanly mind not to be spoiled by the attitude of subservience on the part of patients and the habit of ordering by the physician in charge. In every large community there are still left specimens of medical Dr. Johnsons who from a ruder age have carried down a cross and commanding acerbity of manner that is now out of place and time. In one of our large American cities there is an example known far and wide. His loss of patients does not teach him any lesson, and seems rather to increase his churlishness. He seems to take a special delight in hurting the feelings of his patients by a perverse irascibility. A patient who was shocked by this manner in the very beginning of the examination, suddenly stopped, and in a quiet manner asked the amount of the customary fee, paid it, and without a word walked away. There are better reasons, of course, against unkindness and coarse egotism, but it certainly no longer "pays" for physicians to be ungentlemanly.

**Consumption and Occupation.—**

In recent issues of *Charities*, Lillian Brandt has been publishing some excellent articles on tuberculosis. Part IV treats of occupation in its relation to the disease. The author rightly emphasizes the fact that too narrow deductions cannot be drawn from the figures which give the relative deathrates, but after all qualifications have been made there are many evident lessons which are taught by the diagram reproduced herewith from Miss Brandt's article. The statistics are from the registration States (six New England States, New York, New Jersey, Michigan, and the District of Columbia) for the year 1900. The high mortality in such occupations as those of stone cutters, cigar-makers, printers, etc., are more easily explained than the relatively low rates of machinists,

miners, etc. After all, the mortality rates of physicians is not so high as we should have expected, but why the bacillus of tuberculosis should have been so lenient to bankers, brokers, etc., seems hard to explain!

**Hookworm Disease.**—Dr. Ch. Wardell Stiles, Chief of the Division of Zoology of the Public Health and Marine-Hospital Service, has contributed a work of great importance to parasitology and to medicine, a report (printed by the government) upon the "Prevalence and Geographic Distribution of Hookworm Disease in the United States." In the Old World, hookworm disease was probably known to the Egyptians nearly 3,500 years ago, but its cause was not understood until about the middle of the nineteenth century, when it was shown to be due to an intestinal parasite, *Agchylostoma duodenale*. Until 1893 no authentic cases of this disease were recognized as such in the United States, but between 1893 and 1902 about 35 cases were diagnosed. In 1902 it was shown that a distinct hookworm, *Uncinaria americana*, infests man in this country, and this indicated very strongly that the disease must be present although not generally recognized. It is now established that in addition to the few cases of Old World hookworm disease imported into the United States we have in the south an endemic uncinariasis due to a distinct

cause, *Uncinaria americana*. This disease has been known for years in the south and can be traced in medical writings as far back as 1808, but its nature was not understood. Some cases have been confused with malaria, others have been attributed to dirt-eating. Dr. Stiles says that economically, uncinariasis is very important. It keeps children from school, decreases capacity for both physical and mental labor, and is one of the most important factors in determining the present condition of the poorer whites of the sand and pine districts of the south. The disease is carried from the farms to the cotton mills by the mill hands, but does not

spread much in the mills; nevertheless, it causes a considerable amount of anemia among the operatives. The hookworms are about half an inch long. They live in the small intestine, where they suck blood, produce minute hemorrhages, and in all probability also produce a substance which acts as a poison. They lay eggs which can not develop to maturity in the intestine. These ova escape with the feces and hatch in about 24 hours; the young worm sheds its skin twice and then is ready to infect man. Infection takes place through the mouth, either by the hands soiled with larvæ or by infected food. Infection through the drinking water may possibly occur. Finally, the larvæ may enter the body through the skin and eventually reach the small intestine.

**The Symptoms and Treatment of Hookworm Disease.**—Dr. Stiles divides cases into three groups, the light, in which the symptoms are very obscure; medium, in which the anemia is more or less marked; and severe, represented by the dwarfed, edematous, anemic dirt-eater. Infection occurs chiefly in rural sand districts. Above the frost line the symptoms are more severe in summer than in winter, and whites appear to be more severely affected than negroes. Persons who come in contact with damp earth are more commonly infected than others, so that the disease is found chiefly among farmers, miners, and brickmakers. Severe cases are more common in women and children than in men over 25 years of age. Any one or more symptoms may be absent or subject to variation; the period of incubation (at least before the malady can be diagnosed by finding the eggs) is from four to ten weeks. Stages are not necessarily distinctly defined, but are described as (1) stage of purely local symptoms, corresponding to the light cases; (2) stage of simple anemia, corresponding to the medium cases; and (3) dropsical stage, corresponding more or less to the severe cases. The duration of the disease after isolation from the source of infection has been treated for six years and seven months; how much longer infection will last is not established. In extreme cases there is a general lack of development; the skin is waxy white to yellow or tan; hair is found on the head, but is more or less absent from the body; breasts are undeveloped; nails white; external genitalia more or less rudimentary; face anxious, may be bloated; conjunctiva pale; eyes more or less dry, pupil dilates readily; membranes pale according to the anemia; teeth often irregular; tongue frequently marked with purple or brown spots; cervical pulsations prominent; thorax emaciated; heart beats often visible; abdomen frequently with "pot belly;" extremities emaciated, frequently edematous, and with wounds or ulcers of long standing. The feces are reddish-brown, contain eggs, and may contain blood. Anemia is pronounced, according to degree and duration of infection; blood watery, with decreased red blood-corpuscles and with eosinophilia; "heart disease" is very commonly complained of; hemic murmurs present; pulse 80 to 132 per minute. There is emaciation and great physical weakness. Appetite is poor to ravenous; abnormal appetite often developed for pickles, lemons, salt, coffee, sand, clay,

etc.; pain in epigastrium; constipation or diarrhea. There are headache, dizziness, nervousness, mental lassitude, and stupidity. Menstruation is irregular or absent; if present, it occurs chiefly in winter; there is a marked tendency to abortion. A microscopic examination should be made of the feces to find the eggs; or if feces are placed on white blotting paper, a blood-like stain will be noticed. The two drugs most commonly used in uncinariasis are thymol and male fern. The day before treatment the patient is placed on a milk and soup diet for three days. The directions usually given for thymol treatment are these: Two grams (31 grains) of thymol at 8 a.m.; two grams (31 grains) at 10 a.m.; castor-oil or magnesia at 12 noon. One week later the stools should be examined, and if eggs are still present, treatment should be repeated until the eggs disappear, but it is not best to give the thymol more than one day per week. Some cases of hookworm disease are quite obstinate and require a treatment extending over several weeks. It is, therefore, an unfortunate error to expel a few worms with one or two doses and then dismiss the patient as cured without having made further microscopic examination for eggs.

**The Peruna habit and other forms of alcoholism** should be looked into by its religious and newspaper sponsors. We are indebted to Mrs. Martha M. Allen, the energetic worker of the W. C. T. U., for having asked the Massachusetts State Board of Health to analyze Peruna. In an advertisement of this nostrum a statement was made that "Peruna has among its friends many of the leading temperance workers in this country who give it unstinted praise, and do not hesitate to endorse it by the use of the most extravagant language." The chemist found it contained 23.46% by weight of alcohol. We know of one patient, a young lady, who has been taking large doses of this compound, and who has found it so exhilarating that she has made herself a sort of walking advertisement for the enterprising manufacturers. She would have been indignant if asked to take a "cocktail," or a drink of whisky, containing less alcohol than her prized and secret tippie. The Massachusetts Board found 15.33% of alcohol in *Vinol*; 16.77% in *Lydia Pinkham's Vegetable Compound*; 5.87% in *Sucamp-root*. In *Orangeine* there were found acetanilid, caffeine, and sodium bicarbonate. Concerning acetanilid Dr. Abbott, secretary of the board, says that it should be taken with much caution lest its frequent use degenerate into a confirmed habit. The proprietors of *White Ribbon Remedy* were not going to be trapped in one way—there was no alcohol in the drug, but only milk sugar and ammonium chlorid. It is "as likely," adds Mrs. Allen, "to cure drunkenness as would a blast of east wind." We have entire sympathy with the efforts of the W. C. T. U. to expose the meanest hypocrisy of the worst of liquor sellers, the patent medicine manufacturers.

**An Outrage, Whether Authorized or Not.**—There lie before us three little books issued by a so-named "Imperial Information Bureau" (we had supposed ours to be a democracy) giving lists for traveling

men and others of hotels, physicians, dentists, opticians, druggists, lawyers, banks, etc., in the cities of the parts of the country described in each booklet. Concerning the physicians recommended the company says:

The physicians stand at the head of their profession and have no superiors in their respective localities. We cannot recommend them too highly to life insurance companies and to any and all persons having access to this guide. The insurance companies will find the guide of great value when about to appoint examiners, as we have taken much pains to select men known to have first-class ability in this line. Much time and expense will be saved if the companies will look into the character and general ability of these physicians before making appointments. As to the travelers, they can safely rely upon our selections, when in need of medical advice, and not make haphazard inquiries of the local hotel men, who usually show favoritism. We carefully look into the character and ability of the physicians in every town and then select one of the very ablest and best men. And he is a man who will not neglect the traveler or overcharge him simply because he is transitory. We believe we are doing the travelers, as well as the life insurance companies, a great favor by selecting for them able and courteous physicians upon whom they may call at once when in need of their service.

There is a puzzling variation in the names given in the books. For instance, the "expert surgeons" of Philadelphia highly recommended by the guide books are in one: Keen, Town, Noble, C. P., Noble, W. H.; in another of the books the order and entries are: Keen, Brinton, Forbes, Montgomery, DaCosta, Noble, Town. In the list of "expert gynecologists" none is to be found in Philadelphia, but one man in internal medicine, one in mental and nervous diseases, and none in skin, genitourinary diseases and venereal diseases. In one list there is but one oculist and aurist mentioned in this city, while in a second list there are two "eye men" listed and four "nose and throat." We choose Philadelphia from no invidious reason, as the illogicalities and omissions in other cities are fully as striking.

**"An Advertising Dodge."**—The kind correspondent who sends us the three travelers' guides noticed above writes:

I send you by today's mail an extraordinary publication in three parts, which contains the names of some of the best men and some of the worst in our profession. It is as distinctly an advertising job as an advertisement in the daily papers. The representative of this publication has paid me frequent visits and as a reason for my subscribing has pointed out the names of Keen, of Philadelphia; Osler, of Baltimore; Janeway, of New York, and many others. I, of course, assume that the names of these men were obtained under a misapprehension of the purpose or the real standing of these manuals as clearly outlined in introductory statements. Probably I am too thin-skinned for the present age, but it seems to me that no reputable man can knowingly permit his name to be used in this fashion. Use the books in any way you see fit. I am told that these books are distributed to the extent of 150,000 a year, a statement no doubt somewhat exaggerated. Not the least remarkable feature is the reference to the names of F. C. Shattuck, H. F. Vickery, and T. M. Rotch, of Boston. It is simply incredible that these men can have authorized the use of their names unless blindfolded to the purpose of the book.

In order to spare our subscribers trouble in writing to us we will state that the publisher's imprint on the title page is Imperial Information Bureau, 314 Pioneer Press Building, St. Paul, Minn. The books bear witness that many names are included without authority.

Whether authorized or not such "enterprise" needs a sharp rapping on the appropriate heads.

**The "Index Medicus" in Danger.**—We learn that there have been less than 300 subscriptions thus far made for the revived *Index Medicus*. Unless the professional support of the periodical is greater than this the Carnegie Institution will naturally judge that the need of it is by no means so general and certain as has been represented. We should not forget that such a subscription list is a poor vote of thanks to Dr. Fletcher whose labor, unselfishness, and scholarship deserve a far more generous appreciation on our part. The trustees, it must be remembered, have voted the \$10,000 per annum for three years, during which a test can be made of the real professional desire for the periodical. Every physician interested in the literature of medicine—and every one is really interested directly or indirectly—should at once forward his subscription to the Editor of the *Index Medicus*, care of the Library of the Surgeon-General's office, Washington, D. C.

## EDITORIAL ECHOES

**Osteopathy in Oregon.**—Such a phantasmagoria of absurdities can have but one end; it will run its course and fade out of memory, just as did Perkin's tractors, the blue-glass craze, phrenology, faith-healing, and all that series of delusions. We can afford to wait the inevitable result with the calm patience of nature. In the meantime the osteopaths will interest a number of estimable people in their symptoms who might not otherwise have thought of taking treatment, and if there be anything serious behind their disturbances they will ultimately come to us to be cured. The bill as introduced, however, seriously offended our self-respect by practically declaring these charlatans to be doctors for purposes of revenue and title only, but when it came to the legal responsibilities they were to be so in a purely Pickwickian sense; that is to say, so as not to come within the purview of the already existing State Board of Medical Examiners. They were to have all the privileges of our profession, but none of its responsibilities or penalties. They were nominally, it is true, forbidden to use drugs or to perform major surgery, but what does that avail for men who treat all classes of disorders, both bodily and mental, by manipulation of the bones? In other words, they were to have the full privilege of assuming the title, doing the work and collecting the fees of physicians without being required to pass the same examination or spend more than a third of the same time in preliminary study. Upon these grounds the bill was very properly resented and opposed by the medical men in the Senate, and through the vigorous and skilful tactics of Senators Andrew C. Smith, of Multnomah, and C. J. Smith, of Umatilla, backed by the two other members of the profession, was defeated by a vote of nearly two to one.—[*Medical Sentinel.*]

**Extinct Race.**—From Hopkinsville, Ky., comes the news that Prof. Warren Morehead, curator of the department of archaeology of Phillips Academy, Andover, Mass., has discovered on a farm east of this place what he says was the burying ground of a prehistoric people. Prof. Morehead exhumed ten skeletons, several being in a fair state of preservation. He is making a preliminary investigation in this region, and likely will be followed by a party of archaeologists from Yale College. He pronounces the bones to be those of an extinct race of mound builders. All the skeletons were in receptacles built of flat stones. Stone cups were found in several graves and a stone knife was found in one.

## AMERICAN NEWS AND NOTES.

## GENERAL.

**New Way to Advertise.**—A recent advertisement in a newspaper is as follows:

THE NEW WAY—I now treat all diseases by Jullanism—the law of conscious coordination. JULIAN MACCREA.

**Congress of American Physicians and Surgeons.**—For the Congress of American Physicians and Surgeons, to be held in Washington, D. C., May 12 to 14, 1903, tickets on the fare and one-third plan will be sold May 8 to 13, to be vised at Washington May 12, 13, and 14.

**Trachoma Bars Immigrants.**—The Hamburg-American Line steamship "Armenia," Captain Falk, which arrived from Hamburg via Halifax, had on board 21 Russian Jews, all men, whom the Canadian Immigration Commissioners debarred because all are suffering from trachoma.

**Army Medical School's Honor Men.**—Secretary Root delivered diplomas to the graduates of the Army Medical School, and after an address by Dr. John S. Billings, United States Army (retired), Brigadier-General Carter presented the Hoff memorial medal. The four honor graduates were First Lieutenants Harry L. Gilchrist, Samuel M. Deloffre, John W. Hanner, and Edward M. Talbott.

**Increase Among Criminals.**—The following was recently said by an eminent divine with reference to the increase in the criminal classes in the United States: "In 1850 we had one criminal in every 3,442 of population; in 1890 we had one criminal to every 715 of population; and I dare not look at the figures for 1900, for the proportion of crime has increased to an appalling extent. Explain away this disgraceful decadence of the American people as you will, the fact remains. And bear in mind that these are only statistics of the convicted criminals. Again, in every 218 deaths there is one murder."

**"Around the World via Siberia."**—This is the title of an interesting book lately written by Prof. Nicholas Senn, of Chicago. The book graphically describes the various countries through which the author passed, including the climate, industries, people, etc. Particular attention is paid to Siberia, and the Doctor describes with some detail the fauna and flora of the country, the Army and Navy, the Government, and the people. Special attention is given to the vast realm of Russia, its charity organizations, its hospitals, national religion, its priests, its prisons and prisoners. The Orient is briefly but vividly pictured by this fertile writer, particular attention being paid to the present condition of China and to the Japanese Government, its religion, its medical schools and hospitals, its leper colonies, etc. Excellent illustrations are given of the different countries passed through and their inhabitants. The book is well worthy a perusal by any one having an interest in travel, particularly in the countries passed through by Dr. Senn.

**Increase in the Medical Corps of the Navy.**—Surgeon-General Rixey calls attention to the fact that the Fifty-seventh Congress provided for an increase of 150 members to the medical corps of the Navy, 25 of which are to be appointed each year for six years. This, in addition to the retirement of 10 men each year, makes 35 appointments open to young medical men annually. The appointments are made in the grade of assistant surgeon and are within the reach of well-equipped physicians between the ages of 21 and 30. Examinations are held in Washington, D. C., and at Mare Island, Cal., the board of examiners being in continuous session. Application can be made at any time to the Secretary of the Navy for permission to take the examination. Political influence is not required. The examinations are in three general lines: Physical, professional, and collateral. The physical examination is rather rigid. The professional examination embraces the subjects usually studied in a well-equipped medical college. The collateral examination has to do for the most part with subjects ordinarily studied in common and high schools and colleges. The salary depends upon the relative rank held, varying from about \$1,500 in the case of assistant surgeon, to \$5,500 in the case of the surgeon-general, who holds the rank of rear-admiral. It appears that the professional opportunities now open to young men entering the services are good and are constantly improving. The first assignment of duty is usually to one of the 14 naval hospitals. The young appointee is usually sent soon after his appointment to the Naval Medical School in Washington, where the following subjects are studied: Military medicine, military surgery, tropical medicine, naval hygiene, quarantine, the duties of medical officers, hospital corps drill, and administration, ophthalmology, naval law, manual of the sword, and extracts from tactics, instruction in signals, bacteriology, blood examination, and general laboratory work. After five months of such instruction the assistant surgeon is assigned to sea duty. With the great increase which has been made in the Army of the United States during the past few years there appears to be splendid opportunity for active service and promotion in the Navy of the United States.

**Medical Officers in the United States Navy.**—The Medical Corps of the Navy consists today of the following numbers and grades: One surgeon-general with the rank of admiral (equivalent to brigadier-general in the army); 15 medical directors with the rank of captain (equivalent to colonel in the army); 15 medical inspectors with the rank of commander (equivalent to lieutenant-colonel in the army); 85 surgeons with the rank of lieutenant-commander (equivalent to major in the army); 23 passed assistant surgeons with the rank of lieutenant (equivalent to captain in the army); 56 assistant surgeons with the rank of lieutenant, junior grade (equivalent to first lieutenant in the army), with 152 vacancies. There are 27 vacancies in the grade of assistant surgeon for the year 1903.

## EASTERN STATES.

**Milk Adulteration.**—The report of the Massachusetts State Board of Health shows that an analyses of 6,109 samples of milk offered for sale in Massachusetts showed 28.04% to be adulterated. Other articles of food showed a somewhat smaller percentage of adulteration. Of 3,120 samples examined, 18.9% were not pure.

**Health Insurance.**—The General Assembly of Connecticut has passed a resolution authorizing the Hartford Life Insurance Company "to insure persons against loss of time and expense resulting from disease." The act, however, does not become operative until it is approved by a majority vote of the stockholders. Most of the life insurance companies of Hartford have now taken up health insurance as a special branch of their operations, and in some cases this department of their business has developed into large proportions.

**Smoke Nuisance to Be Abated.**—It is stated that an active campaign against the smoke nuisance is to be carried out by the street department in Boston. The smoke inspector and his deputies have sent a copy of the law to a number of violators, and also the following notice: "In accordance with the provisions of the above act, the Mayor of Boston has designated the superintendent of streets as the official to be charged with its enforcement. Complaint has been made that smoke from the chimney on your premises is emitted in violation of this law. You are hereby notified that immediate steps must be taken by you to remedy this nuisance in compliance with the above law."

**Cattle Inspection Almost Completed.**—Most of the 51 townships in Massachusetts that were visited by the foot and mouth disease have been thoroughly inspected by United States Inspectors from the Bureau of Animal Industry. In the different communities the inspectors have gone from barn to barn and examined the animals, but the only place where they found the disease and where without their effort it might have been discovered was in a Quincy quarry. Part of the force of inspectors have been taken from Massachusetts and sent to New Hampshire to follow up the same line of work. Foot and mouth disease has been completely stamped out in Massachusetts so far as any evidence at the present time shows, but there probably remains some cases in New Hampshire.

**Amendments to Medical Practice Act.**—The State Board of Medical Examiners of New Jersey has secured amendments to the Medical Practice Act of that State by which the academic standards for admission to the State examinations have been raised from a competent common school education to a diploma issued after four years of study in a normal, manual training or high school of the first grade in that State, or its equivalent. The medical requirements have been increased from three to four courses of medical lectures of at least seven months each in different calendar years prior to receiving the degree of doctor of medicine. The amendments go into effect on July 4 next. After that date candidates for examination or for the endorsement of a license issued by a recognized examining board of another State will be obliged to comply with the new standard of requirements for a New Jersey license.

## NEW YORK.

**Pure Food Bill Passed.**—The Assembly of New York State has passed the Pure Food bill. No food that is adulterated or misbranded can under the terms of the bill be manufactured or sold. The terms of the bill will bear upon certain candy and pickle makers.

**Milk Trust in Syracuse.**—It is stated that capitalists have bought up 75% of all the milk routes in the vicinity of Syracuse, and that hereafter all milk is to be sold in bottles by the new company. It is said that the price of milk will be reduced and this is thought to be for the purpose of freezing out the smaller dealers that the remaining routes may be secured by the capitalists, and that then the price will be raised.

**Waste Paper to be Baled.**—Street Cleaning Commissioner Woodbury has decided to experiment in this city with a contrivance, which is now used in Boston, for baling waste paper and street sweepings. The machine is a box-like affair into which paper and sweepings can be shoveled as it is driven through the streets. It is equipped with mechanism driven by a small gasoline motor for compressing the refuse into bales and binding the bales with strips of wire.

**Tuberculous Cattle Sent to New York.**—Information was received by the State Agricultural Commissioner in Albany that diseased cattle had been shipped from Newport, Herkimer county, N. Y., to the Brooklyn slaughter-house in New York, and the meat was to be sold to New York consumers. The Commissioner at once sent an agent who intercepted the car in the yards in New York City. A report has been received by the Commissioner declaring that a postmortem examination of the cattle showed them to be the most diseased lot of animals that had ever been detained and the meat would have been wholly unfit for consumption. Of 20 cows found in the cars three were in a dying condition and soon expired and others were found far gone with tuberculosis, while three were suffering from pneumonia.

**Mr. Carnegie's Gift.**—The *New York Sun* is authority for the following: Andrew Carnegie has offered to pay all the bills of students of Cornell University who were stricken with typhoid fever during the recent epidemic in Ithaca. President Schurman today received a letter from Mr. Carnegie to that effect. The offer applies not only to indigent students, but to all cases where the student or his parent will permit it. Each student who has been sick will immediately be communicated with, so that it can be ascertained how much of a gift Mr. Carnegie's offer will mean. It is estimated that it will total at least \$50,000. This gift comes at a very opportune time, for a large percentage of the students who fell ill with the fever are men who support themselves. At a recent mass meeting of students \$1,000 was raised to help these students out, but the amount did not go very far.

**Icewater for the Poor.**—The work of the Women's Municipal League in New York City is becoming a prominent feature in supplying the poor with cool water. It began last summer to erect icewater fountains in needy districts at a cost of about \$175 each, while the cost of supplying the ice for each fountain during the year was about \$75. This year more extensive work is being contemplated on the part of the League, and appeal is made to the public for contributions for this beneficent purpose. It in part says: "New York has a tenement-house population of over 2,000,000. There are, so far as we have been able to find out, only about 35 icewater fountains to meet the needs of these people, to assuage the thirst of the passerby, the teamster, the weary woman, the little child, the street laborer—and midsummer days in New York are very hot. The city during the present administration is doing splendid work in providing parks, comfort stations, vacation schools, etc., for its citizens, and it is hoped will some time see the way clear to give this necessity also; but, just as kindergartens were started by private initiative, we must not wait for the city, and so ask you to help by the placing of these fountains next summer to make the people more comfortable and the saloons less necessary to them."

**New York's Charity.**—Frank Leslie's *Weekly* is authority for the following statement: Charity finds a wide field of expression in New York. In all there are probably 2,000 different institutions, conducted by churches, by societies, and supported by subscriptions, by the endowments of the wealthy, or by the persistent efforts of individuals. There is a charity for the mother before her child is born, for the city has its free lying-in hospitals; there is a charity for the newborn babe, should it be deserted by its parents, for it finds its way into the care of the organizations for foundlings. There are many homes for boys and girls, some of these homes modest and poor, some of them most costly and elaborate; there are free schools of all sorts for youths and young girls; there are free employment places for grown men and women who are out of work and unfortunate; and then, there are homes for the aged, for men and for women, and for husbands and wives together, when their days of strength and usefulness have passed, and have left them unprovided for in their last years. And finally, there is a charity which conducts the funeral, for instance, whose members may provide against going to the potter's field, securing a last resting place for their bones that is not a pauper's grave. Thus, to the newborn babe, to the strong man and to tottering old age is the hand of charity extended.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**Prominent Donor Honored.**—Mr. Henry Phipps, of Pittsburgh, who gave \$1,000,000 to found in Philadelphia an institution for the study and treatment of tuberculosis, has been elected an honorary member of the Pennsylvania Society for the Prevention of Tuberculosis.

**Twenty-two Pound Baby.**—From Washington, Pa., comes the news that Mrs. Thomas Allison, who lives at Midland, near here, gave birth to a son weighing 22 pounds. The child is said to be the heaviest ever born in Washington county and is healthy. The mother is doing well. The father is a coal miner.

**Defaulting Treasurer Sentenced.**—J. Howard Clemenson, defaulting treasurer of the Pennsylvania Epileptic Hospital and Colony Farm at Oakbourne, Pa., has been sentenced to eight years in the Eastern Penitentiary on the charge of embezzlement. The judge in his sentence said: "The man who stole from the poor, weak, and sick, deserves no consideration." The default amounted to about \$25,000.

**Intoxication from Gasoline.**—It is stated that physicians in Philadelphia, having noticed for some time past the prevalence of intoxication among boys caused by the inhalation of gasoline fumes, have united in requesting an autopsy on the body of a boy who was in the habit of inhaling gasoline and who was killed by an explosion of gas in a tank car. It was asserted that such necropsy would be of the greatest value in indicating the treatment of this form of intoxication and showing the extent to which the organs are affected.

**Clinics by Distinguished European Surgeons.**—Prof. Hans Kehr, of Halberstadt, Germany, will hold a clinic at the Jefferson Medical College Hospital at 1 o'clock on Saturday, May 9, 1903, and Prof. J. von Mikulicz-Radecki, of Breslau, will hold a clinic also on the succeeding Saturday, May 16, at the Jefferson Hospital at 1 o'clock. To both of these clinics members of the profession are cordially invited. In order that they may have suitable cases for their clinics members of the profession who have cases of gallstone for Prof. Kehr's clinic or cases of carcinoma or other surgical diseases of the stomach or intestines for Prof. von Mikulicz's, will kindly communicate with Dr. W. W. Keen.

**Department of Public Health and Charities Created.**—Governor Pennypacker, of Pennsylvania, has signed a bill establishing the Department of Public Health and Charities in Philadelphia. Among other provisions the bill reads as follows: "The Department of Public Health and Charities shall be under the charge of a director and an assistant director, whom the mayor shall appoint, to which department shall be confided the care, management, administration and supervision of the public health, charities, almshouses, hospitals, and all other similar institutions, the control or government of which is intrusted to the city. The Director of Public Health and Charities, as chief executive officer thereof, shall appoint, supervise, and control all the subordinate officers and employes attached to the department, and shall appoint all vaccine physicians and health inspectors; and all hospitals belonging to the municipality where provision is made for the care of contagious diseases shall be under the immediate supervision and control of the Director of Public Health and Charities."

**Amount of Water Consumed.**—It is asserted that in Philadelphia 250 gallons of water per capita are consumed each day. This, according to the chief of the Bureau of Filtration of the Water Department, is 100 gallons more per capita than should be, and that it warrants the installation of the meter system. Comparison with the consumption in other cities makes a showing unfavorable to Philadelphia: In Cleveland the consumption is 150 gallons; in Detroit, 146; in Cincinnati, 121; in Boston, 143; in St. Louis, 159, and in New York, 120 per capita daily. All these cities have large manufacturing interests and it is said that not one of them has the meter system generally applied, though in most of them there is a greater number of meters used than in Philadelphia. In Providence, R. I., which is one of the few large cities in which the meter system is generally used, the average daily consumption per capita is 54 gallons; in Milwaukee, under a like system, the consumption is 80 gallons. It is stated that Hamburg, Berlin, Rome and Naples and other large foreign cities are coming more and more to use the meter system.

#### SOUTHERN STATES.

**Cambridge Hospital.**—Contracts have been awarded for constructing a hospital to cost \$35,000 at Cambridge, Md.

**Leprosy in Texas.**—State Health Officer Tabor announced April 18 the existence of a case of leprosy in Galveston. This makes three known cases in Texas, the others being in Webb county. Dr. Tabor has asked the State Legislature for an \$8,000 appropriation to fight the disease.

**Suit Against Western Union Telegraph Company.**—The *Baltimore News* is authority for the statement that Dr. Howard Kelly has brought suit for \$2,000 against the Western Union Telegraph Company because of alleged neglect on the part of the company prevented him from attending an important surgical operation in Cambridge, Md., October 13, 1902. It is alleged that Dr. Kelly left Boston by train on October 12, 1902, and that telegrams were sent to intercept him at both New Haven and at Trenton, neither of which were delivered, consequently Dr. Kelly received no news of the contemplated operation, which, of course, was not performed by him.

**Valuable Gift to the Fricke Library.**—The Fricke Library of the Medical and Chirurgical Faculty of Maryland is the recipient of a present from Dr. William Osler, consisting of 123 theses for the degree of medical doctor by students of North America at the University of Edinburgh, Scotland, from 1760 to 1873, and secured by Dr. Osler from an Edinburgh publisher. Among the theses are some by the most distinguished of the old physicians of this country, among them being theses by Samuel Bard, Caspar Wistar, Philip Syng Physick, William Shippen, and others. Forty-three of the theses are by Virginians, and 23 by South Carolinians, the remainder from students in other parts of the country. The books are bound in different colors according to the State from which the men came, and most of them are in an excellent state of preservation.

## WESTERN STATES.

**The Medical Registration bill of Colorado** has been vetoed by the Governor through eddyite and press influence which has been brought to bear upon him.

**May Not be Tried for Grave-robbing.**—It is stated that Dr. Alexander, demonstrator of anatomy in the Central College of Physicians and Surgeons of Indianapolis, charged with complicity in grave-robbing, may never be tried, owing to the fact that none of the negro ghouls in jail awaiting trial will testify against the doctor.

**Births in Illinois.**—The State Board of Health of Illinois has compiled statistics on the reports of births in the State during 1902. The summary shows that a total of 76,608 births occurred in that period. Of the foregoing 38,671 were males, 37,325 females, and the sex of 612 was not stated in the reports to the authorities. There were reported also 572 twin births, 15 triplets, and 1,767 still births.

**Pure Food Law Defined.**—It is stated that the Supreme Court of Michigan has set aside the conviction and ordered a new trial in the case of Charles W. Jennings, who was convicted under the State Pure Food Law of selling a compound in imitation of lemon extract. The Court makes the important ruling that if the articles complained of contained all the ingredients and in quantities as prescribed by the pharmacopeia, which are adapted to use as food, and nothing was eliminated except such ingredients as could be dispensed with without injury to the product as a food product, there was no violation of the law.

**Work in Chinatown, San Francisco.**—The report of Surgeon Glennan, of San Francisco, for the week ended March 28, 1903, gives a summary of the work accomplished in Chinatown during the previous week. Buildings inspected, 63; re-inspected, 34; rooms inspected, 976; persons, 847; sick, 45; dead, 3; necropsies, 1; cases of plague, 0; rats examined bacteriologically, 43; places disinfected, 520; sewers flushed 7 times; streets swept and sprinkled with bichlorid solution, 3. Thus it appears that good and effective work is being done in a district which so long teemed with disease and was a source of danger, not only to the city of San Francisco, but to the entire country as well.

**Another Death from Plague.**—The public health report issued from the Marine-Hospital Service on April 8 recorded another death from bubonic plague in San Francisco. This is the first death from this disease since December 11, and it was hoped that the rigid method of inspection and sanitation adopted by local and federal authorities had stamped out the disease. Acting under this belief, Mexico recently abolished the quarantine against San Francisco; this quarantine may now be reestablished. It is stated that the work of the allied health authorities is still forging ahead, demolishing the pest houses of Chinatown, although the board is being strongly opposed by many property owners and others in the city, for purely business reasons.

**The Army and the Canteen.**—Major-General Blunt, of the Ordnance Department at Rock Island, has made a report against the continuance of the system of conducting the post exchange since the abolition of the canteen. After citing some of his objections to the system adopted in lieu of the canteen, General Blunt says: "Since the middle of last February, when the general order went into effect, there have been 11 court-martial cases in this detachment of about 80 men for the offense of drunkenness or other offense incident thereto, as compared with only 12 trials during the five years prior to last February. The post exchange, with its sale of beer and light wines under the regulations in force to last February was, in my opinion, the greatest influence for the promotion of sobriety and discipline in the army which I have observed during my 29 years' service as a commissioned officer. The detrimental effect upon this detachment of prohibiting the sale of beer and light wines is made very evident by the increase of 900% in the number of courts-martial during the last six months."

**Mortality of Michigan.**—During March the total number of deaths returned to the Department of State was 3,054, or an increase of 278 over the preceding month. The deathrate, however, was exactly the same as for the preceding month, being 14.4 per 1,000 population. The mortality was slightly higher than for March of the preceding year. By ages there were 582 deaths of infants under 1 year, 181 deaths of children aged 1 to 4 years, both inclusive, and 951 deaths of persons aged 65 years and over. Important causes of death were as follow: Tuberculosis of the lungs, 197; other forms of tuberculosis, 40; typhoid fever, 48; diphtheria and croup, 34; scarlet fever, 22; measles, 29; whoopingcough, 34; pneumonia, 403; diarrheal diseases, under 2 years, 51; influenza, 140; cancer, 143; accidents and violence, 150. Comparing March with the preceding month, there was an increase of mortality from all the causes stated above, with the exception of diphtheria and croup, which diseases showed considerable decrease. The mortality from influenza was nearly double that of the preceding month. The deathrate was slightly higher than for March, 1902. There were 3 deaths reported from smallpox during the month, against 5 deaths returned from this cause for February.

**Arizona's Laws.**—Contrary to what appears to be a general impression that Arizona has no law governing the practice of medicine, we note an act of that Territory regulating medical practice. It appears that before one can legally practise medicine he must have obtained a diploma regularly issued by a medical college legally organized under the laws of the State or Territory wherein such college should have been located at time of issuance of diploma; or shall have passed a State's examination under certain provisions of the territorial law; or shall have practised medicine for five consecutive years in the Territory of Arizona, immediately preceding the act. He must be a bona fide resident of Arizona and shall have attained the age of 21 years. The act authorizes a Board of Medical Examiners for Arizona, which shall consist of five members appointed by the Governor, three of whom shall be physicians of the regular school, one of the homeopathic school and one of the eclectic school of medicine. All candidates for examination to practise are given the same questions in physiology, anatomy, pathology, chemistry, practical surgery, obstetrics, and gynecology. In other subjects they may elect to take the examination from the member of the board which represents their respective school of medicine. License granted by the Board of Medical Examiners may be revoked by them at any time for grossly immoral or unprofessional conduct, after due hearing has been given the accused.

**What Constitutes Practice of Medicine?**—Arizona's legal definition could with profit be appropriated by the many States of the Union. We give the section in reference to this subject: Any person shall be regarded as practising medicine within the meaning of this act who shall, within this Territory, (a) by advertisement, or by any notice, sign or other indication, or by any statement, printed, written, or oral, in public or in private, made, done or procured by himself or herself, or any other, at his or her request, for him or her, claim, announce, make known or pretend his or her ability and willingness to diagnose or prognosticate any human diseases, ills, deformities, defects, wounds or injuries; (b) or who shall so advertise or make known or claim his or her ability and willingness to prescribe or administer any drug, medicine, treatment, method or practice, or to perform any operation, or manipulation, or apply any apparatus or appliance for cure, amelioration, correction, reduction or modification of any human disease, ill, deformity, defect, wound or injury, for hire, fee, compensation or reward, promised, offered, expected, received or accepted, directly or indirectly; (c) or who shall within this Territory diagnose or prognosticate any human diseases, ills, deformities, defects, wounds or injuries, for hire, fee, reward, or compensation, promised, offered, expected, received or accepted, directly or indirectly; (d) or who shall within this Territory prescribe or administer any drug, medicine, treatment, method or practice, or perform any operation, or manipulation, or apply any apparatus or appliance for the cure, alleviation, amelioration, correction or modification of any human disease, ill, deformity, defect, wound or injury, for hire, fee, compensation, or reward, promised, offered, expected, received or accepted, directly or indirectly; (e) or who shall act as the agent of any person, firm or corporation, in the practice of medicine as hereinbefore set forth, except it be in the advertisement of practice of dentistry, midwifery, or pharmacy, or in the usual business of opticians, or of vendors of dental or surgical instruments, apparatus or appliances. Any person or persons violating any of the provisions of this act upon conviction thereof shall be fined in any sum not less than one hundred (\$100) dollars, nor more than one thousand (\$1,000) dollars, or by imprisonment in the county jail for a period of not less than three (3) months, nor more than one (1) year, or both such fine and imprisonment, at the discretion of the courts.

## FOREIGN NEWS AND NOTES

## GENERAL.

**Eighty Skeletons in Hulk of "Reina Christina."**—The warship "Reina Christina," which was sunk in Manila Bay by Admiral Dewey, has been floated and beached. The skeletons of 80 of her crew were found in the hulk. Captain Albert R. Couden, commanding the naval station at Cavite, took charge of the remains of the Spanish sailors, expressing a desire to give them an American naval funeral. The Spanish residents, however, are anxious to ship the skeletons to Spain, and it is suggested that the United States transport "Sumner" convey them to Spain by way of the Suez canal in June.

**Hammurabi's Famous Babylonian Code.**—The last number of the *Records of the Past* prints a translation of this famous code; that which pertained to the surgeon's art reads as follows: If a surgeon makes a severe wound with the operating knife on a patient, and the patient dies; or opens a tumor of the eye on any one and the eye is lost, the surgeon shall have his hands chopped off. If a surgeon performs a serious operation on the slave of a freedman with an operating knife, and kills the slave, he shall give the owner a slave in the deceased one's stead. If the surgeon has opened a tumor on the eye of a slave with an operating knife, and the eye is destroyed, the surgeon is to pay one-half the price (value) of the slave to the owner.

## GREAT BRITAIN.

**Salicin and Salicylates.**—The death of Thomas John MacLagan, of Edinburgh, calls the attention of the profession to the fact that he discovered the curative action of salicin and salicylates upon rheumatism. As a result of his investigation and experiments the method of treating rheumatism was completely revolutionized, as the salicylates have been for a number of years almost constantly employed in the treatment of this affection, particularly acute rheumatic fever. It appears that the investigation which led to the discovery was upon entirely empirical ground. Dr. MacLagan supposed that rheumatism was miasmatic in origin, similar to malaria, and he was led to experiment with the drug *Salix alba* and with Meadow Sweet. He thus discovered the peculiar effect of salicin and its derivatives upon diseases of the rheumatic type. One can hardly overestimate the importance of this discovery since attacks of acute rheumatic fever, especially if they be repeated frequently, lead to grave cardiac diseases, which often lead to permanent impairment of the heart. This discovery has been of special value in shortening the attack, reducing the fever, and otherwise controlling the disease, no doubt in many instances preventing grave cardiac disease as a sequel.

## CONTINENTAL EUROPE.

**Drinking Evil in the German Army.**—The Hereditary Prince of Saxe-Meiningen, commander of the Sixth Army Corps, who recently issued an order advising soldiers to lodge complaints when they were ill-treated, has issued another corps order against drunkenness. He points out to the privates the damaging effects of alcohol on the health and usefulness of men and directs the regimental doctors to demonstrate to the soldiers its evil effects authoritatively and in a kindly manner.

**Alcohol and Civilization.**—Home Secretary von Posadowsky-Wehner formally opened the International Antialcohol Congress in Berlin. In his speech he pointed out that the increased mental and physical strain occasioned by the growth of civilization was apt to lead to excessive indulgence in drink. Legislation could only lend mechanical aid to the temperance movement. The real remedy must come from a higher sense of morality on the part of the people, which need not interfere with enjoyment of life.

**Mixed the Babies in an Incubator.**—It is stated by an exchange that suit has been brought in the courts of Amsterdam by a father who claims that in February last year a newly-born child was taken from the mother's care to be reared in an incubator. In accordance with medical advice the infant was packed in a wadding and hurried to the hospital, where the incubators stand ready to receive weakly babies. Meanwhile, in compliance with Dutch law, the father had the birth of a son registered, and the child was given the name of Franciscus Gerardus there and then. At the hospital a receipt was taken for the baby boy and he was put into one of the incubators. Some weeks passed and the parents received notice that their child was well enough to be taken away. Imagine the father's surprise when he went to fetch his son to have a baby girl thrust into his arms! The hospital nurse declared some mistake had been made by the parents. The parents, nurse and other witnesses declared the mistake was on the part of the hospital authorities. The baby girl was not wanted by the parents of the missing baby boy, and nobody else owned her. The father took proceedings against the mayor of the city, who is the nominal head of the hospital, and claimed £240 damages for his lost son. During the time the child was in the incubator the outside of the machine was painted, and, according to the plaintiff's advocate, the cards on which are written the particulars regarding the inmates were mixed up. A touch of romance is added to the case by the offer of an anonymous lady, who undertakes to pay the compensation claimed by the parents and adopt the girl who ought to be a boy. Judgment will be given next month.

## OBITUARIES.

**Thomas John MacLagan**, of Edinburgh, Scotland, March 20, aged 65. He obtained the Edinburgh degree of Doctor of Medicine in 1860. In 1879 he came to London, and speedily became a most successful physician, with several Royalties among his patients. In 1882 he became a member of the Royal College of Physicians of London. One of the first things that brought him to the notice of the profession was his paper on the Treatment of Rheumatic Fever by Salicin published in the *Lancet* in March, 1876. His discovery of the curative action of this drug led to the adoption of salicylates in the treatment of rheumatism. In 1881 he published a monograph on "Rheumatism, its Nature, Pathology and Successful Treatment;" a second edition of this work appeared in 1896. He also published other works, among which were "The Germ Theory of Disease" and "Fever: A Clinical Study." At the time of his death he was writing another book, which will be eventually published although it is not completed.

**William F. Smith**, of Baltimore, Md., April 14, aged 85. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1889. He was subsequently appointed resident physician at the City Hospital. Dr. Smith became a member of the faculty of the College of Physicians and Surgeons, and filled the chair of anatomy until ill health forced him to resign. He was also professor of anatomy at the Baltimore College of Dental Surgery.

**Albert G. Edwards**, at Perry, Okla., April 1, aged 65. He was graduated from the Missouri Medical College, St. Louis, in 1859, and from the University Medical College, Kansas City, Mo., in 1892. He had served as president of the Northern Kansas and Marshall County Medical Societies and of the Society of Surgeons of the St. Joseph and Grand Island Railway. He was also a member of the American Association of Railway Surgeons.

**James D. Craig**, of Chicago, Ill., April 13, aged 70. He was graduated from the medical department of the State University of Iowa in 1881, and for a number of years served as president of the Michigan State Homeopathic Medical Association. Five years ago he was elected professor of physical chemistry in the National Medical College of Chicago; he held this position for four years.

**George Anthony Collamore**, in Toledo, Ohio, April 8, aged 69. He was graduated from the Harvard Medical School in 1859, was a member of the American Medical Association, a charter member of the Toledo Medical Society, and served as its president several times. He had also served as secretary and president of the Ohio State Medical Society.

**Matthew Gardner**, in San Francisco, Cal., April 18, aged 56. He was graduated from the McGill University, Montreal, Can., in 1871. He was chief surgeon of the Southern Pacific Hospital system, and a member of the American Medical Association, California State Medical Society, and the San Francisco County Medical Society.

**Chauncey Ayres**, at Stamford, Conn., April 14, aged 95. He was graduated from the Yale Medical School in 1831 and was their oldest graduate. In 1832 he served as one of the surgeons in the New York Cholera Hospital. Later he became surgeon of the United States Coast Survey.

**Jean B. V. Laborde**, of Paris, France, died recently at the age of 73 years. He was a member of the Académie de Médecine and became well known to the profession through his method of restoring asphyxiated persons by rhythmical tractions of the tongue.

**Hiram S. Roberts**, in Manhattan, Kan., April 1, aged 62. He was graduated from the Jefferson Medical College, Philadelphia, in 1866. He was at one time president of the Kansas Medical Society, and also served as a member of the State Board of Health.

**Frederick Nehrbo**, of Brooklyn, N. Y., April 13. He was graduated from the Long Island College Hospital in 1891. He had served on the medical staff of the Kings Park and Flatbush Hospitals.

**Joseph F. Harrell**, in Whiteville, N. C., March 31, aged 70. He was graduated from the Castleton (Vt.) Medical College in 1855 and was a member of the North Carolina State Medical Society.

**John E. Sanborn**, in Melrose, Mass., April 1, aged 79. He was graduated from the Harvard University Medical School in 1850. He served as a surgeon during the Civil war.

**William C. Fritz**, in Buffalo, N. Y., March 31, aged 36. He was graduated from the University of Buffalo in 1892, and was a member of the American Medical Association.

**E. H. Williams**, in Walterboro, S. C., March 31, aged 45. He was graduated from the Medical College of the State of South Carolina, Charleston, in 1879.

**Charles Howard**, of St. Paul, Ind., April 18. He was graduated from the department of medicine of the University of Indianapolis in 1896.

**Alfred L. Murtha**, in Brooklyn, N. Y., March 22, aged 25. He was graduated from the Baltimore University School of Medicine in 1901.

**Reinhard H. Weber**, in Philadelphia, March 30, aged 59. He was graduated from the Jefferson Medical College, Philadelphia, in 1866.

**Charles L. Siegel**, near Richmond, Va., April 4, aged 83. He was graduated from the Medical College of Virginia, Richmond, in 1891.

**William D. Hutchings**, in Madison, Ind., April 3. He was graduated from Indiana Central Medical College, Indianapolis, in 1851.

**John MacLay**, in Richmond, Kan., April 5, aged 55. He was graduated from the Jefferson Medical College, Philadelphia, in 1882.

**I. H. Hand**, in Leary, Ga., March 22, aged 80. He was graduated from the Reform Medical College of Georgia, Macon, in 1851.

**S. Hartwell Chapman**, of New Haven, Conn., April 15, aged 59. He was graduated from the Yale Medical School in 1866.

**A. G. North**, in Hampton, Ga., March 29, aged 47. He was graduated from the Atlanta (Ga.) Medical College in 1879.

**John A. Edmiston**, in Clinton, Ill., April 5. He was graduated from the Rush Medical College, Chicago, in 1866.

**E. Darwin Ayres**, in Little Rock, Ark., April 8. He was graduated from the New York University in 1852.

**J. H. Bryant**, in Los Angeles, Cal., April 5, aged 69.

**William B. Town**, in Geneva, Mich., April 1.

**J. L. Rowland**, at Salyersville, Ky., April 4.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

THE DANGERS OF DRUG USING WITHOUT GUIDANCE.<sup>1</sup>

BY

J. MADISON TAYLOR, A.M., M.D.,  
of Philadelphia.

If a physician were to prescribe the many powerful, poisonous, or otherwise to be avoided materials which are employed in the treatment of bodily ailments, by telling his patient to go to the nearest wholesale drug house and buy a lot of this or that particular drug and use it at his or her discretion, he would be adjudged an extremely dangerous person, and receive well merited blame. If we were to tell the patient that his liver or kidneys clearly showed faults or damage, and that it would be well to try one or more of the various "sure cures" for liver or kidney disease until one was encountered which might prove capable of modifying his symptoms, he would speedily forfeit the confidence of the community, unless it were a shade less confiding than the average community, which can, as a rule, stand a large measure of medical nonsense.

If, however, he were to tell his patient to approach the aforesaid drug emporium and choose liberally of whatever was there offered, and give a faithful trial to all the various well exploited compounds, according to the very graphic descriptions and recommendations inscribed on the labels, or the beautiful circulars which accompany them, and thus select that which he should find best suited to his ailment, the medical adviser might get some praise for the breadth of view, but little for judgment. Yet many sufferers and a large proportion of the intelligent populace of a country, our country anyhow, are pursuing this course at most times and places, laying up for shrewd manufacturing folk princely fortunes, and for themselves heaven only knows how much of ill-fortune in disordered organs; or equally deplored, failing to get, by the exercise of such undirected choice, advice which might check the incipience of disease and save much suffering and shortening of life. Upon what economic ground can self-prescribing be defended? Careful articles have been written to show that drugs and nostrums, bought and consumed, extra medical advice or supervision, approach closely in value the total amount paid the medical profession in fees. If the honorariums of the surgeons for large operations, and large expert medical fees be omitted, it is fair to assume that the aggregate receipts of regular routine medical earnings would foot up to no less than the grand total from self-prescribed drugs and nostrums.

What possible good can follow this widespread use of these endless pseudo remedies? The question demands answer from those who defend this course by their actions. But perhaps the poor deluded victims of the habit or practice, or what you choose to call the custom, are not capable of offering reasons. The query might be put to the makers of nostrums, but they can always furnish most subtle reasons for everything. Again, they are in the main honest workers and often most scientific, as science is generally defined. They know their chemistry, and many of them their physiology, as few of the medical practitioners can claim to do. We are compelled to look to them or to the large manufacturing chemists, with their highly paid experts and enormous and elaborate laboratories, to tell us much that cannot well be learned otherwise.

Ofentimes much that these manufacturing chemists discover we ought to know from other sources. The trouble is they present their data from a commercial standpoint, and much of it and in too verbose a form.

It requires a quality of training, a critical faculty far in excess of that of all but a minute fraction of clinicians, even specialists, to sift out the measure of grain from the bushels of well-meant, semiscientific chaff.

The character of much of the research work of even the trained medical men again is so inchoate, so lacking in con-

sistent relationships to the work of other men, so removed from sound physiologic principles that the rank and file of clinicians are apt to remain in a perpetual maze in their endeavors to reconcile the endless "conclusions" of these research workers reach to clinical facts. If medical science is to fulfil its brilliant promise or its optimistic hopes it would certainly seem to need the fostering aid of men of critical judgment, prophets of power and wisdom, whose sole aim shall be to simplify, to connote, to bring medical thought ever steadily back to fundamental truths, based upon elemental physiology. And these we need much more than increments of research work in pharmacology or experimental therapeutics, certainly in so far as the effects of drugs are thus studied.

The obvious need is for therapeutic teaching which shall disregard unflinchingly glittering new facts until they are demonstrated to be of intrinsic worth, to present broad principles capable of being accepted by all, for there are enough of such principles evolved to form a firm working basis, permitting all reasonable elastic amplifications when needed. It may be claimed that this is done; but few practical physicians will fail to recognize that their own early teaching leaves much to be desired of clean physiologic principles. We read in current journalism daily of the utter overthrow of the confident teaching of our student days. All this is called inevitable progress, yet it must be admitted that truths are for all time, not for the span of our short life and experience; and "the institutes of medicine," as physiology was wisely aforesaid called, when stripped of progressive conjectures ought to constitute a working hypothesis good for eternity. We need professorships of physiologic clinicism or clinical physiology and one of physiologic diagnosis. The science of diagnosis, to fulfill its highest purposes, must be made to begin from within, to proceed along elemental principles of vasomotor tonus, the ebb and flow of the nutrient fluids by alternations in the control agents, the vasodilators and vasoconstrictors, rather than from external surface indications.

What shall we do to stem the tide, the steadily increasing tide of drug using, of reckless, of senseless, of undirected or foolishly directed drug using? Is such a state one of high civilization, an evidence of an intelligent scientific age? It is to be feared we will stand arraigned in later ages as a drug consuming race and this an epoch of dose swallowing. Is it that the medical men are to blame? Assuredly we are, unless we keep our heads and decline to be hurried in our pharmacologic judgments by both drug manufacturers and laboratory physicians. The stimulus to change our principles of action too often comes from quacks and charlatans. The time was when these fellows outdid us in the variety and picturesqueness of their nostrums and we followed. Now the tide is turning the other way, and we had best stand clear of over use of drugs and turn our attention to the great field of scientific climatology and mechanotherapy, the use of waters and heat and cold, and light and special rays, and the like whereby the greatest results are yet to be had.

Above all, the medical practitioners will do well to take heed of the abundant facts demonstrated by manual therapy, which has already become a great heritage, and though well recorded is still scattered, unsystematic and not yet authoritative and unfortunately ignored by those who should know better and make use of the agency themselves.

Why do medical men, who alone can use them knowingly, relegate remedial movements and manipulations to loosely and briefly trained folk whom they regard as their inferiors, called masseurs, bonesetters, physical professors, and such, and content themselves with administering an ever increasing variety of drugs?

Chiefly because we are indolent or indifferent and follow along well-beaten paths which are lines of least resistance. We, all of us, are imbued with the ideas of feticism more or less, which our homeopathic brethren have largely fostered. It is so easy to lean on the confident assertions of those high in authority, those teachers who have had it personally revealed to them by private advices from the Throne of Wisdom, precisely how certain drugs act on the ultimate atom. To be sure we need this faith and need it badly till our works justify our faith. Our medicines assuredly do at times help our patients

<sup>1</sup>Read at a meeting of the American Academy of Medicine, March 21, 1903.

mightily. Especially in emergencies and when we cannot continue personal supervision. But the pity of all this is that our faith is blindly amplified in those who have little or no capacity or training to judge of the effects thus wrought, and who, trusting to the marvelous recuperative powers of human cells, surpass us in confidence in the curative powers of drugs. We set the example, we praise the agents, we or our colleagues of the manufacturing guild sing largely of wonders wrought and to be wrought, and the public, having much desire to get well and keep well, give us a Roland for our Oliver and take undirected ten times the potions and pills we would think already too much.

And some of these self-selected medicines are most seductive, fostering evil appetites, containing as they do hurtful amounts of alcohol or other narcotics. This is true of the much advertised concentrated foods, as to the virtues of which people of much influence who should know better lend their names. Most wines or preparations of drugs containing wines are taken independent of professional direction. Especially are these harmful when they are the menstruum of narcotic drugs, some of which stimulate or awaken morbid passions, and most inculcate or increase the appetite for alcohol. The one influence on which we ought to be able to depend to limit the overuse of hurtful drug preparations should be the clergy, and they would thus accomplish far greater good than by hurling carefully tempered anathemas at the amusements of the rich and at Sunday open-air sports.

Again, one suggestion to which time forbids more than a mere allusion: If the overuse of drugs is perilous, what of the adulterations also consumed? But that is another story.

## ULTRAVIOLET RAY ANESTHESIA IN MINOR SURGERY.

BY

THOMAS W. BROCKBANK, M.D.,  
of Philadelphia.

More or less attention has been given recently to the treatment of certain forms of disease by the ultraviolet rays, and this being a comparatively new field of study it is very desirable that all men who have had a chance to study the conditions best suited for the use of this method and the class of cases or conditions to which it is most applicable should report their results that ultimately its proper field of usefulness and its therapeutic limitations may be determined.

With this end in view I desire to report two recent cases in which I used the ultraviolet rays for the purpose of producing local anesthesia of the skin.

CASE I.—Mr. McK., aged 24, called at my office March 16, suffering from a wound received while at work as a grinder in the Germantown Tool Works. On examination I found a clean incised wound of the left forearm extending from the head of the ulna parallel with the bone for a distance of two inches, exposing the tendons of the muscles in that region throughout its entire length. After cleansing the parts in the usual manner I exposed the injured area for 15 minutes to the rays from a No. 4 Munnin lamp, at the end of which time I put in five interrupted silk sutures without causing the patient any discomfort. I dusted the area with an antiseptic, dusting equal parts of ur-a-sol and aristol powder, covered with 10% iodoform gauze, a small compress of absorbent cotton and a roller bandage. The wound healed nicely and gave no trouble.

CASE II.—Fatty tumor. Mrs. S., a widow, aged 45, consulted me March 25 in reference to a swelling just below the left breast. Said she had noticed it for over a year, it gave no pain and enlarged very slowly. She had been advised to have it removed but had not done so because she dreaded taking an anesthetic. Examination showed a fatty tumor. Her purpose in consulting me was to have it removed if possible by electrolysis. I advised removal with the knife under violet ray anesthesia to which she consented. After thoroughly cleansing the site of the operation I exposed it to a No. 4 lamp at eight inches for 20 minutes, and at slightly greater distance during removal. I made an incision two inches long down to the tumor without causing sufficient pain to give any distress. After breaking up adhesion I shelled the tumor out without difficulty. The hemorrhage was slight and readily controlled by pressure. Edges of wound were brought together and held by fine interrupted silk sutures without complaint on part of patient. Dressed with antiseptic powder and iodoform gauze and compress held in place by adhesive strips and a roller

bandage. Patient suffered no shock or distress of any kind, was taken to her home in carriage and put to bed. Dressings were examined on second day and found perfectly dry; were left alone till fourth day when they were removed. Wound was healed perfectly, stitches were removed and an iodoform gauze dressing applied to remain for two days.

These two cases illustrate nicely the anesthetic properties of the violet rays and suggests a class of cases to which they are applicable. As my experience extends in the use of this new agent I will from time to time make further reports and hope others who work along these lines will do the same.

## SELF-PERFORMED SURGICAL OPERATIONS.

BY

H. E. RANDALL, M.D.,  
of Lapeer, Mich.

In Gould and Pyle's "Anomalies and Curiosities of Medicine," under the title "Self-performed Surgical Operations," p. 703, a case is reported with the remark that this is probably the only instance in which a patient suffering from vesical calculus tried to crush and break the stone himself.

An old book, "Surgeons and Hospitals of Paris," written by F. Campbell Stewart, M.D., and published by A. Burke, Buffalo, which belongs to Dr. Kay, of Attica, relates the case of General Claude Martine. In the biography of Civiale the following occurs: "Frequent attempts had been made by the older surgeons to accomplish the desirable end of removing stone from the bladder without having recourse to lithotomy; and even as far back as 400 years before Christ Hippocrates conceived the idea that such a result was practicable. Since his time and through almost every succeeding age numerous attempts, always progressing, have been made both by professional men and those wholly unacquainted with the principles of our art. No positive advance was made, however, notwithstanding the valuable fact communicated by the experience of General Claude Martine, who positively accomplished the partial destruction of a stone contained in his own bladder by the assistance of a small file, which he introduced through a catheter, and with which he broke off small fragments from the calculus, which were afterward expelled."

## USES OF APOMORPHIA.

BY

W. A. HOWARD, M.D.,  
of Waco, Texas.

To the Editor of American Medicine:—In your issue of March 28 Dr. E. R. Shannon speaks of the varied conditions in which he has successfully applied apomorphia. I have used it with success in all the diseases of which he speaks except hiccough and angina pectoris. Various anginas are relieved by its use, but caution is necessary in diagnosis, as in those due to bronchial edema its use is contraindicated. However, there are still a few diseases which have been the *bête noire* of all physicians in which much rest can be given to both patient and physician by the administration of apomorphia. Asthma yields gracefully to its influence, as all those spasmodic cramps so common in those of a rheumatic diathesis, their night's sleep gained. Strychnin poisoning is much alleviated by its prompt action in relaxing the spasms. In all those conditions in which morphia is required to secure rest and sleep, given in 5 mg. ( $\frac{1}{2}$  grain) doses, combined with apomorph. 3 mg. ( $\frac{1}{2}$  grain) or more, we get far better results than with large doses of the former given alone.

Men's Public Laundry.—In Philadelphia for the past two years the Board of Trustees of the Public Bath Association have found it necessary to exclude men from the Gaskill Street Laundry in order not to lose the patronage of women, since which time the number of women patrons has greatly increased. It is now announced that ground has been secured nearby where a new public bath house and laundry for women will be built, leaving the old institution to be used as a men's public laundry. The cost of the new site and building will be about \$8,000.

## ORIGINAL ARTICLES

## ON VOLUMETRIC TESTING FOR SUGAR.

BY

JOHN MARSHALL,

Professor of Chemistry and Toxicology, University of Pennsylvania,

AND

LEON A. RYAN, PH.D.,

Assistant Demonstrator of Chemistry, University of Pennsylvania.

The title given above is that of a paper published by F. Waldo Whitney, M.D., in the *New York Medical Journal*, January 25, 1896, page 119. The paper in the form of an alleged copyrighted reprint is being used by a chemical company in New York for the purpose of vending the solution described in the paper, and indeed the original publication in the New York journal has a foot-note appended to the effect that "physicians can procure the reagent accurately compounded as described" from the chemical company. Furthermore, in a circular issued by the chemical company it is stated that the solution is used in certain laboratories, among them being the laboratory of the University of Pennsylvania. This is an erroneous statement so far as the University of Pennsylvania is concerned. The solution has never been used in the laboratory of the University of Pennsylvania.

A physician of our acquaintance, who has for some time past been using the solution, sent us the pamphlet with the request that the formula for the preparation of the solution as given in the paper be so simplified that the solution could be prepared by a person possessing a fair knowledge of chemistry. The indefiniteness in description of the preparation of the solution and the statement that "aque dest. q.s." to make the solution of such strength that 3.696 cc. shall correspond to 0.00526 gram of glucose give reason for the request of the physician. In endeavoring to comply with the request of the inquirer we found that if the solution be prepared according to the published formula of Whitney (and it was so prepared by us), in which all of the constituents, solid and liquid, are taken in parts by weight, the volume of the solution will be 385 cc. even without the addition of "aque dest. q.s." The value in terms of glucose of such a solution will depend upon the quantity of cupric sulfate employed in the preparation of the solution. In order that the quantity of cupric sulfate stated by Whitney (2.5587 grams) shall be in such dilution so that 3.696 cc. of the liquid shall contain an amount of cupric oxide that will be reduced to cuprous oxide by 0.00526 gram of glucose the volume of the liquid should be 259.3 cc., whereas the solution prepared according to Whitney's directions, even without the addition of "aque dest. q.s.," amounts to 385 cc., a volume far exceeding the volume (259.3 cc.) which the solution should be if 3.696 cc. are to correspond to 0.00526 gram of glucose. Whitney explains why 0.00526 gram is taken instead of a single number, as is usual in such solutions to express the value of the 3.696 cc. in terms of glucose, by the statement that it is equivalent to one-thirtieth of a grain. The fraction of a gram named (0.00526), however, is equivalent to approximately one-twelfth of a grain, apothecaries' weight, and not one-thirtieth of a grain.

If the solution were made according to Whitney and "aque dest. q.s." were not added the solution, as said before, would measure 385 cc. If this solution were used in quantitative determinations of glucose the value of each 3.696 cc. expressed in terms of glucose would be 0.00354 gram, a quantity somewhat less than 0.00526 gram, and if "aque dest." were added its value in terms of glucose would be still less than 0.00354 gram.

Even if a solution containing the ingredients pro-

posed by Whitney were made so that each 3.696 cc. should actually correspond to 0.00526 gram of glucose it does not seem to us that it would possess any advantages over ordinary Fehling's solution prepared as shall be described below, provided the solution of cupric sulfate and the solution of sodium potassium tartrate (Rochelle salt) in sodium hydroxid shall, for the purpose of preventing decomposition, be kept in separate bottles.

## FEHLING'S SOLUTION ON THE BASIS OF THE PREPARATION OF 1,000 CC.

Well crystallized, non-effloresced, chemically pure cupric sulfate is pulverized and immediately spread on and pressed between sheets of bibulous paper to remove moisture which may have been held mechanically by the crystals employed. Exactly 34.687 grams of the pulverized and dried material are quickly weighed and dissolved in about 400 cc. of distilled water at ordinary temperature, and when complete solution has occurred the liquid is diluted to exactly 500 cc. by the addition of distilled water. This liquid is then thoroughly agitated so that the solution shall become homogeneous in its content of cupric sulfate. It should be placed in a bottle stoppered with a rubber stopper.

Approximately 173 grams of pulverized sodium potassium tartrate (Rochelle salt) are dissolved in about 480 cc. of sodium hydroxid solution of 1.140 specific gravity. When complete solution has taken place the liquid is diluted with distilled water to a volume of 500 cc. This solution should be placed in a bottle stoppered with a rubber stopper.

When equal volumes of the cupric sulfate solution and of the Rochelle salt solution are mixed Fehling's solution is produced and 1 cc. of it will correspond to 0.005 gram glucose.

In employing this solution in making rapid determinations of the quantity of glucose in urine, determinations which are sufficiently accurate for clinical purposes, 5 cc. of the Rochelle salt solution may be added to 5 cc. of the cupric sulfate solution, thus making 10 cc. of Fehling's solution. One cc. of this Fehling's solution should be taken from the vessel and placed in a test-tube and diluted with about 4 cc. of water, and the liquid should be heated to the boiling point. The heated liquid should be held in various positions in reference to the source of light in the room, in order to observe whether any decomposition has occurred in the liquid itself. The production of a reddish-brown precipitate of cuprous oxide which may remain in suspension in the liquid would indicate that such decomposition had occurred. If, under these conditions, a precipitate of cuprous oxide should be produced, the Fehling's solution is unfit for use. However, thus far in our experience we have not found a Fehling's solution prepared from the two solutions kept separately that has shown evidence of decomposition when tested by diluting with water and heating to the boiling point.

The 1 cc. of Fehling's solution which had been diluted with about four volumes of water and heated to the boiling point to ascertain whether decomposition of the solution itself had occurred, is now ready to be used in the determination. To the solution in the test-tube the urine is added from a pipet, a drop at a time (and the number of drops used is noted), and the liquid is heated to about the boiling temperature after the addition of each drop of urine. The addition of the urine, a drop at a time, and heating the liquid after the addition of each drop, is repeated until finally the blue color of the liquid has disappeared. As two drops of urine are approximately equal to one-tenth of a cubic centimeter, therefore the number of drops of urine employed divided by two will furnish a number which, when expressed in tenths, will approximately correspond to the volume in tenths of a cubic centimeter of the urine employed.

The following table expresses the percentage of glucose present in the urine, as indicated by the quantity of the urine in tenths of a cubic centimeter, required to

exactly decolorize 1 cc. of Fehling's solution diluted with 4 cc. of water :

Cc of urine.	Glucose, percent.	Cc. of urine.	Glucose, percent.
0.1.....	5.0	0.4.....	1.25
0.12.....	4.2	0.45.....	1.1
0.14.....	3.5	0.5.....	1.0
0.16.....	3.1	0.6.....	0.83
0.18.....	2.7	0.7.....	0.71
0.2.....	2.5	0.8.....	0.62
0.25.....	2.0	0.9.....	0.55
0.3.....	1.66	1.0.....	0.5
0.35.....	1.4		

Instead of using the table the following rule may be employed :

Divide the whole number 5 by the number of tenths, converted into whole numbers, of urine employed. The result will be the approximate percentage of glucose.

EXAMPLE: If 12 drops of urine had been required for the decolorization of 1 cc. of Fehling's solution, and two drops of urine are approximately equal to one-tenth of a cubic centimeter, then 12 divided by 2 would give a number (6) which expressed in tenths would represent the number of tenths of a cubic centimeter corresponding to the drops of urine employed, namely, 0.6. This expressed as a whole number and used as a divisor of the number 5 would result  $5 \div 6 = 0.83\%$  of glucose. According to the table, 0.6 cc. represents a urine containing 0.83% of glucose.

Or, to avoid calculation, the number of drops of urine employed to decolorize the one cubic centimeter of Fehling's solution may be noted and the approximate percentage of glucose directly ascertained by consulting the following table :

Drops.	Glucose, percent.	Drops.	Glucose, percent.
1.....		14.....	0.71
2.....	5.0	15.....	0.66
3.....	3.3	16.....	0.62
4.....	2.5	17.....	0.58
5.....	2	18.....	0.55
6.....	1.66	19.....	0.52
7.....	1.4	20.....	0.5
8.....	1.25	21.....	0.47
9.....	1.10	22.....	0.45
10.....	1	23.....	0.43
11.....	0.9	24.....	0.41
12.....	0.83	25.....	0.4
13.....	0.76		

The international atomic weights (oxygen = 16) were employed in making the calculations for this paper.

## A CONTRIBUTION TO THE STUDY OF MANUBRIAL DULNESS, ESPECIALLY AS RELATED TO ENLARGED BRONCHIAL GLANDS.

BY

H. B. WHITNEY, M.D.,

of Denver, Colo.

Professor of Medicine, Denver and Gross Medical College of Denver, Colo.; Visiting Physician Arapahoe County Hospital, St. Luke's Hospital, National Jewish Hospital for Consumptives, etc.

Among the many signs of disease of the organs of the mediastinum, percussion affords some of the most important. Normally we expect to find good resonance over the whole sternum; a resonance of possibly slightly higher pitch than that of the adjoining regions, but still scarcely distinguishable from ordinary pulmonary resonance. Occasionally, however, there are exceptions to this rule. Those pertaining to the lower half—the normal enlarged precordia of childhood, for example—do not interest us here. I refer rather to a normal dulness of the manubrium, usually not pronounced, and due, perhaps, to unusual thickness of the bone, or possibly to a rachitic protrusion. Such a dulness is of approximately the same contour as the bone itself; and its chief characteristic as distinguished from pathologic conditions is its symmetric shape. I should always be suspicious of the pathologic significance of any slightly dull area over the upper sternum which, extending but little beyond the

borders of the bone, should show no difference between its right and left boundary.

Pathologic areas of dulness are usually irregular in outline, lying chiefly either to the right or left of the median line. In my experience such areas are oftenest small and not appreciable on superficial examination. The dulness is rarely absolute, sometimes very slight. Large aneurysms or mediastinal growths of sufficient size to give rise to a pronounced area of flatness are certainly exceptional.

The following cases are reported with a view chiefly to the study of the significance of dull areas over the upper sternum. Some of them present also other features of general interest.

CASE I.—J. F. S., aged 43, entered the hospital February 23, 1898. He was an habitual hard drinker for several years, otherwise his history is negative up to two years ago. At this time he had an attack of dropsy with cough and dyspnea, and since then his legs have been edematous much of the time. He was able, however, to work until three weeks ago, when dyspnea again came on and steadily increased.

*Physical Examination.*—Kyphotic since childhood, hence is much under size, with a very prominent abdomen and projecting sternum. Pulse is 120, small and weak, respirations 30 and difficult. Face and hands are turgescant and cyanotic. There is extensive edema of feet and legs, moderate of the abdomen, very slight of the lungs. The liver extends about one inch

Fig. 1.

Fig. 2.

below the margin of the ribs. Heart is generally enlarged, the precordia extending three inches to the right of the median line, and to the anterior axillary line on the left. A very slight systolic souffle is heard at the apex.

Under rest in bed with at first digitalis and diuretin and afterward strophanthus, a very remarkable improvement was noticed on March 5. Cyanosis had entirely disappeared and edema nearly so. A souffle was no longer heard, and the extension of precordial dulness to the right was now only one and one-half instead of three inches. Respiration was wholly normal. On this day for the first time, though undoubtedly present before, an area of dulness to the left of the sternum was noticed, as shown in the figure.

The degree of dulness was but slight, and over this area respiration was practically normal. With the exception of a slight difference in the strength of the two pulses, which the patient states had been noticeable for years, there were no symptoms which could possibly be attributed to mediastinal pressure or irritation. In short, apart from this slight dulness the case appeared to be a simple one of cardiac dilation and insufficiency, probably mitral in origin. The patient left the hospital about a month later in excellent condition.

CASE II.—A. G., aged 51, a miner, was admitted to the hospital on March 22, 1898. He gave a history of several attacks of rheumatism in the past 30 years. He has had a cough for the past year with expectoration of half a teacupful in 24 hours. There was no hemorrhage. He has lost 12 pounds in weight in the last two months. His strength has diminished and he complains of dyspnea on lying down. For 10 days the feet have been swollen for the first time.

*Physical Examination.*—The patient is pale, thin, weak, slightly cyanotic, and is confined to his bed. There is moderate dyspnea and marked edema of the legs. Lungs apparently normal except for a slight dulness at both bases behind. The heart shows all the signs of aortic regurgitation: marked enlargement, both to the right and left, precordial throbbing, pulsation of carotids and a double aortic murmur. The pulse is regular but vibratory and markedly Corrigan. The arteries are very atheromatous and in the carotids and femorals a single sound—a systolic souffle—is heard. Over the upper sternum there is unilateral dulness as in Fig. 3.

The patient was in the hospital off and on for about five months. During this time he developed also a pericardial effusion, which subsequently subsided, leaving about the same precordial area as before. When he eventually left the hospital his edema had disappeared and he was up and about in fairly good general condition. At no time was there any tracheal tug,

or pulsus differens, or local pulsation, or other sign of aneurysm. His subsequent history is unknown.

**CASE III.**—A. D., miner, entered the hospital April 29, 1898. He gives a history of slight cough for about two years with daily expectoration of half an ounce of at times slightly reddish sputum. He has lost about 35 pounds in weight. His chief complaint is of aphonia and difficulty in respiration.

**Physical Examination.**—The patient is poorly nourished, very slightly cyanotic, not cachectic. He can talk only in a whisper. Marked difficulty of respiration as if there were some laryngeal obstruction. No fever at entrance nor at any time until death.

Examination of the lungs showed slight dulness behind over the left apex and interscapular region with somewhat diminished respiration over this area and over left front. The right lung was markedly emphysematous, extending in the mammillary line as low as the eighth rib. Over both lungs, front and back, there were scattered dryish rales like those of chronic bronchitis with asthma. The cardiac area extended  $\frac{1}{2}$  to 1 inch to the left of the left mammillary line and to the left sternal border toward the right. There were no scuffles, but the second pulmonic was much accentuated. Above was found the dull, almost flat, area shown in Fig. 4; perhaps not very sharply defined toward the left, but sufficiently circumscribed. Here respiration was very much diminished and at times slightly bronchial; rales were scarcely more prominent than elsewhere. In the left intraclavicular region was a gland the size of a walnut. Examination of the throat showed paralysis of the left cord, but was otherwise negative. The right radial artery was markedly atheromatous and had a pulse much feebler than, though synchronous with, the left. There was no tug or carotid pulsation, no edema. Sputum examination was negative. Heart's action was feeble—there was certainly no evidence of a hypertrophied left ventricle.

This case suggested strongly mediastinal tumor or possibly aneurysm in several particulars, especially the laryngeal paralysis, pulsus differens, and diminished respiratory murmur on the left. During the three months or so which elapsed before death there occurred no marked change except progressive weakness, and toward the last the development of slight

Fig. 3.

Fig. 4.

Fig. 5.

enlargement of the heart toward the right, together with slight edema of the feet. More moisture also was heard over the upper left lung and the respiratory murmur became still more markedly diminished. The final termination was from pulmonary edema.

The *autopsy* in this case showed a very high degree of pneumoconiosis. The pleuras were adherent and thickened throughout. The upper portions of both lungs were black and showed much fibrous thickening. This was most pronounced at the left apex, and especially corresponding to the dull area near the sternum, where the lung tissue and bronchial glands were converted into a dense black homogeneous tissue, which cut like tough cheese. There were no cavities. The recurrent laryngeal nerve, and in part the trachea, were doubtless enveloped in this mass of hyperplastic tissue. The heart showed considerable dilation of the right chambers and also a dilation of the pulmonary artery which was somewhat short of aneurysmal. The dull area, however, was undoubtedly due to the bronchial adenopathy with surrounding condensation of lung tissue.

**CASE IV.**—J. E., aged 63, a painter, was admitted to the hospital on January 12, 1902. He gives an indefinite history of cough and expectoration for a long time, 10 years or more, but without loss of flesh, hemorrhage or other signs of pulmonary tuberculosis. About two weeks ago he was attacked with a sudden, sharp pain in the region of the left nipple, and this has persisted ever since, with slight bloody expectoration on the seventh and a little dyspnea. There was no rigor, but some chilly sensations. He was not confined to bed.

**Physical Examination.**—He is fairly well nourished, and does not give the impression of being very ill. He has constant cough, with abundant mucopurulent expectoration, and slight, irregular fever. Respirations are but slightly increased. Chief complaint is of pain in the left chest, though this apparently disturbs him but little.

Percussion of the precordial area showed a very peculiar condition, as indicated in Fig. 5.

In the first place there was found, above and to the right of the manubrium, a dull area continuous below with the pre-

cordia. The latter showed no increase beyond normal limits toward the right; indeed, it seemed hardly to reach the left sternal border, as if the heart were slightly displaced toward the left. On the left the cardiac area appeared to be very much increased. There was a sharply defined dulness extending two to three inches beyond the mammillary line, and curving upward so as to simulate an enlarged precordia. The apex of the heart was heard loudest in about its normal position. The heart sounds were clear, and but little if at all distant. Examination of the lungs was negative, with the important exception of a very great diminution of the respiratory murmur throughout the left front and back without adventitious sounds or alteration of resonance.

On the day following admission exploratory puncture was made at x, about an inch outside the left nipple, and a clear fluid was obtained. This seemed to confirm the diagnosis which had been made of pericardial effusion. It was thought to be very extraordinary that the latter had not produced the usual increase of dulness to the right; but the right lung was markedly emphysematous, as shown by its extension nearly to the free margin of the ribs in the right mammillary line, and even in the absence of any precedent it was thought, very illogically as must now be admitted, that the emphysematous lung might overlap and conceal the distended pericardium, as it not infrequently does an enlarged heart. It is greatly doubted whether this could ever occur in any such degree as was here presumed.

The other physical signs in the patient were chiefly negative; pulses were synchronous, there was no tracheal tug, no throbbing of carotids, nor any other sign of exaggerated heart action. Nothing was heard over the area of manubrial dulness, except diminished respiration. There was no change in the larynx or pupils. Bacilli were not found in the sputum, which had no odor. The urine was negative and there was no edema.

The diagnosis in this case seemed to be acute pericardial effusion, with chronic bronchitis and probable enlargement of the bronchial glands. The subsequent history until the final catastrophe apparently confirmed this diagnosis. In three weeks the precordial dulness had nearly returned to normal, although in subsiding an irregularity of the outer curve developed, which should, perhaps, have aroused fresh suspicion that the fluid withdrawn had not come from the pericardium. (See dotted line in Fig. 5.)

The prognosis in this case seemed favorable until February 25, about six weeks after admission, when a sudden rigor was followed by a rise of temperature to 104° and by the appearance at about the third rib in the left mammillary line of an area of slightly bronchial respiration and a friction sound synchronous with the heart. There was also great pain over the precordia. The patient soon became unconscious and died in about 24 hours after the rigor.

**Autopsy.**—Only those facts need be stated which have immediate relation to the questions of diagnosis raised by the clinical picture. The heart was very slightly enlarged, but there was no endocarditis or pericarditis. The remnants of a small encapsulated pleuritic effusion were found just to the left of the precordial area. Both lungs showed a considerable degree of pneumoconiosis with chronic bronchitis and emphysema, particularly of the right lung. Beneath the manubrium, chiefly on the left, was a very large mass of much enlarged, black, dense, and in places slightly cheesy glands, which so enveloped the left bronchus that its lumen close to the trachea had become very much narrowed, so as to admit only the tip of the little finger. These glands, as in the foregoing case, were not sharply defined, but more or less welded together with masses of indurated tissue in the adjacent lung. There were no cavities or bronchiectases. The pleuras were greatly thickened and adherent, and in one place there was a tiny purulent collection between the layers of false membrane. It seems quite probable, indeed almost certain, that a secondary tuberculous invasion had taken place, involving at least the pleura and bronchial glands. It was expected to find an acute pneumonic process in the region where bronchial respiration had recently appeared; nothing definite was found here, but in the presence of old fibroid changes it was difficult to decide whether or not an acute pneumonic infection had begun. However, the patient was a wornout subject, old for his age, and in such individuals slight causes are often sufficient to account for a sudden fatal termination.

This case presents one or two points of interest aside from its relation to the others reported. It must be very seldom indeed that an encapsulated pleuritic effusion develops in just such a way as to simulate the outer precordial curve. Usually when such an effusion dulness is continuous with that of the heart the resulting figure is irregular and bears no resemblance in outline to an enlarged precordia. Here also the manubrial dulness

from bronchial adenopathy added to the confusion, producing the marked increase in the vertical dimension of the precordia which is so characteristic of pericardial effusion. If the pleuritic effusion had pushed the heart to the right the deception would have been almost undiscoverable; as it was the mistake ought not to have been made. Although the subsequent appearance of an apparent pericardial friction seemed to confirm the diagnosis, the autopsy showed this to have been epicardial and really pleuritic.

Although but two of these cases came to autopsy and the significance of the physical signs thus became entirely clear, they are all, perhaps, of some slight value and interest in connection with mediastinal percussion. One's first thought on discovery of manubrial dulness is naturally of aneurysm. This will be the more obtrusive in proportion to the prominence of pressure symptoms, of which unilateral absence of respiratory murmur and adductor paralysis are certainly among the most suggestive. Much the same may be said of malignant mediastinal growths, which will demand earnest consideration in proportion to the evidences of progressive cachexia and involvement of the cervical glands. Aside from the more acute inflammatory processes, such as abscess, pericardial effusion and pneumonia, and the normal peculiarity mentioned at the beginning of the paper, the only other explanation of manubrial or parasternal dulness would be ordinary pulmonary tuberculosis, a simple dilation of one of the great vessels not sufficient to constitute an aneurysm, and the condition of enlarged bronchial glands with possible pneumoconiosis illustrated by Cases III and IV.

Ordinary pulmonary tuberculosis would rarely give rise to doubt. The process is too diffuse. It involves other regions than the manubrial with at least equal intensity, and other characteristic symptoms are usually prominent. I can recall but one case in which the consolidation of tuberculosis assumed such a form as to simulate a mediastinal tumor.

It is a very interesting and important question whether a simply dilated aorta may or often does produce dulness; such an aorta, for example, as is not infrequently associated with atheroma, especially when there is also hypertrophy of the left ventricle. Weil states that it is not at all uncommon to find a very small area of dulness at the sternal end of the second rib on the right as a result of aortic dilation. He also states that dilation of the pulmonary artery may produce a similar dull area on the left, not so often, however, as aneurysm of the transverse or descending aorta. Sansom says that when the aorta is generally dilated in cases of atheroma a dull area may be found over the manubrium with symmetric edges like the longitudinal section of a lemon or pear. This statement is manifestly quite at variance with that of Weil, who finds no manubrial dulness; and the pear shape referred to reminds one forcibly of the shape of the manubrium itself and the normal area of dulness which I have already referred to several times as existing in exceptional cases. If I may judge anything from my own experience, any abnormal area of dulness from a simply dilated aorta must be an exceedingly rare occurrence. Though familiar with the foregoing statement of Weil for 15 years, and on the constant watch for some such evidence of a dilated aorta, I can recall but one case in which I have succeeded in finding it as confirmed by autopsy. Assuredly it is no frequent symptom in cases of atheromatous aorta. I can find no authority for believing, nor is it rational to suppose that any simple dilation of either the aorta or pulmonary artery could possibly cause a prolonged vertical zone of dulness to the left of the median line, like that found for example in Case II. The shape of the dull area in this patient bears a striking resemblance to that of Cases III and IV, in both of which the cause proved to be a bronchial adenopathy.

Enlargement of the bronchial glands with or without

a surrounding induration of the pulmonary tissue would not appear from my own experience to be a very rare cause of sternal or parasternal dulness. Whether it is a mere coincidence that in all of the four cases reported and in others previously seen the dulness was always greatest or chiefly to the left of the median line, is a matter of doubt. There is certainly reason for supposing that a left-sided adenopathy would be earlier perceptible because the left primary bronchus emerges from beneath the aortic arch which covers the corresponding structures upon the right.

The chief diagnostic importance of bronchial adenopathy lies in its differentiation from aneurysm or mediastinal growth. We have seen that pressure symptoms of adenopathy may be very pronounced. In Case III there was recurrent paralysis and tracheal stenosis and in both Cases III and IV compression of the left bronchus. It is easy to see that in the presence of such symptoms diagnosis may at times be very difficult. Undoubtedly chief stress must be laid upon occupation and history. If the patient has been engaged in one of the various occupations which involve the constant inhalation of fine particles of dust, if in addition there is a history of chronic cough and expectoration, and if especially there are found in the lungs physical signs of either local or general bronchitis, a plausible explanation of any manubrial dulness is not far to seek. The assumption of bronchial adenopathy will then be strengthened by the absence of pulsation, tracheal tug, pain, or possibly also of souffles. Or, to put it another way, in the presence of manubrial dulness the entire absence on the one hand of any sign of aneurysm and on the other of any suggestion of malignancy, such as cachexia or enlarged cervical glands, should lead the more quickly to a most careful investigation both of the patient's antecedents and the condition of the lungs, with especial reference to pneumoconiosis, such as areas of slight consolidation or a more or less general bronchitis. A simple suspicion of the truth is perhaps the most important foundation for an eventually assured diagnosis; possibly the condition is often overlooked because it is not thought of as of practical diagnostic importance.

It would appear further that considerable importance should be attached to the site, contour, and definiteness of the dull area. It should be borne in mind that most aneurysms cause a dull area, if any, to the right of the median line—referring, of course, to those early stages which are most difficult to detect; whereas the dulness of adenopathy would appear to be most frequent upon the left. Further, the dulness of aneurysm at an early period is likely to be small, while that of adenopathy, owing to the frequent condensation of surrounding lung tissue, is more apt to be diffuse, extending perhaps up and down the sternum, as in the cases mentioned, and passing a little more gradually into the pulmonary resonance of the corresponding side. Since in many of the cases of pneumoconiosis there develops a secondary tuberculous infection the diagnostic significance of continued fever or bacilli in the sputum is apparent.

**Fatal Human Bite.**—Dr. Gruning, a young Russian doctor of great promise, has lost his life through being bitten by a little boy whose sufferings from diphtheria he was heroically trying to relieve.

**"Expectorate" and "Spit."**—In a statement given out recently by Commissioner Lederle of the Board of Health it is set forth that letters have been received objecting to the use of the word "spit" in the Board of Health ordinances, and asking that the word "expectorate" be substituted. In this connection Commissioner Lederle makes public a letter received by the Health Department from Theodore Roosevelt, when the latter was Police Commissioner, asking that the word "spit" be used instead of "expectorate." The letter follows:

POLICE HEADQUARTERS, NEW YORK, March 21, 1896.  
The Hon. Charles E. Wilson, President Health Board.

Dear President Wilson:—Can't you have our form of notice changed so as to read "spit," instead of "expectorate?" Expectorate is a vile word and the Health Board ought to use good English.

THEODORE ROOSEVELT.

**A STUDY OF WEIGHTS IN PULMONARY TUBERCULOSIS.**

Based on the Weight Charts of Twelve Hundred Patients at the Adirondack Cottage Sanitarium.

BY

LAWRASON BROWN, M.D.,  
of Saranac Lake, N. Y.

Resident Physician Adirondack Cottage Sanitarium.

Probably in no widely spread disease is wasting of the body more a feature than in pulmonary tuberculosis. So striking is the loss of flesh that for ages the term phthisis or consumption has been applied almost exclusively to this disease. The treatment of pulmonary tuberculosis by specific drugs or sera has not yet yielded the results which had been hoped for. That treatment, therefore, which enables the patient most quickly to regain his lost weight and to raise his lowered vitality should be followed. This is best accomplished by the so-called hygienic-dietetic treatment. The results of this treatment, founded by Brehmer and first introduced into this country by Trudeau, have been much discussed from many points of view. It is a striking fact, however, that while so much importance has been attached to the gain or loss of weight by the consumptive the subject has received comparatively slight attention. The report of a sanatorium is never complete without a statement of the gain or loss in weight of the patients, but the figures are rarely analyzed except in a few sanatoriums where they afford a basis for discharging patients who have gained a few pounds in weight as "improved."

The cause of loss in weight in pulmonary tuberculosis has been much discussed. The wasting affects all the organs of the body<sup>1</sup> but the liver, which often undergoes a fatty change. The fact that the digestive organs are often early affected is suggestive of toxin absorption. Cornet<sup>2</sup> attributes this to absorption of protein from the tuberculous area. Loss of weight is not dependent on the fever, he holds, but both are due to the absorption of certain toxins. This is in all probability the cause of the loss of appetite and lessened assimilation, of the vomiting, and of other gastric disturbances. The ratio of the surface of the body to its bulk is rapidly increased when weight is lost and consequently the skin is of more service to the lungs in aiding excretion and so helps to prolong life. Patients may have an enormous appetite and gain but little, a fact too frequently seen. Others, however, may eat a small amount and gain. Patients who are so fond of meat that they eat little else are less likely to gain as much as good general eaters. It seems, therefore, that it is not the amount taken in but the amount assimilated that is of value to the animal economy. Milk and eggs, with codliver-oil carefully administered during the winter season, have great influence on the bodily weight of consumptives. The weight thus acquired, however, is often quickly lost. The explanation of this observation rests less upon the hypothesis of Dr. Dobell,<sup>3</sup> "the stability of the fats of the animal body in resisting too rapid oxidation is dependent upon the degree of solidity which they possess at the temperature of the living animal at any given time," than upon the fact that such observations are usually made in advanced cases when the patients have lost much weight and would quickly lose any weight gained, even if the ingestion of "material capable of supplying the adipose tissue with solid fat" was the cause of the temporary gain.

Fever and loss of weight go hand in hand. Many patients who have had high fever gain in weight when the fever decreases, although a continuously elevated temperature may still be present. Antipyretics when they decrease afternoon fever and enable the patient to eat are of value. Patients with fever need an amount of food greater than normal to maintain their weight and they frequently digest well enormous amounts of food

when kept out-of-doors. It is surprising what foods many can digest and assimilate while having elevated temperatures. Patients with an evening rise of temperature should take the greater part of their nourishment earlier in the day.

Rest at first and systematic exercise later enable patients to gain most weight. If the patient is doing well little exercise should be taken until the weight approaches normal. Exercise often enables a patient to gain who has ceased to gain while at rest, and weight gained while exercising is more enduring than that gained at rest. Exercise should not fatigue, and the patient should not get out of breath nor get overheated. It should be so timed that a half hour's rest can be taken before and after meals. The best results in regard to weight are obtained when the patient, after a sufficient period of rest, begins with a five-minutes' walk in the morning and gradually increases his exercise. It should be regulated by the time of actual exercising. Afternoon walks should be half as long as those of the morning. Exercise, however, should always be taken in the open air. Forced muscular activity affects the body weight more seriously than in health, but moderate

A typical weight-chart.

physical and mental exercise in quiescent cases has no harmful influence on the bodyweight. Change of climate is often a great stimulus to gain in weight, and change from one place to another in the same climate is very beneficial. This may be so even when patients leave conditions almost ideal for those far less perfect. Those who come from poor hygienic conditions do well and gain much in the same climate if under good hygienic and dietetic treatment. These patients may even gain weight while the disease advances. Patients who have always lived in good hygienic surroundings and had good food require more often a change of climate to stimulate assimilation. Elevation seems to have little effect upon gain in weight, and, in fact, may cause a slight loss at first. Meissen, at Hohenhonnef (altitude 735 feet), publishes that his patients gain an average of about one pound per week, while under Turban, at Davos (altitude 5,115 feet), the patients gain only one-third of a pound per week. Meissen, however, uses suralimentation.

The country influences the weight more advantageously than the city. Jacoud believed that patients living in the country are much less liable to digestive disturbances than those living in the city. Residence

among one's friends in the city for 10 days often does good; after that time patients may lose weight. Pleasant surroundings have a marked effect on the weight, and homesickness frequently prevents gain in weight at first. Congenial associates at the table are of great importance, and in sanatoriums those who have occupied the same walks in life should, so far as possible, be placed together in the dining hall. A patient who

hearts of those patients who do not follow this rule suffer. The functions of the skin are interfered with; colds may be caught easily and so the weakened lungs injured. The diet in these cases should be limited very gradually and the muscular work increased. Two pounds per month is a loss rapid enough. Such patients gain rapidly in weight without any perceptible improvement of the local signs. Death may supervene

has bad table manners may keep a number of refined women from gaining in weight, by taking away all appetite. For this reason in all sanatoriums drawing their patients from all classes, small tables seating 6 to 10 patients are much preferable to those seating more.

when they have made considerable gain in weight.<sup>4</sup> Chlorotic patients are generally stout. They may lose weight as the general pulmonary condition improves, but unfortunately the weight may continue to decrease and the patient grow worse. The gain in weight is first

While increase of weight is a desideratum for most consumptives at first, later it may become a source of danger. "To eat and drink well kills the bacilli," "You must eat once for yourself and once for the bacilli," are phrases often quoted in sanatoriums for the tuberculous. Every patient has a limit in weight which should not be passed, and when this limit is reached the patient should be made to exercise systematically. The

evident in the chest which in many patients shows marked emaciation. The abdomen is probably the part next affected, especially in males. The hips in women are frequently much enlarged as well as the arms. A few patients gain more on the legs but this seems exceptional and occurs most frequently in women. The face is often the best index of gain or loss in weight, while a general gain is perhaps the most common occurrence.

Loss of weight is often one of the earliest symptoms of pulmonary tuberculosis. The gastric onset is so widely recognized it needs only be mentioned. The loss may be so insidious as to attract little attention, or on the other hand may be very rapid and even reach from one-third to two-fifths of the earlier weight if the patient is not carried off by complications. During the later stages of the disease when diarrhea sets in, patients,

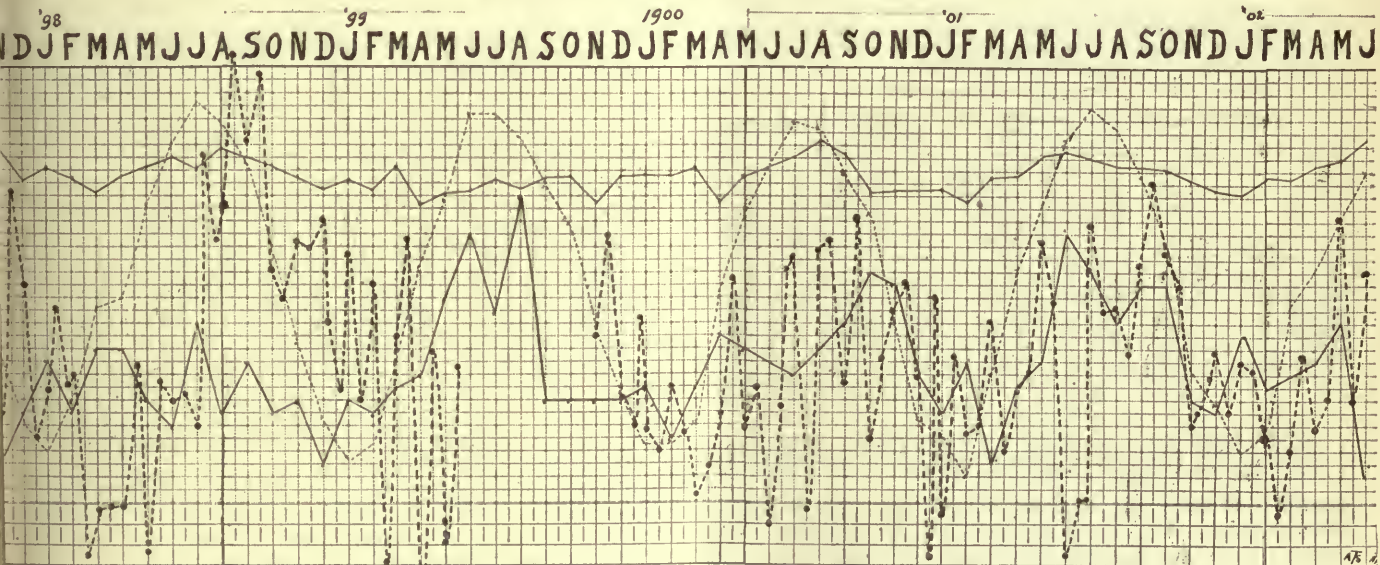

places more dependence upon the weight chart uninfluenced by suralimentation for estimation of the progress of the disease than upon a temperature chart disturbed by antipyretics. A regular constant uninterrupted gain of weight continued for two months is of favorable prognostic value, but the gain of a few pounds is not a sure guarantee of improvement. In nine out of ten cases the general state is ameliorated first and the

[Continued from page 654.]

as a rule, lose weight rapidly. If a patient loses one-fourth of his normal theoretical weight his nutrition is apt to be unsettled, while if one-third is lost his chances of recovery are very slight. A quick, constant, continuous loss of weight indicates as surely as any other phenomenon that a patient is rapidly losing ground. The fact that patients with extensive edema may be up and about should be kept in mind, as this may mask

pulmonary condition later. It is rare for patients who have lost weight to improve without gaining weight. In order to determine whether the amount gained has any bearing upon the prognosis all the patients who have gained 20 pounds or more have been tabulated. (See Tables 1, 2, 3.) Of the patients who gained 20 pounds or more there were 164; 96, or 58%, men and 68, or 42%, women. The highest gains recorded were 50

[Continued from page 654.]

loss in weight. One patient of this class was known to vary 10 to 12 pounds in weight per week. "It is more important to know the conditions under which a patient gains in weight than to know the amount of weight gained." Increase in weight is, as a rule, a very favorable symptom. Some hold indeed that without a gain in weight even if the stethoscopic signs are ameliorated, the patient cannot be considered improved. Wolff<sup>5</sup>

pounds, in 3 men (1 of whom is well, 1 dead, 1 untraced), and 49 in a woman with a cavity (now at home and well). Of these patients 130, or 78%, spent at least one winter in the Adirondacks. That patients do not retain all the weight gained is seen from the fact that only 64, or 38%, were at their highest weight when discharged from the Sanitarium. Of this number 19, or 35%, were men. Of the 60 patients discharged as appar-

ently cured 46, or 77%, have been traced and of these 40, or 87%, are alive and able to work at present. It should be noted that of the patients "apparently cured" 38, or 63%, were in an incipient stage; 22, or 37%, in an advanced stage. Of the 84 patients discharged "arrested" 70, or 83%, have been traced; 40, or 56%, of these are alive and able to work, 15, or 21%, alive but unable to work. Of those discharged "improved" numbering 20, 15, or 75%, have been traced. Of these 3, or 15%, are alive and able to work; 8, or 40%, alive but unable to work.

On comparing these figures with the results from 1,000 consecutive patients (Table 4) who were discharged from two to eight years ago it was seen that a larger

number of incipient and advanced cases are included among those who have gained over 20 pounds. The results may best be seen from Table 4. The figures in this table are all given in percentages and it is seen that a greater proportion of patients with incipient and advanced cases are discharged apparently cured among those who have gained over 20 pounds than among the whole number of patients. The same is true of those discharged with their disease arrested, but there is not such a striking difference in the figures. In advanced cases the disease is arrested in a far greater number of cases among those who have gained at least 20 pounds. The table shows

also the condition in 1902 of 1,000 patients (Class I) who were discharged from two to eight years ago in comparison with 164 (Class II) who were discharged from June, 1893, practically up to June, 1902. This fact should, of course, account somewhat for the relatively better showing of the patients who have gained over 20 pounds. Of the 1,000 patients it is seen that nearly 27% remained well for a period of from two to eight years after discharge, while of the 164 patients over 39% are still well. Of the 1,000, 33% are able to work, while of the other class over 50% are able to work. These figures include, of course, all of the cases. If the patients who have not been traced are deducted, the percentages will be much higher, i. e., 63% of the "164 patients" are able to work, and 44% of the "one thousand."

But while patients who gain over 20 pounds do better as a rule, a large gain in weight does not assure one of cure. The 22 patients who have died gained over 28 pounds on an average, two pounds more than those classed as cured. The explanation of this lies in all probability in the fact that many who have lost greatly regained flesh for a time and then relapsed and died. Nor does the average gain of the patients correspond to the condition of the lungs as those in whom the disease was far advanced gained on an average more than those

TABLE 5.—Showing the average gain and loss in weight per year of all patients discharged since 1892.

in whom it was advanced. The same holds true when the condition of the patients in 1902 is taken into consideration. The patients classified as "chronic" are the only ones who gained less than those who were well. In Table 5 is shown the average gain and loss in weight in pounds of all the patients from November, 1892, to November, 1902. The patients have been divided into two classes, according to the length of their residence in the institution. The first class remained three months or less, the second class over three months and averaged during the last three or four years less than eight months. The patients who remained under three months number 170 and gained 7.3 pounds on an aver-

age. The other class, numbering 849, gained on an average 10.8 pounds. Both classes (1,019) gained an average of 10.2 pounds; 180 patients lost weight averaging four pounds; 86 patients remained stationary or were not weighed.

Warmth and sunshine are not necessary factors for gain in weight; in fact many patients do better in winter. Such is the experience of Gabrilowitch.<sup>6</sup> Cold weather, he believes, stimulates the patient much more than warm. Some patients, however, have an antipathy to cold and these are frequently found to gain more in a warm, equable climate. Great dryness is not always conducive to gain in weight. Gabrilowitch has shown that patients gain even when there is little sunshine. At Halila the possible amount of sunshine is three times greater during the summer than during the winter and there are many more clear days during this season, yet the patients gain more during the winter and do better at this time. The average gain in weight per patient every two weeks at the Adirondack Cottage Sanitarium expressed in pounds has been charted to show its relation to the number of new cases admitted during each month and to the percentage of patients who gained weight (Chart 1). It will be noted that the percentage of the patients who gain rises or falls directly as the amount gained expressed in pounds rises or falls. For this reason in Chart II the percentage of the patients who gained has been neglected. It should not be overlooked that only the gain in weight has been charted and that when the line indicating the average gain in weight falls it does not mean that there has been a loss in weight. The loss in weight has not been tabulated, but on going over the figures it happens that when fewest patients gain, *i. e.*, when most patients lose, the average loss is greatest. To determine whether the time of the year in which patients were admitted has much bearing upon the amount gained, the average weights on admission of 100 patients admitted in January and of 100 admitted in July were calculated. The difference was about five pounds more in those admitted in January, an increase readily accounted for by the greater amount of clothing worn during the winter. The number of patients admitted does not seem to influence the amount of weight gained.

In Chart II the average gain per patient every two weeks expressed in pounds has been compared with the monthly precipitation, the number of clear days per month and the mean monthly temperature. A study of the charts will show that more patients gain and that that gain is larger from August to January. This is the period when the temperature begins to fall, but it also includes the greatest number of cloudy days. The precipitation departs slightly from the average during this period. Patients who have held their own or lost slightly during the early summer often begin to gain in August. This period of gaining extends to Christmas, when often the patient has surpassed his normal weight. During January, February and March the weight fluctuates and gradually begins to lessen. It is at this time that a radical change in the life of the patient, a change of environment and later of climate for a few months proves of great benefit. From 1899 to 1902, owing to the large number of patients who have applied for admission to the Sanitarium, there has been a long waiting list and patients have remained in the village at times for several months. This of course would influence the charts, as no record was kept of their weights before admission. During part of 1896 and 1899 records of patients' weights were not obtainable.

It is of interest to note that Malling-Hansen from his study of children concludes that most weight is gained from August to the end of November or the middle of December. From this time to March or April the gain is less, while from March or April to August there is a loss in weight. Hartmann<sup>7</sup> who quotes Malling-Hansen's conclusions, concludes from a study of 48 anemic

children that such children gain more in summer than in winter, irrespective of good or bad weather.

	Average loss in w'ght on admission.	Average highest gain in pounds.	Time required in months.	Condition in 1902.		
				Well.	Dead.	Chronic.
Men .....	12.5	12.4	4.9	3	7	.....
Women..	10.2	13.5	5.1	5	4	1

TABLE 6.—On comparing ten men and ten women, chosen at random from the same class of patients (three incipient and seven advanced) at the Sanitarium during the year 1897, it is found that the women lost less weight than the men, and gained more in a slightly longer period.

In tabulating I have used Dr. Trudeau's classification, which is substantially as follows:

*Incipient Stage.*—Slight local, with little or no constitutional involvement.

*Advanced Stage.*—The localized disease—process extensive or in an advanced stage; or slight local pulmonic invasion with rather marked constitutional involvement or with complications.

*Far Advanced Stage.*—Marked signs of pulmonic disintegration with marked constitutional symptoms.

*Improved Condition.*—Physical signs showing process less active, or general health improved with symptoms relieved or abated.

*Arrested.*—No activity in process in lungs, with absence of fever and other constitutional symptoms.

*Apparently Cured.*—Abnormal physical signs absent or if present only slight and indicative of healed lesion. Absence for some months of pyrexia and of sputum or of sputum containing tubercle bacilli.

*Perfectly Cured.*—Abnormal physical signs absent or if present only slight and indicative of healed lesion. Absence for two or more years of pyrexia or of sputum or sputum containing tubercle bacilli.

CONCLUSIONS.

1. Toxin absorption in the tuberculous area causes reduced assimilation and fever. Loss of weight is in all probability due to this.
2. It is not the amount eaten but the amount assimilated that is of value to the consumptive.
3. Carefully regulated rest and exercise are of most importance as regards the bodily weight in pulmonary tuberculosis. Forced muscular activity is always injurious.
4. Assimilation is often markedly increased by change of residence or of climate.
5. Excessive gain in weight may be injurious.
6. The gain in weight is usually first evident on the chest, next upon the abdomen in men and on the hips in women.
7. A quick, constant and continuous loss of weight indicates as surely as any other phenomenon that a patient is rapidly losing ground.
8. A gain of a few pounds is of little value in prognosis, but if the gain is constant and continuous over a period of two months, the patient is probably improving.
9. The weight gained affords no sure data for prognosis, but on the whole patients who gain over 20 pounds do better than those who gain less.
10. Sunshine and dryness are not necessary factors of gain in weight. Cold weather stimulates assimilation and gain in weight more than warm.

**Influenza in Chicago.**—The Bulletin of the Health Department of Chicago for the week ended April 4 states that influenza has been more prevalent during the first four months of 1903 than at any time since 1891, and of the 350 deaths last month in excess of the number for March, 1902, 330 are shown by the physicians' certificates to be due, not to influenza direct, but to influenza as a fatally complicating cause of death from pneumonia, tuberculosis, Bright's disease, heart disease, bronchitis, measles, and whoopingcough, in about this order of frequency.

WOUNDS OF THE THORAX.<sup>1</sup>

BY

ISAAC R. TRIMBLE, M.D.,  
of Baltimore, Md.

Professor of Anatomy and Clinical Surgery, College of Physicians and Surgeons, Baltimore, Md.

Operations involving the resection of ribs and the opening of the thoracic cavity for various troubles date back to the time of Hippocrates, 400 B.C. What we practise today is nothing new, but we have advanced step by step, each operator aiding by his experience those who come after him. During the last 25 years considerable has been done owing to the improved technic and to our increased knowledge of surgical pathology.

Whether we shall open up every wounded chest or whether we shall let them all go on the expectant plan is a question which has the weight of authoritative precedent on both sides. The truth lies perhaps in the middle ground as in so many other questions. Each case must be judged by itself. The nature of the case, the surroundings and the skill and technic of the operator must all be taken into consideration. Each patient should get our best judgment. A careful study of the anatomy of the chest and its contents is essential before doing any operative work upon it. Besides this the experience of other surgeons should be considered and their cases gone over.

An article in the *Annals of Surgery* of May, 1902, by Dr. W. G. LeBoutillier gives a good history of thoracic injuries involving the lungs and also the result of these injuries in his cases. The article by Dr. J. B. Murphy, of Chicago, read at the American Medical Association, 1898, "On Surgery of the Lungs," is by far the most complete that I have been able to find. Dr. H. B. Loomis, of New York, quoting an article in the *Medical Record*, of September 29, 1900, speaks of the introduction of nitrogen gas into the pleura to check hemorrhage and, by pressure, to prevent motion of the lungs and assist the healing of the tuberculous foci. This idea was advanced by Dr. Murphy in 1898. He found that when air was let into the pleural cavity it was absorbed in from a few hours to a few days. First, oxygen is absorbed most readily, second, carbon dioxide, and third, nitrogen gas, is absorbed very slowly, in fact nitrogen gas will remain in the pleural cavity and be unabsorbed from a few weeks to several months. So in diseases of the lung, Dr. Murphy used the latter gas to produce constant pressure and keep the lung collapsed and in that way to assist the cure. It has been found that after 12 or 18 months' pressure from gas the lungs are able to resume their function. Dr. Murphy says that to depend upon the introduction of gas into the pleural cavity, and trusting by that pressure to stop bleeding from an injured lung, has not been followed by good results. As in the case mentioned by Dr. Loomis, if the bleeding is from within the lung itself, one can see that the pressure and collapse of the lung by the gas would accomplish our object of checking hemorrhage, but in my opinion it is not good surgery to fill the cavity with the gas in hopes of checking hemorrhage when we do not know from what point it comes. Our duty in chest injury is to remove the foreign body, if there be one, cleanse the part, cutting off all lacerated tissues, and put the parts at rest so they will be better able to resist infection, and when infection does occur give free drainage and watch for all other complications that may arise.

Contusions of the chest or simple break of a rib without any complications are treated by putting the parts at rest. In contusions of the chest the only symptom of injury may be hemoptysis which may come on at once or be delayed several days, and may be due to injury of the lung or to some tuberculous foci in the lung.

In chest injuries we look for pneumothorax, hemoptysis and emphysema, "the lungs may be injured without any of these symptoms, and yet having any one of these alone we can not say positively that the lung has been injured."

In the article of Dr. W. G. LeBoutillier, he mentions a case of rupture of the lung without fracture of the rib. It was in a boy who had been run over by a wagon, the wheels passing across his chest. When he was first seen he was in profound shock, having dyspnea, weak pulse, and increased respiration. The dyspnea was relieved by aspirating the right chest and evacuating the air. The boy lingered for some time, and on autopsy the only lesions were two small ruptures of the lower lobe of the right lung.

*Penetrating wounds of the thorax* may injure the intercostal arteries, heart, or large vessels, lung or diaphragm and may also extend into the abdominal cavity and injure its contents. Dr. Matas, of New Orleans, in the Transactions of the Louisiana State Medical Society, gives 245 reports on cases of injury to the chest, the majority of them being penetrating wounds. He states that hemorrhages are fatal that occur from the heart, aorta, large vessels, veins and arteries and the hilus of the lung, vena cava and vena azygos.

*Emphysema* is not always present, and may be due to the escape of air from the injured lung into the tissues, or may come from air entering the lacerated tissue and not from the lung. An alveolus of the lung may be ruptured and the rupture not extend through the visceral layer of the pleura. The air escaping into the connective tissue of the lung will travel to the hilus and then by the way of the mediastinum and be found at the root of the neck or around the lower end of the sternum. In extreme cases of emphysema it may be found necessary to incise the skin to allow the escape of air from the tissue. Emphysema is generally due to a fractured rib puncturing the lung.

*Pneumothorax.*—In lesions of the chest walls, air enters the cavity during respiration, but air from a ruptured bronchus enters the cavity during expiration. In the latter case air entering the cavity may not get out and a plus pressure is exerted and death may follow from pressure or rupture into the mediastinum. This has occurred from a very small lesion of the lung in which air has escaped some time into the pleura or a small external opening into the pleura. Pneumothorax may be due to escape of air from the lung, bronchus or through the external wound into the thoracic cavity. The symptoms will be partial or complete collapse of the lung. Should the wound be a large one, five or six respirations will be sufficient to produce a collapsed lung, but should the wound be small and remain open some time, it may also produce collapse of the lung. The symptoms are the bulging of the intercostal spaces on the affected side, displacement of the heart, mediastinum and diaphragm and a corresponding displacement of the abdominal contents. Absence of respiratory murmur, a tympanitic note on percussion, and distant bronchial breathing are also present. The breathing and heart's action will be correspondingly difficult in proportion to the amount of pressure in the pleural cavity. The cavity can be aspirated or the contents of the cavity turned out through the external opening. If the intrathoracic pressure continues and becomes greater, it is an indication that there is an opening of a valvular nature. This is an indication to aspirate or to turn out the air and blood clots from the pleura by an operation. The air in the pleura cavity compresses the lung, and in that way puts the parts at rest and assists in the healing of the ruptured air vesicles or bloodvessels.

In wounds of the thorax we cleanse the openings of entrance and exit, if there be any, and should the symptoms be urgent we operate and put the parts at rest, by this means assisting the healing process. If there is fluid in the pleural cavity, we should aspirate and if we

<sup>1</sup> Read at the Convention of Railway Surgeons, Atlantic City, N. J., June 28, 1902.

find pus we must resect a rib and give free drainage. Do not at the first opening of the chest irrigate the pleural cavity. A simple opening through the intercostal muscle may suffice to empty the cavity, but it will be found better to resect one or two ribs, about the eighth and ninth ribs, at the posterior angle of the scapular, giving an opening two or three inches long, which will be sufficient for drainage. Should the pneumothorax increase to such an extent as to rupture the mediastinum death will occur from collapse of both lungs.

*Hemothorax.*—This may be due to a lacerated lung or some thoracic vessel at the root of the lung or from injury to the heart which bleeds through the pericardium into the pleural cavity. The bleeding may also be from the internal mammary vessel or intercostal vessels. Should the bleeding take place slowly the entire thoracic cavity may be filled with fluid, the heart be pushed out of position, bulging of the intercostal spaces, depression of the diaphragm and a corresponding displacement of the abdominal contents be noted. There will be loss of vesicular murmur on that side, and there will be a flatness on percussion and loss of vocal fremitus. The patient lies on the affected side. Should the bleeding be from an intercostal artery, enlarge the opening, resect a rib if necessary and tie both ends of the artery. Never attempt to check the bleeding of an artery by plugging the wound. This means of checking hemorrhage may succeed at times, but it is a dangerous expedient, for through the slipping of the plug the patient may be lost. Should the bleeding be from the interval mammary some blood may be found external to the pleura and also in the mediastinum. In bleeding from this artery we must cut down on the bleeding point, resecting a rib or two if necessary, and a part of the sternum if that is required to expose fully the vessels. Both ends of the bleeding vessel should be tied. Should the hemorrhage of the lungs be excessive and a fatal termination feared, it is best to make a free opening in the chest, grasp the lung and bring it into the wound, examine each lobe and when the bleeding point has been found sew it up with interrupted absorbable material and replace the lung into the pleural cavity. If the lung is much lacerated we can tie off a part of a lobe or entire lobe, or even more if that be necessary, and then replace the remaining portion of the lung into the cavity. Should the pericardium be injured, enlarge the opening into the thorax, compress the lung against the hilus to stop its movements, and sew up the precordial opening, but should the wound extend to the heart itself we can sew up the muscle walls of the heart by interrupted stitches, then cleanse the pericardium and sew it up, or if preferred a drain can be left in the pericardium and extend outside the chest. Should the wound extend into the abdominal cavity, we will have to enlarge the opening of the thorax so as to get a clear view of the injury of the diaphragm, and through the latter we can examine the contents of the abdomen which may be injured. If the abdominal viscera are injured they may be repaired through this opening, or a laparotomy may be done. Dr. Murphy in a number of cases has found this the best way to attack the injured diaphragm, that is, through the pleural cavity. He mentions a case in which he had his assistant resect a rib, enlarge the opening found in the diaphragm, examine the abdominal contents, cleanse the parts, sew up the opening in the diaphragm, and then sew up the opening in the pleural cavity. The patient made an uninterrupted recovery. More or less pleuritic effusion will be found in hemothorax. Should this effusion be sufficient to interfere with respiration it will have to be removed by aspiration, but should it be a septic pleurisy it will have to be removed by a large opening. The best time to aspirate in hemothorax is about two weeks after the injury. At that time the blood-clot will have separated from the serum. If the bloody serum will not flow through the aspirating

needle the clot will have to be removed by operation. Aspiration of the cavity can be done every few days or every few weeks, according as the needs of the patient demand.

*Hernia of the Lung.*—This is rarely seen. It may be subcutaneous or compound. In the former a blow on the chest may rupture the parietal pleura along with the intercostal muscle and a part of the lung become caught in the opening. The treatment is constant pressure and if that is not successful the return of the lung to the pleural cavity is recommended; an opening through the skin should be made, the opening between the ribs enlarged, and the lung replaced. The external opening should be closed. Should the hernia be compound cleanse the lung and return it to the pleural cavity. If it should be severely lacerated or gangrenous when seen that portion of the lung will have to be amputated and the stump returned to the pleural cavity. Dr. Murphy quotes from Paget the treatment given in 1499 by a doctor in Bologna. He saw the patient six days after the hernia had taken place. The lung was covered with pus and insects. After the doctor got permission from the priest to treat the patient he cut off the necrotic lung and with it about one-eighth of an inch of necrotic skin surrounding it. He then put on some red powder and kept the parts bathed with warm water. The patient made a good recovery. The doctor stated that if he had seen the patient at once he would have washed the lung and kept it warm by splitting a chicken down the back and applying it, keeping up constant pressure, and if that did not succeed he would have enlarged the opening by a wedge of wood to facilitate the reduction of the prolapsed lung. This is exactly the treatment we recommend today, but in a modified manner.

*Gunshot Wound of the Lung.*—Small balls make a small hole at entrance and exit and unless a large vessel is injured the bleeding is not excessive. Foreign material is rarely carried into the lung. The treatment is to cleanse the opening in the pleura and remove any foreign bodies or splinters found in the pleura or in the lung and then pack the opening in the pleura. Of course after closing or draining the pleura one must be on the lookout for traumatic pleurisy and pneumonia, also pericarditis and endocarditis, for these sequels often follow injuries to the lung and pleura. The lung itself bleeds little from such injuries. In severely lacerated wounds resulting from foreign bodies being driven into the lung we use the Röntgen ray for diagnosis and by taking several pictures in various positions of the chest and marking the planes on the body through which we take the picture we can approximate the position of the foreign body in the lung where these planes cross. The opening should be enlarged and the foreign body removed. The pulling of a wounded lung into the opening of the chest not only plugs the opening and prevents the entrance of air into the pleura, but it assists in the restoration of the normal functions of the wounded lung by equalizing the respiration. A compression of the lung against the mediastinum stops its motion and unless the pressure is so great as to rupture the mediastinum the compression of the lung by supporting the mediastinum assists in the respiratory movements of the uninjured side. The surgical procedure that I have just spoken of is of grave nature, therefore we must be prepared to anticipate the various symptoms of shock, collapse, cessation of respiration, and heart failure. We may be compelled at any time to desist from the operation owing to the critical condition of the patient. Gradual compression of a lung by fluid or air introduced into the pleural cavity gives only a transient discomfort, the other lung takes up the double function and the breathing goes on without any discomfort. We must not forget the complications that arise in the pleura, lung or heart after these operations. Should septic inflammation of the pleura or pericardium be found we must drain off the effusion. It may take several weeks or months for

a collapsed lung which has been bound down by adhesions to return to its normal condition. When it is impossible for the lung to expand we may have to do a large osteoplastic resection of the chest wall, which will allow the collapse of the chest wall on the lung.

*Wounds of the Heart.*—The article by Dr. H. M. Sherman, of California, read at the American Medical Association of this year, is most instructive and thorough. In all injuries of the pericardium or heart, to expose fully the bleeding point we must go through the pleural cavity, hence we have to deal with two serous cavities. Interrupted stitching of the heart muscle is the correct way to stop the bleeding from the organ. As sepsis very often follows these wounds the question of draining or not draining these serous cavities comes up. Should the wound be closed one must be ready to drain it at the first symptoms of sepsis. Dr. Sherman found that after wounds of the heart he could best sew up the openings by putting in two steady stitches on each side of the wound, and by pulling them across each other the wound could be closed; then he puts in his interrupted stitches, placing them well down in the muscle wall of the heart, using either silk or catgut as suture material. When we are placing stitches the heart will be found to be beating so rapidly that we do not take any cognizance of either diastole or systole. In operating on wounds of the heart the collapse of the lung and cessation of respiration are more to be feared than the stopping of the heart-beat. In penetrating wounds of the chest or in injuries of the lung we have most often a partial or complete collapse of the lung from pneumothorax or hemothorax, or both. At this time the sound lung is doing the work of both lungs. The first shock of this extra work is over and the respiration, as a general thing, has become regular by the time we begin to operate. By opening the chest we allow the vibration of the mediastinum, and that prevents the proper filling of the lung by the strong piston movement of the diaphragm; hence, it is expedient to compress the lung against the mediastinum to prevent its vibration, or to pull the lung into the wound of the chest and in that way the respiratory efforts will be assisted and the proper filling of the uninjured lung by air will take place. The escape of a small amount of air into the pleura is not a serious consequence; it is absorbed in a very short while. Should there have been any emphysema there will be for some time a thickening of the pleura and adhesions between the parietal and visceral pleura, which will prevent the collapse of the lung when the opening into the chest is made.

Dr. J. D. Bryant, of New York, in the *Medical News* of July 28, 1900, mentioned the case of a young man who was hurt by having a shaft of a wagon driven into his chest. The third, fourth, and fifth ribs on the right side were broken and there was severe laceration of the tissue and soft parts and the parietal pleura. He cleansed the injured parts and removed the badly lacerated tissue and broken ribs and then placed the sides of the wound in apposition. A subsequent empyema developed, which was drained, leaving a cavity which had an opening above. This Dr. Bryant succeeded in closing by constant aspiration of the suppurating cavity. One would think that the better way to have treated this suppurating cavity would have been to open it from the bottom and done away with the aspiration from above.

The following cases which I will narrate are taken as examples from a number in my service:

CASE I.—March, 1901; a railroad man, aged 30, was caught between the bumpers of two cars on the short side of the curve. I saw him half an hour afterward at his home. Upon examination I found a weak, thready pulse; increased and difficult respiration; cold, clammy sweat over his body. The chest and back were emphysematous. There was hemoptysis, some pneumothorax, great dyspnea, and an anxious expression. The third, fourth, and fifth ribs on the left side were broken. The acromial end of the clavicle was dislocated upward and

the ligaments were torn off. The chest and back were severely contused.

*Treatment.*—The man was stimulated, the shoulder was covered with cotton, and snug bandages were applied around the shoulders and chest. The man developed on the left side traumatic pleurisy and pneumonia, the pleurisy extending up to the spine of the scapula. He was critically ill for three weeks, when the symptoms slowly subsided and he made a good recovery, returning to his work four months after the injury.

CASE II.—In February, 1892, a young woman was shot through the fleshy part of her left arm above the elbow, the bullet passing into the chest below the sixth rib at the axillary border. The bullet was from a small pistol. She had slight hemoptysis, and there was pain on deep inspiration. The wound was cleansed and dressed. A local pleurisy and pneumonia developed. She expectorated bloody sputum for 10 days. In four weeks all symptoms had disappeared, and she left the hospital. The bullet was not located.

CASE III.—In January, 1892, a white man, aged 50, fell, while drunk, across the iron rail of a railroad track, striking his left side and breaking the sixth, seventh, and eighth ribs. When seen a few hours after the injury there was some shock, weak rapid pulse, some emphysema around the chest and some hemoptysis. The chest was compressed with adhesive straps extending completely around the body. At the end of 24 hours he developed a severe case of delirium tremens, which continued for 12 days. A pleurisy developed on the injured side, and the fluid extending up to the border of the third rib completely compressed the lung. There was displacement of the heart to the right side and difficult respiration and irregular pulse. The man laid on the affected side. The temperature was 100°; respirations, 50; pulse 110. Two weeks after the injury the chest was aspirated and two quarts of bloody serum withdrawn with great relief to the patient. This aspiration was repeated three times. The fluid at each subsequent aspiration was less in amount and not so discolored with blood. The lung expanded, and at the end of three months the patient left the hospital and returned to his work.

CASE IV.—In February, 1900, a man, aged 35, came into the hospital having been shot 16 hours before. On examination two bullet wounds were found to the left of the median line above the umbilicus and on the outer edge of the rectus muscle. The temperature was 101°, pulse 120, weak and thready, respirations 40. Heart sounds were very indistinct. There was shock, an anxious expression of the face, and the body was cold and covered with perspiration. The abdomen was distended and powder marks were found around the wound. There was dulness at the base of the right side of the chest, which extended up to the border of the scapula, showing evidences of some internal hemorrhage. The man was stimulated and salt solution put under his skin. A laparotomy was done. There were four openings found in the small intestines, and several mesenteric vessels were cut. The abdominal cavity was filled with bloody clots and extravasated intestinal contents. The abdominal cavity was cleansed thoroughly with hot salt solution, the openings in the intestines and the mesentery were closed. At this stage of the operation the man was severely shocked, the abdomen was filled with salt solution and the wound was closed. The man was given more salt solution under his skin and an enema of hot coffee. He was put to bed but continued to grow worse and showed evidence of internal hemorrhage, the right chest becoming slowly filled with fluid. He died 62 hours after being shot. At no time after the first operation did I feel justified in subjecting the patient to another one. At the autopsy the wounds of the intestines and the mesentery were found to be closed and intact. On examining the diaphragm a bullet wound was found which extended into the pericardium. It made two holes through the right auricle and then through the pericardium again and then cut a small opening in the outer side of the vena azygos major. The pericardium was filled with blood and two well-formed blood clots were found in the openings of the auricle. Some blood had escaped from the pericardium into the right pleura. This cavity was filled with blood from the wounded azygos major vein. At the time of the operation I did not find the opening through the diaphragm. Had an opening been found in the diaphragm the man's condition was such that I could not have extended the time of the operation, and even had the operation been continued, the autopsy showed that he could not have been saved.

CASE V.—November, 1901, a conductor on a street railway got into a fight and was stabbed with a small penknife in the chest. Dr. A. C. Harrison saw him a few minutes after the injury and ordered him sent at once to the hospital. The man was extremely nervous and fearful of death. There was some blood on the chest that had escaped through a small wound at the left border of the sternum in the first intercostal space. The skin was cut about one-quarter of an inch in length and parallel to the rib. The skin was cleansed, and under a local anesthetic the wound was enlarged and an opening found that extended into the thoracic cavity. Some blood was found in the muscles under the skin. There was some flatness at the back of the left pleural cavity. From the direction of the wound it seemed that the internal mammary artery or some larger vessel near the heart had been severed, and there was evidently some internal hemorrhage going on. Under a

general anesthetic a large flap of skin and muscle was turned back, the sternal end of the second rib and its cartilages and a part of the sternum were cut away. This gave an opening into the chest cavity, and the bleeding points of the internal mammary vessels were found retracted some distance from the stab wound. These bleeding points were caught and tied. There was a small stab wound of the lung, which was not bleeding to any extent, and nothing was done with it. At this time the respiration became irregular and the lung collapsed. The face was very much cyanosed, and respiration ceased. The heart-beat was irregular and rapid. The wound was packed, the man inverted, artificial respiration done, tongue pulled forward, salt solution given under the skin, and strychnin and whisky hypodermically. After about two minutes respiration began slowly, and shortly after that all the symptoms of collapse disappeared. The wound was closed and a dressing applied. The man continued to improve, and at the end of three weeks he was going about the ward. The blood in the pleural cavity was gradually absorbed, and no inflammatory conditions followed the operation. He returned to his work two months after the injury. This was a clear case for operation, and no one would have hesitated to operate if they had seen the patient at the time we did. Should we have not operated the results would have necessarily been fatal.

Dr. T. H. White, of Connellsville, Pa., mentioned a case of a railroad man who had been under his care. His chest had been severely injured and there were several broken ribs. The man got along very well for three weeks, having at times some slight dyspnea and cough and expectoration streaked with blood. Three weeks after the injury he was walking around the ward when he suddenly felt great oppression, and had a violent hemorrhage from the mouth. He died in a very few minutes. At the autopsy a portion of a broken rib was found imbedded in the lung. It had produced ulceration of the lung and some of the large vessels, from which the hemorrhage had taken place. In all cases in which there is a foreign body in the lung we should operate and remove the foreign body, otherwise the result will follow sooner or later that in Dr. White's case. There will either be a sudden death due to hemorrhage, or there will be a prolonged illness due to suppuration in the lung, and death from pyemia.

Dr. J. W. MacDonald, of Fairmount, W. Va., mentioned a case which he had in his service April, 1892. The man had been shot one inch to the left of the sternum in the third intercostal space. When seen, one hour after the shooting, there was great shock, dyspnea, and slight expectoration of blood. Evidently the lung had been injured, but whether some large vessel had been hit, it was impossible to say. The man was moved to the x-ray room and several photographs were taken of the chest in the different positions. In each picture a shadow was seen which seemed to be about two inches from the angle of the sixth rib. The rib was therefore resected, and by retracting the edges of the wound the lung was grasped and a bullet was found one inch from the surface of the lung. The lung was incised, the bullet removed, and the hemorrhage, which was rather profuse at first, was checked by a solution of adrenal wiped over the surface of the cut lung. The wound was closed, and at the lower point a drain was left in the pleural cavity for three days. The man made an uninterrupted recovery.

In May of this year I made some observations on the thorax of dogs. The dogs were given .13 to .26 gram (2 to 4 grains) of morphia hypodermically half an hour before operation. Under ether anesthesia the skin was prepared as in all operations, and thoroughly aseptic precautions were taken through all stages of the work.

CASE I.—On May 27 a dog of medium size was anesthetized and the third and fourth ribs on the left side were resected for three inches. This gave a large opening into the thorax. The respiration immediately became rapid and panting. After six to eight respiratory efforts the lung collapsed and there was a parallel ballooning up of the collapsed lung with the expiratory effort of the right lung. Respiration then ceased, the heart-beat continued rapid and weak. The wound was packed with gauze and the dog elevated, the tongue pulled forward and artificial respiration begun. In about two minutes slow and irregular respirations began and soon became normal. The gauze was removed from the wound and the same symptoms recurred. The lung was then grasped and

pulled into the wound, completely closing it. Artificial respiration was begun again as before and in about two minutes the dog slowly revived. The lung was then allowed to escape into the chest and after a few respirations the same excitement, panting respiration and rapid heart-beat were noticed. The lung was then compressed against the hilum and artificial respiration begun as before and the dog soon revived. The two upper lobes of the left lung were then pulled out and a double ligature passed through the lung at the hilum and the lobes were cut off. I will say here that we always find the dog's lung of many more divisions than that of the human being. The visceral pleura was sewed over the cut surface of the lung and the stump put back into the chest. The wound was closed with interrupted sutures and the skin with silkwormgut, and a collodion dressing applied. On May 28 the dog was a little sick but walked around and drank milk and water. He had very little fever and continued to improve and grow fat. On June 24 the dog was killed, the chest opened, the stump was found thoroughly healed, the ligature around the base of the lung was buried in the adhesions, and the lower lobes of the lung were doing their proper work. There were some plastic bands running across the upper part of the thoracic cavity which had contracted, allowing the pleural surfaces to become adherent. There were no signs of suppuration in either pleura or the pericardium.

CASE II.—On May 28 a dog of medium size was anesthetized and the fourth and fifth ribs on the right side resected. All the respiratory symptoms were noted as in the first dog. The lung was then brought into the wound and the upper lobe was split from the hilum to the free border and allowed to bleed freely. It was then sewed with interrupted silk sutures on both sides of the incision. These sutures were sufficient to stop the bleeding. The thoracic cavity was wiped out and the chest closed by interrupted buried sutures, the skin closed by silkwormgut and the collodion dressing applied. On May 29, 30 and 31, the dog was very sick and showed all evidences of septic infection. The dog died May 31. At autopsy the chest contained one pint of dirty thin septic pus. Lung was collapsed and covered with a layer of fibrinous exudate. There had been no bleeding into the cavity of the chest. There was also a septic pleurisy on the left side. There was septic pericarditis and endocarditis.

CASE III.—On May 28 a dog of medium size was anesthetized, the fourth and fifth ribs on the right side were resected, the chest freely opened, and all phenomena as in Case I noted. The lower lobe was then pulled out of the opening and was cut off at the hilum and sutured as in the first case. The dog did well for three days, then a pleurisy and pneumonia developed on both sides and on the sixth day the dog died. On autopsy there was a double septic pleurisy and pneumonia with septic pericarditis and endocarditis.

CASE IV.—On May 28 a dog of medium size was anesthetized and the fifth and sixth ribs on the left side were resected, the chest opened, and the lung pulled into the wound. The upper lobes were ligated at the hilum and cut off. Respiration at this time ceased and the dog could not be resuscitated; the heart continued to beat for five minutes after respiration had ceased. This dog died from shock, as the right lung had not collapsed.

CASE V.—On May 30 a dog of medium size was anesthetized, and the left chest freely opened. After eight respiratory efforts both lungs collapsed. This dog could not be resuscitated; the heart continued to beat for six minutes after respiration ceased.

CASE VI.—On May 30 a dog of medium size was anesthetized and the third, fourth, and fifth ribs on the left side were resected. The lung was compressed against the hilum and a large opening made into the pericardium. The left ventricle of the heart was stabbed, the wound extending into the ventricular cavity, which was shown by blood spurting out of the wound during each systole. A finger placed over the opening controlled the bleeding. The right lung at this time collapsed and the dog could not be resuscitated. The heart continued to beat for some minutes afterward.

CASE VII.—On May 30 a dog was anesthetized, the left chest freely opened, the pericardium was drawn into the wound and opened. The left auricle was cut into and it bled freely. The opening was caught up and closed by a ligature, the heart continuing to beat. The ventricle was then opened freely and bleeding was controlled by two deep interrupted sutures. The lungs of this dog also collapsed and it could not be resuscitated.

For operating on the chests of dogs, we should have at hand artificial means for continuing the respiration; the mediastinum in dogs is thin and in many cases there is a direct communication between both pleural cavities. The opening of one side of the chest is practically the same as making an opening into both sides. There is nearly always a collapse of both lungs. By opening the chest we interfere with the action of the diaphragm, and until the chest cavity is closed the lung should be inflated and emptied by artificial means. The immediate thing to be feared in all chest wounds is the collapse of the lung and not the cessation of the heart-beat. Inflammation

tions most frequently follow operations of the pleura, lung or pericardium, and by extensions of these inflammations septic pleurisy, pneumonia and pericarditis develop and the inflammatory products are carried by the medium of circulation into other parts of the body. The lung can be cut and sewed up and regain its normal functions. A large part of a lung can be removed and still the animal continue to live. To open the pericardium we must go through the pleural cavity. None of the dogs lived upon whom the heart had been operated, and these dogs did not die from hemorrhage but they died from collapse of the lung. I found it was possible to close wounds of the ventricle with interrupted stitches. The closing of the wounds of the auricle is far more difficult, owing to the thin walls.

Dr. Sherman's article, to which I have already referred, gives most excellent advice in such wounds. His plan of taking two stitches parallel to the wound of the heart as retaining sutures is a great advantage in steadying the heart when the interrupted sutures are inserted. The stitches into the ventricle should not go down into the ventricular cavity. To place these stitches you must work quickly and take no account of diastole or systole. If the heart is caught with a pair of forceps it will jump and tear itself away from the bite of the forceps, therefore in dealing with a wounded heart it must not be given rough usage. The stitches which are passed quickly and then tied do not seem to excite it. It is impossible to drain wounds of the thorax, of the pericardium, or of the heart of dogs, but in operating upon the human pericardium and heart the advisability of drainage is an open question. If we feel certain of asepsis then the cavities may be closed, but if not it is best to drain each cavity at the lowest point. Should there be any signs of sepsis in the closed cavity we must open it at once and give free drainage.

### TRANSIENT UNILATERAL OPHTHALMOPLEGIA EXTERIOR OF PERIPHERICAL ORIGIN WITH ATROPHY OF THE OPTIC NERVE.

BY

CHARLES J. KIPP, M.D.,

of Newark, N. J.

Mrs. E. E., aged 35, a very healthy-looking woman, consulted me for the first time August 4, 1902. Before her marriage she had an attack of facial erysipelas, followed by falling out of the hair. The first pregnancy resulted in miscarriage at six months, following a fall. The second pregnancy resulted in birth at full term of a healthy child, who is still living and in good health. The next pregnancy ended in miscarriage at two months. The next year she gave birth to a healthy child, who died from cholera infantum when nine months old. In each of the following two years she gave birth to a healthy child, both of whom died from diseases of the respiratory organs. Shortly before the birth of the last of these she had paralysis of the right side of the face, which lasted two months and passed away. Five months before she came to me she had given birth to twins, one of whom has since died from cholera infantum. The other is living and in good health. She nursed the twins for two months, when her milk gave out. Soon after this she began to have severe pains over the right eye. This pain has continued uninterruptedly, and has increased in severity up to now. Two months ago she first noticed dimness of vision of the right eye. Now she is blind in this eye.

I found that she had perception of light only. The pupil was somewhat larger than that of the left eye, but otherwise the eye was normal in appearance. There were no changes in the fundus oculi. The mobility of the eye was unimpaired. There was marked anesthesia of the skin of the lids and of the ocular conjunctiva of this eye. The left eye was normal and vision five-fifths. As she had pain on pushing the globe backward, I looked upon the case as one of retrobulbar optic neuritis, and prescribed potassium iodid, .65 grams (10 grains), three times daily.

An examination of the urine showed absence of albumin and sugar. She denied having had symptoms of syphilis.

A week later I saw the woman again and found no change since the preceding visit. Seven days after this last visit I noticed a drooping of the right upper lid, which could be raised, however, for a moment by strong effort. The lid was neither swollen nor red. There was no other change except that the pain over the right eye was much less. A week later I found

complete ophthalmoplegia exterior of the same eye. The ptosis continued, but she could raise the lid more easily than before. There was no protrusion of the globe. The eye could not be moved in any direction except very slightly downward. When told to look down the eyeball would be rolled in and down. The pupil was still active. It contracted somewhat when strong light was thrown in the eye; it reacted consensually and contracted as much as that of the left eye on convergence. The fundus oculi remained normal except slight blanching of the optic nerve papillæ. The pain over the right eye had now entirely subsided and ptosis had disappeared completely. The ophthalmoplegia continued for about two weeks. After this time it gradually passed away and in about two weeks more no trace of it remained. The globe could be moved in all directions as well as the left one. By this time the optic disk had become quite white and the vessels were much smaller than those of the other eye. The pupil was somewhat larger than that of the left eye, and did not react to direct illumination, but still contracted consensually and in convergence. At the present time she has no perception of light in this eye. The left eye remains normal. There was at no time a paresis or paralysis of the second branch of the fifth nerve.

This case seems to me to be of more than ordinary interest for several reasons. One of these is its comparative rarity. In Wilbrand and Saenger's great work, "Die Neurologie des Auges," a few similar cases are mentioned on page 321, but none just like it. In the cases there mentioned syphilis was present and gummas or gummous exudation at the base of the skull, or periorbitis of the superior orbital fissure or optic foramen was the cause of the eye trouble. In my own case the patient denied having had a primary sore and secondary symptoms, but the abortions and perhaps also the fact that the pain and the paralysis passed away very quickly under the administration of potassium iodid make it at least probable that syphilis cannot be excluded. As to the nature of the lesion causing the atrophy of the optic nerve and the ophthalmoplegia we can only conjecture. It would seem, however, most probable that it was a periostitis, a circumscribed gummous meningitis, or a gamma at the base of the middle fossa, just back of the orbit. It probably first attacked the optic nerve between the chiasm and the optic foramen and then spread to the back of the sphenoid fissure where it compressed the branches of the third, sixth, fourth, and branches, and the first branch of the fifth.

That the disease of the optic nerve was not an inflammation is pretty certain as no signs of retrobulbar neuritis were present at any time and that the lesion was not in the orbit is shown by the absence of the slightest protrusion of the globe.

Speaking of such cases Wilbrand and Saenger (op. cit.) say "if the gummous process extends to the periosteal tissue which occludes the orbital fissure, this circumscribed inflammation will endanger the motor nerves of the globe to a still greater degree, as the oculomotorius and the upper branch of the fifth are here crowded together in a small space. The symptoms caused by this appear often very suddenly, and consist in complete ptosis and paralysis of all the interior and exterior nerves of the globe, with anesthesia of the cornea, the conjunctiva and other regions supplied by the first branch of the fifth nerve, as well as of great impairment of vision or blindness through involvement of the optic nerve, which passes through the neighboring optic foramen." In my case the interior muscles were not affected.

Why the nerve twigs supplying the ciliary muscle and the sphincter pupillæ should have escaped the fate of all the other branches of the third nerve is difficult to explain, unless we assume that their location in the trunk of the nerve shields them to a greater extent than the rest against pressure. I do not know that any one has thus far shown such to be the case. Bernheimer<sup>1</sup> says: "My investigations concerning the further course of the fibers of the center of the sphincter in the trunk of the oculomotorius are not yet completed, but I think I can say at this time that these fibers lie close to

<sup>1</sup> Graefe-Saemisch's Handbuch der Augenheilkunde, second edition, Bd. viii, Chap. xi, second supplement, p. 91.

one another not only in the cerebrum near the median cleft, but that they also further on toward the orbit form a compact bundle, which to all appearances occupies the central portion of the trunk." There is also on record an anatomic examination of a part of the trunk of this nerve before its passage through the dura, in a case of paralysis of the third nerve, in which the ciliary muscle and the sphincter were but slightly involved. The case is published by Ackermann:<sup>1</sup>

A young man developed suddenly diplopia, for which he went to an eye clinic in Halle. Two months later his left eye was found to have ptosis and paralysis of the superior rectus muscle, the internal rectus and the inferior rectus. The accommodation was but little injured and the pupil was active, though sluggish. He died five days later. The autopsy showed among other lesions that the third nerve, at about 1½ centimeters before entering the dura, was surrounded by a rigid fold of arachnoid like a ring, and held very tense by an old partly organized blood clot the size of a pea, situated in the arachnoid. The trunk itself at this point was constricted by a deep furrow which reduced its size to that of a thick twine thread. The microscopic examination showed that at this point the nerve was changed to a thin strand of delicate fibers, closely surrounded by the sheath. With a low magnifying power nothing like nerve substance could be seen, only crumbled fragments of medullary substance were visible. While in sections of the lateral portion no signs of preserved nerve fibers could be seen even with a high magnifying power, there could be seen in sections of the medial portion a small number of well stained fibers. They could be traced for some distance in some slides, but their course could be followed much more satisfactorily in a series of consecutive sections through the atrophic portion of the nerve. These preserved fibers were substantially confined to the medial third and in sagittal sections occupied about its middle.

Ackermann thinks that the result of his investigations is of some importance as it gives us information as to the position of the nerve fibers which supply the inner muscles of the eye. He says: "As all the muscles with the exception of the ciliary muscle and the sphincter were completely paralyzed, the nerve fibers found in the trunk of the nerve must be regarded as those belonging to the muscles not paralyzed. The position of these fibers would therefore be in the middle portion in the regions of the medial third of the nerve. Like the other nerve fibers their course is not in a straight line in the trunk of the nerve, but they lie in different planes in different parts and frequently cross other nerve bundles." (Of course what has been said applies only to the described part of the nerve, about 1½ centimeters in front of its entrance into the dura.) This central position in the trunk of the nerve which protects it in an unusual degree against external insults furnishes us with an explanation of certain facts observed in paralysis of the oculomotorius. It brings us nearer to an understanding of the symptom-complex known as ophthalmoplegia exterior, in which the fibers supplying the muscle of accommodation and the sphincter papillæ remain intact while all others are destroyed, and in which nuclear paralysis is not present. He also points out that if such a grave insult as the one which, in his case, struck the nerve causing strangulation of all the entire nerve and destruction of nearly all the fibers around it was incapable of destroying all accommodative and papillary fibers that they will resist less severe injuries still more readily. It would be imaginable that in our case in which the pressure was exerted equally all around, the central position afforded a special protection. Nevertheless this must, in all other cases in which direct lesions reach the nerve, be of great advantage.

My case would seem to furnish further clinical support of the view that cases of ophthalmoplegia exterior are not necessarily of nuclear origin. Wilbrand and Saenger have this to say on this point: "Moreover, the clinical symptoms of an isolated ptosis and of an isolated ophthalmoplegia exterior caused by luetic affection of the trunk of the oculomotorius are the very ones which have so shaken Mauthner's doctrine, held to be well

founded, that at present we are unable to give either a test-proof definition or a trustworthy diagnostic sign for a supposed nuclear paralysis. And when, through a gummosus alteration confined to the trunk of the oculomotorius, an isolated ptosis is actually observed, as the only paralysis of this nerve trunk, it is allowable to transfer this diagnostic experience to other nerves, and v. Graefe's dictum that as a consequence of disease of a nerve trunk the muscles supplied by it must all be paralyzed, has only a limited validity in the future.

Bernheimer<sup>1</sup> says on this point: "It may even occur that it, the oculomotorius, is not affected in the entire diameter either by inflammation, degeneration, or pressure atrophy; that only separate fiber bundles are put out of function. This condition we meet not infrequently; we see isolated paralysis of a single or several bundles of the oculomotorius make its appearance, which seems most likely to be due to an intracerebral disturbance of nuclear or fascicular origin, while in fact the cause is to be looked for in a partial inflammation, degeneration, or pressure atrophy, which may even remain permanently partial of the trunk of the oculomotorius."

## GLYCOSURIA GRAVIDARUM.

BY

WILLIAM RUOFF, M.D.,

of Philadelphia.

That this important complication is not so uncommon as it is unrecognized is due to the neglect of most obstetricians to analyze carefully the urine of all their patients. Were this done more systematically, reports would be fuller and more frequent.

When we consider that important nutritive changes are taking place during the entire course of gestation, and that every solid and fluid constituent of the body is being affected, it seems only rational to anticipate functional disturbances in other organs than those in immediate relationship with the uterus. For instance, the kidneys are particularly affected.

Glycosuria gravidarum does not differ essentially from glycosuria in the nongravid subject. The presence of sugar in the urine, high specific gravity, polyuria, loss of strength, progressive emaciation, and great thirst make the picture complete. Vulvar pruritus is frequent, hydramnios has been observed, and asthma likewise. Ocular disturbance led to an analysis in one case.

The etiology of this disease has been plausibly explained by Oddi and Vicarelli,<sup>1</sup> who found that during gestation there is a largely increased consumption of hydrocarbons derived from the waste of nitrogenous material resulting from fetal nutrition and growth. This was found upon analyzing the air respired by pregnant women. Also heredity, acquired and hereditary syphilis, and pancreatic disease play important roles.

Diabetes insipidus and physiologic diabetes<sup>2</sup> must not be confused with true diabetes gravidarum; nor is the mere reaction of Fehling's solution conclusive evidence of true glycosuria, since phloroglucin, a so-called glucosid found in many cases, gives a similar reaction. It constitutes a type of glycosuria giving rise to no constitutional or systemic disturbance, nor is it found in the blood.<sup>3</sup> Conjugal diabetes is diabetes existing simultaneously in man and wife. Climacteric diabetes is described by Lawson Tait<sup>4</sup> as a special form beginning at or near the menopause and running a benign course and terminating in recovery after a few years.

In this paper glycosuria will only be discussed gynecologically. Amenorrhœa develops sooner or later; dysmenorrhœa and menorrhœgia are frequent, depending greatly

<sup>1</sup> Klinische Monatsblätter für Augenheilkunde, November, 1902, p. 306.

<sup>1</sup> Op. cit., Bd. viii, Chap. xi, Supplement II, p. 78.

upon local inflammatory changes. Vulvar eczema, pruritus, granular erosions of the cervix, and fungoid endometritis are also met. Persistent menstrual flow during pregnancy has also been reported.<sup>5</sup>

Diabetes is more rare among women than men and there is ground for belief that apart from its weakening and debilitating constitutional effect it has a special influence upon the sexual centers, producing impotence (although an opposite effect has been noted<sup>6</sup>). Senator<sup>7</sup> notes with wonder "that conception has even taken place in diabetics."

The frequency of glycosuria gravidarum is a matter of speculation. Foreign investigators give some startling figures. Of 125 cases 60, or 48%, were affected.<sup>26</sup> Keim found 4 in 19 cases. Greisinger<sup>8</sup> reports 2 in 53 cases; Duncan<sup>9</sup> 1 in 104 cases. Hirst<sup>10</sup> claims that not over 1% are affected. Dorland<sup>11</sup> claims 15% to 50%, with a maternal mortality of 25%. The Boston Lying-in Hospital has not had a case in 10,000 pregnancies.<sup>12</sup>

Glycosuria gravidarum may develop during pregnancy or conversely pregnancy may occur during glycosuria. In the latter event its malignancy is early established, usually before quickening, frequently resulting in the destruction of the fetus in utero at or about the fifth or seventh month, though not necessarily expelled until later or at term and showing the usual characteristics of maceration and decomposition. An infusion of the epiderm in one case gave positive sugar reaction.<sup>12</sup>

Those infants born at term invariably die early, living but a few hours, or at most, a few months; if still-born death results from degeneration of the placenta or apoplexy.

Puerperal glycosuria is probably a constant quantity. Brucke<sup>13</sup> contends that this is a physiologic condition due to lactation. Iwanoff,<sup>14</sup> Lecocq,<sup>15</sup> and Hempil<sup>16</sup> agree with him, qualifying their statement that it increases in proportion to the activity of the mammary secretions. Seegens and Lehman<sup>17</sup> deny these assertions in toto. Lecote<sup>18</sup> believes the reaction of the copper test is due to salts of urine. Weiderholt<sup>19</sup> substantially agrees with him. Du Moulins,<sup>20</sup> Gubler and Chailley,<sup>21</sup> Louvet,<sup>22</sup> De Sinety,<sup>18</sup> and Johannowsky<sup>24</sup> all emphatically declare their belief in Brucke's theory. It remained for Kaltenbach<sup>25</sup> to settle conclusively this vexing problem. He found after an exhaustive and painstaking chemical analysis of 34 puerperal cases that the urines all contained sugar at some time and some few all the time. He concluded it was a constant factor, forming a sort of resorption diabetes; also that any untoward disturbance of the milk secretion from mastitis, puerperal fever, or death of the fetus, augmented the quantity of sugar.

The treatment of glycosuria gravidarum does not differ very materially from that in the nongravid subject, viz., diet, exercise, massage, and the usual medical treatment directed to the cause if found. If, however, there is imminent danger of death to either mother or child, or both, premature labor should be considered.

Beside my own the following cases have been collected from various sources, notably from Fry's paper on "Diabetes Mellitus in Pregnancy:"<sup>26</sup>

Warner<sup>27</sup> (one case; nine pregnancies, five at term and four miscarriages).—First pregnancy, labor at term—instrumental, child living, diabetes not suspected; second pregnancy, 2½ years later, pruritus pudendi at 5 months, labor at term, child died two weeks before birth; third pregnancy, 1 year later, child stillborn, labor at term; fourth pregnancy, 13 months later, child dead; fifth pregnancy, 10 months later, miscarriage at 5 months; sixth pregnancy, 4 months later, miscarriage at 2 months; seventh pregnancy, 3 months later, miscarriage at 6 weeks; eighth pregnancy, 10 months later, miscarriage at 2 months; ninth pregnancy, 2 years later, delivered at term, child dead 7 weeks previous. Quantity of urine rose from three to six gallons per diem, containing 8% of sugar to the ounce. In a personal letter dated February 16, 1903, Dr. Warner states these quotations upon the polyuria are authentic. The woman continued in poor health until her demise, some months after confinement.

Brooks (one case).—Glycosuria discovered at 7 months,

labor induced at the eighth month; child small and emaciated. Both living; no subsequent report upon diabetes persisting.

Duncans (three cases).—First case: Premature death of fetus; labor before term, mother died on third day. Second case: Glycosuria at quickening in the eleventh pregnancy, child dead, diabetes persisting, disappeared after one month, returned in five months, and patient died three months later. Third case (three pregnancies during glycosuria): First pregnancy, fetus dead at eighth month; second pregnancy, fetus dead at term, decomposed; third pregnancy, glycosuria discovered at fifth month; premature labor induced, fetus decomposed, mother died on third day.

Fry (one case; two pregnancies).—First pregnancy, labor normal, child living; second pregnancy, glycosuria discovered at fifth month, labor at seventh month, male child, well formed, dead some days before birth, mother died four days later.

Reid (one case; two pregnancies).—First pregnancy, macerated fetus at term; second pregnancy, four months later, diabetes discovered early, fetus dead at eighth month, resulting in premature labor, glycosuria persisting.

Newman (one case; three pregnancies).—First pregnancy, diabetes existed two or three years before conception; result, labor normal, child living; second pregnancy, normal; third pregnancy, labor at seventh month, child dead, mother died three days later.

Husband (one case; three pregnancies).—Diabetes in third pregnancy, premature labor at eighth month, child died a few hours after, mother died a few months later; liquor amnii saccharine.

Davidson (one case; four pregnancies).—Labor at eighth month, child feeble, lived 13 hours, diabetes disappeared, relapse, and death of mother four months later.

Seegens (one case; three pregnancies).—All three ended in miscarriage at middle of gestation, mother died after third pregnancy.

Lecorché<sup>28</sup> (one case; two pregnancies).—First pregnancy, glycosuria throughout, labor normal, glycosuria persisting in both mother and child; second pregnancy, labor normal, child living, also mother.

Taylor (one case; three pregnancies, all diabetic).—First pregnancy resulted in a miscarriage; second pregnancy, labor normal, child living, persisting glycosuria; third pregnancy, same as second, glycosuria persisting.

Bennwitz (one case; six pregnancies).—Glycosuria during fourth, fifth and sixth pregnancy. Child prematurely born dead in fifth pregnancy, also menstruated during this pregnancy.

Winckel (one case; two pregnancies).—First child stillborn, second child alive.

Harmon<sup>29</sup> (one case; two pregnancies).—First pregnancy, normal; second pregnancy, glycosuria discovered at fourth month, both living.

Born<sup>30</sup> (one case; one pregnancy).—Glycosuria possibly existing several years before conception; seen first at fifth month, urine not examined until a few hours before death (one month later), contained 8% sugar.

Hehir<sup>31</sup> (two cases; two pregnancies).—First case, patient aborted at fifth month, lived only 12 hours; second case, patient suffered from obesity; glycosuria existed for two years, labor at term, child dead and macerated; both liquor amnii and an infusion of the epidermis of the child showed positive reaction for sugar.

Williams (three cases).—First case (mother and three sisters diabetic): First pregnancy, glycosuria after first confinement, labor at term; second pregnancy, glycosuria, child alive at term, glycosuria persisting; third pregnancy, labor at term, child living, mother died after third confinement. Second case: Glycosuria early in pregnancy, sixth child dead at eighth month; had one abortion, in fourth pregnancy; mother died four months after last confinement. Third case: First pregnancy, labor normal, glycosuria (?); second pregnancy, labor normal, glycosuria (?); third pregnancy, labor normal, glycosuria (?); fourth pregnancy, labor normal, glycosuria negative; fifth pregnancy, labor normal, glycosuria negative; sixth pregnancy, glycosuria; seventh pregnancy, glycosuria, mother recovered.

Ferriels.<sup>32</sup>—Glycosuria discovered in tenth pregnancy, labor at term, died 15 months later of gangrene and phthisis. Postmortem, tumor of medulla oblongata.

Poulet.<sup>33</sup>—Girl of 16, pregnant at 15, glycosuria developed early; miscarried at eighth month; living.

Bennett<sup>33</sup> (one case).—Reports incomplete.

Esterle<sup>33</sup> (one case).—Reports incomplete.

Packard.<sup>34</sup>—Multipara covering period of 21 years, during which time she had numerous miscarriages and two stillbirths.

My own case is as follows:

Mrs. C. G., aged 25, of German extraction; family history negative; previous history of having always been well; her first child was born dead in 1893, but she recovered without any unusual symptoms persisting.

Second pregnancy, one year later (1894); in July, she complained of asthma, aggravated by hydramnios, also of pruritus pudendi; both yielded slowly to treatment, labor came on three months later, at term, transverse position, L. Scap. Ant.

Under anesthesia she was delivered per podalic version with good results. The child weighed nine pounds and was apparently healthy, but died suddenly twelve hours later. My attention being drawn to the patient's great thirst, I was reminded of the sticky character of the liquor amnii, which prompted me to examine her urine, which showed 4% sugar, sp. gr. 1.032, Roberts' test. She recovered and the sugar gradually disappeared.

Fourteen months later (1895) she was again delivered of a stillborn male child. No sugar.

In 1897 she was again pregnant, with sugar in varying quantities from fourth month on. Labor at term, instrumental, child (male) dead, weight ten pounds; recovery, sugar again disappeared.

She remained fairly well, showing no trace of sugar until January 23, 1898, when she applied to me for distressing tenderness of thighs and a feeling of fullness in the abdomen, menses scanty and thin, constipated, polyuria and great thirst. She tires on the least exertion, but has not lost flesh. Urine, sp. gr. 1.040, containing 5% sugar for a. m. specimen and 7% for p. m. specimen; quantity, 180 ounces per diem.

February 11: She missed expected menstrual period. Urine showed 5% sugar for a. m. and 6% for p. m. Fermentation test. Codein, 3 cg. (½ grain) t.i.d. diet. March 14: No appreciable difference; urine, a. m., 1.030 = 4%; p. m., 1.032 = 5%. Fermentation test. Codein was pushed 3 cg. (½ grain) per day until slight effect. March 19: Amount of urine voided, 6½ pints (104 ounces); codein continued, adding podophyllin in small doses until March 29. On this date the urine passed was 80 ounces, sp. gr. 1.032, containing 4 grains sugar to the ounce, or about 1%. Codein diminished gradually until May 14, when urine showed 1.5% sugar for a. m. and 2.5% for p. m. Codein increased. May 17: Urine, 48 ounces per day. Sugar, a. m. = trace; p. m., 3.5%. May 27: Urine, 60 ounces; a. m., 1% = 1.020; p. m., 1.5% = 1.028. Codein increased to 6.5 cg. (1 grain) four times daily. July 24: Sugar in small quantities, refused to continue diet or codein. September 3: Labor induced at eighth month. Child lived three months; sugar disappeared; mother living.

In reviewing this case I was struck by the spontaneous disappearance of sugar in the second pregnancy, only to reappear in the fourth; the repeated stillbirths; the death of the infant after the second labor; the death of the child three months after birth, of inanition, in the fourth instance. In her third pregnancy potassium iodid in ascending doses to saturation was prescribed, hoping to counteract any latent syphilitic taint, but the results were negative. The inference is that glycosuria in the mother was the ultimate cause of death in her offspring. The father is healthy.

All other conditions being equal glycosuria has no effect on labor, this is the consensus of opinion of all writers. Hydramnios has been remarked in several cases. Transverse position a mere coincident. Degeneration of placenta also occurred. Sticky nature of amniotic fluid has been commented upon. This saccharine reaction of amniotic fluid is due to the maternal secretions and not to any fetal urine, since micturition is not established functionally until after birth.

To recapitulate, we have a total of 28 pregnancies with 66 births, with results as follow:

Number of cases reported.....	28
Number of pregnancies.....	66
Number of mothers living.....	15
Number of mothers dead.....	13
Number of labors at term.....	42
Number of miscarriages.....	9
Number of premature labors.....	15
Number of children living.....	81
Number of children dead.....	25
Percentage of mortality to mothers.....	46%
Percentage of mortality to children.....	31

These results need no exhaustive argument to convince the most skeptical of the gravity of glycosuria gravidarum; even syphilis can hardly show so alarming a condition as this.

CONCLUSIONS.

Glycosuria gravidarum may arise at any stage of pregnancy. It is not so serious as when diabetes antedates pregnancy.

It may disappear in one pregnancy and reappear in another, and end fatally after successive attacks. It frequently arises during parturition, but is of no great importance.

Labor is not materially affected, other conditions being equal.

Pregnancy is most likely to be interrupted. Is very destructive to the fetus. More so than syphilis. Maternal mortality is nearly 50%. Diabetics should not marry. Death is usually by coma, no case of eclampsia having ever occurred in a diabetic.

SPECIAL ARTICLES

THE BUREAU OF GOVERNMENT LABORATORIES FOR THE PHILIPPINE ISLANDS: SCIENTIFIC POSITIONS UNDER IT, ETC.

BY

RICHARD P. STRONG, M.D.,

Director Biological Laboratory, Manila, Philippine Islands.

The Bureau of Government Laboratories for the Philippine Islands has now been organized for nearly a year and is at present quartered in a temporary building. The commission has decided upon the erection of a comprehensive and fitting structure for scientific work. The land has been secured and the government architect is already at work upon the building. This new Laboratory will be fitted with all modern appliances for thorough scientific work. It will be supplied with gas, water, vacuum, and steam and air pressure. Electric power is to be furnished wherever it is needed and the equipment will be complete. The scheme of the bureau contemplates a central institution in which laboratory work shall be done for all the bureaus which may need scientific assistance, so that a scattering of individual laboratories and a consequent loss of efficiency and equipment is avoided.

The work is separated into two divisions, a Biological and Chemical Laboratory, each occupying a wing of the new building, with the Serum Institute located in the rear in conjunction with the power-house. The building is divided into sixty rooms, so that separate lines of work can be carried on in individual quarters, each person engaged in scientific investigations being thus enabled to have his apparatus and appliances in the most convenient form. The division of the space is as follows:

GROUND FLOOR.

- Physical laboratory with constant temperature room below.
- Assay laboratory.
- Balance room.
- Combustion room.
- Distilling room.
- Research room for vegetable products.
- Chemical stores.
- Apparatus stores.
- Storekeeper's office.

Bacteriological diagnosis, two rooms.  
Animal parasites.  
Culture media.  
Mechanic.  
Incubator and cold storage.

## FIRST FLOOR.

Mineral analysis.  
Chemical director's laboratory.  
Chemical director's office.  
Sugar and food analysis.  
Library.  
Plant pathology.  
Biological director's office.  
Biological director's laboratory.  
Biological research.  
Spectroscopic rooms.  
Clinical research.  
Pharmacology.  
Balance room.  
Photography.  
Collections.  
Pathology.  
Physiological chemist.  
Three research rooms.  
Outdoor laboratory.

## POWER-HOUSE.

Cold storage plant and cold storage rooms.  
Serum packing room.  
Serum laboratory.  
Serum kitchen.  
Crematory.  
Engine room.  
Boiler room.

The plans of the Bureau contemplate research work not only in the realm of tropical diseases of both man and animals, but also in the resources of the islands.

The work during the past year has included a large number of analyses for the Board of Health, Custom House, Mining Bureau, Forestry Bureau, and Agricultural Department, diagnostic work for the various government hospitals, and investigations in tropical diseases, as well as researches on gutta-percha, rubber, and gums found in the islands. The scope of the work is continually widening, and there is no doubt but that the Bureau offers large opportunities for young men who desire to acquaint themselves with the conditions in the tropics and to advance our knowledge of lines of work which are each year concentrating more and more the interest of the scientific world.

The positions in the Bureau, outside of the Directors, are all under the Civil Service, and qualifications can be obtained through the Civil Service Commission at Washington. The scheme of the Bureau contemplates the following additions to the laboratory force during the next year:

One soil and water analyst . . . . .	\$1,500
One plant pathologist . . . . .	2,500
One physical chemist . . . . .	2,400
One analytical chemist and mineral analyst . . . . .	2,000
One assayer . . . . .	1,500
One entomologist . . . . .	2,500
One animal parasitologist . . . . .	2,500
One pathologist . . . . .	2,400
One drug assayer and toxicologist . . . . .	1,500

The candidates for the higher salaried positions, by understanding, will not be subjected to a rigid examination, but their previous research work, university degrees and general knowledge will qualify them, after the facts have been submitted to the Civil Service Board and found satisfactory.

The salaries for young men are good, and although expenses in Manila are at present higher than in the United States, nevertheless the difference in salaries is large enough so that prospective workers will be better paid here than they would be in America. It is the intention to engage none but the most efficient workers in the corps, and it is hoped that in the course of a few years a connection with the Bureau of Government Laboratories will be equivalent to a certificate of their superior attainments.

The plan of the institution contemplates the reservation of a certain number of research rooms in the laboratory building. These are to be at the disposal of independent investigators who wish to come to the islands for a temporary period as the guests of the Laboratories. These workers will be furnished all the laboratory facilities they desire, and it is hoped that the opportunities offered will render scientific study in the

tropics easy of access to all who have planned to undertake certain lines of work in which they are interested.

The recent report of the Director of the Biological Laboratory at Manila, P. I., says that while the practising physician of today, even in temperate climates, continually calls upon the clinical laboratory for diagnostic aid, the medical man of tropical countries must much oftener feel the need of the microscope end of the laboratory for the intelligent and correct diagnosis of his cases. Particularly is this so in regard to the febrile and intestinal diseases of hot countries, and without the accurate diagnosis of which much of the treatment must necessarily often be doubtful and of no avail. Thus in Manila we find typhoid, malaria, dengue, Malta fever, occasionally filariasis and a group of unclassified febrile disturbances. Without laboratory aid it is sometimes impossible to differentiate between these febrile conditions, while with such help the diagnosis is often at once rendered clear and final. For example, in typhoid and Malta fever we have specific serum reactions, while in malaria the hematozoon of Laveran is present in the blood. In filariasis, the discovery of the nematodal parasite in the circulation at once determines the nature of the disease, while in dengue fever, the absence of all these manifestations and the presence of a normal leukocyte count give us often valuable aid in differentiation. The laboratory examinations are, therefore, indispensable in this class of cases. So in regard to the intestinal troubles. Acute amebic dysentery must be frequently differentiated in the laboratory from bacillary dysentery, the former by the presence of the ameba dysenteriae in the stools and the latter by its specific serum reaction. How necessary this early differentiation is at once becomes evident when one considers how different is the treatment in each of these diseases. Likewise in regard to the specific diarrheas, such, for example, as owe their origin to *Strongyloides intestinalis* and *Balantidium coli*, and which are not amenable to ordinary treatment and soon result in chronic disease, it is impossible to correctly diagnose these affections without microscopic aid. Further than this, we shall only mention one other example of this group of animal parasitic diseases common here, namely, uncinariasis. In this malady, in severe cases, the untreated or incorrectly treated patients soon arrive at an advanced state of chronic anemia with marked debility and wasting. The diagnosis of the condition can only certainly be made by a microscopic examination of the feces, which examination also differentiates at once the affection from other forms of anemia. With the nature of the disease understood the parasite may be immediately attacked and the patient soon put on the road to recovery, while without such differentiation the individual often suffers for months and grows steadily worse under all treatment other than that directed against the uncinaria.

In still another class of cases, namely, those that are not only of importance to the individual infected, but also to the general public health, and upon the early and definite diagnosis of which so much depends in regard to the safety of the community, the laboratory must again be consulted for a final decision. Examples of such diseases are seen in bubonic plague and Asiatic cholera. Before the appearance of an epidemic it might be clinically impossible to differentiate a few cases of the latter disease from cases of cholera nostras of severe type, and only by laboratory aid could such a distinction be made possible. At the beginning of our recent epidemic we were able through such aid to strongly suspect the presence of Asiatic cholera within four hours of the appearance of the first case in Manila, and such a suspicion was made a certainty and the specific organism isolated and identified within 48 hours of this time. The importance of this fact can hardly be overestimated, as without such a laboratory diagnosis it would have been impossible to convince a large number of physicians for probably several weeks that Asiatic cholera really existed in the city. In regard to bubonic plague it is often possible by laboratory tests to diagnose the disease some time before the clinical symptoms are such that the malady may be definitely identified by them, and the early diagnosis of the first case of plague in a community is a most important factor in the suppression of the disease in that vicinity. The above instances have been cited merely as illustrations (of which many more might be given) of the importance of the Biological Laboratory in

Manila in its relation to the practising physician here in the problems that present themselves daily to him and of its direct practical value in the study of human tropical disease in which not only the physician, but the afflicted individual or even the community may be benefited.

Of its relation to the study of animal diseases I shall not weary you with many instances, but shall merely mention here that the diagnosis of such diseases as surra, glanders and farcy, pseudofarcy, hog cholera and swine plague and other diseases, all present here, are being diagnosed and differentiated very frequently in our Biological Laboratory<sup>1</sup> and that the presence in the Philippines of all of the above diseases was first recognized in the Laboratory. I, however, wish to mention particularly the discovery and report of a form of pseudofarcy occurring here which was formerly mistaken by veterinarians, from its clinical manifestations, for true farcy or cutaneous glanders, and the fact that a considerable number of horses suffering from this disease were destroyed. Through Circular No. 1<sup>2</sup> an effort was made to acquaint veterinarians and horse-owners with this malady, and doubtless now many animals will be saved that would formerly have been promptly killed. This serves merely as an example of the close relation of the Laboratory to important economic interests. Since Circular No. 1 has been published, a number of veterinarians have visited the Laboratory and admitted that they had destroyed horses which were probably suffering from this pseudofarcy. Specimens have also been sent for diagnosis which have proved to be from cases of this disease.

From, however, still two other points of view must the importance of the Biological Laboratory, particularly in Manila, be considered, and from both of these it is probably of equal or even of greater importance than from those points mentioned above, although it will perhaps sometimes be difficult to convince the laymen of this fact.

We refer, first, to its educational value, not only to the practising physician both native and foreign, but to the community in general. The other point of view is the influence it will exert on the progress of research in tropical diseases of man and animals in these islands. At this moment, however, it seems that the time is hardly ripe for the discussion of both of these questions. Still, in regard to the education of physicians and of the people, it may already be stated that the laboratory is today doing a much larger amount of diagnostic work than it did formerly, and that this work is increasing daily. The practising physicians, both native and foreign, and the doctors of veterinary medicine are continually making use of it in the diagnosis and differentiation of those diseases already mentioned in this article and in other affections. Occasionally a physician submits a specimen to the Laboratory for examination. The return blank informs him of the presence of some parasite which he had not suspected, or one which may be even unfamiliar or unknown to him. He is then of necessity compelled to inquire into the nature of the parasite and the treatment of the disease which it produces, and his knowledge is increased thereby, and the patient indirectly benefited. It has not been difficult for the writer to see the influence which the Laboratory has had upon the practice of both human and veterinary medicine in these islands. Educational influence exerted formerly by the Army Pathological Laboratory and the Laboratory of the Board of Health (both at present disbanded), and now by the Biological Laboratory can be easily traced. For some time after arriving in these islands, three and a-half years ago, it was a very rare thing for a blood or fecal examination to be performed for diagnostic purposes. The diagnoses in a certain class of cases were "guessed at." Today it is comparatively unusual here for a physician to treat a case of intestinal disease without a microscopic examination of the excreta. The people of Manila have likewise shared in this education, and it is not unusual for them now to suggest or ask during their illnesses that a laboratory examination of their blood or feces be made. Also in their daily hygiene, their choice of food and drinking

<sup>1</sup> The importance of the certain and early differentiation and diagnosis of these diseases is obvious. For example, an animal infected with surra endangers every other horse in the immediate vicinity. The same may be said of glanders for horses, rinderpest for cattle, and hog cholera and swine plague for pigs.

<sup>2</sup> See page 34 of the report.

water and in their protection of themselves against mosquitos they have been informed and instructed by the Laboratory (though sometimes indirectly). The value of its educational influence upon the veterinarians here is at once apparent from what has already been said, and we shall not dwell upon this topic further.

In regard to its influence upon the progress of research in the islands, we shall merely add that by laboratory aid only has it been possible to demonstrate the presence of both human and animal diseases in these islands which were hitherto unknown to exist here. Likewise, many new points have been added to our knowledge of these and other prevalent diseases.

1.—Puerperal Fever.—C. S. Bacon notes that puerperal infection carries off more women in the prime of life than any other disease except tuberculosis. This is due to failure of recognition by the laity and the profession of the importance of the management of labor. The writer discusses the differentiation of true infection and sapremia and the treatment of both. [H.M.]

2.—Flatfoot in Infants and Children.—R. W. Lovett describes the method of walking on the inner border of the foot in an attitude suggesting knock-knee, and believes that a lacing about the ankle makes it easier for the muscles to exert their force. Making the inner edge of the sole and heel thicker than the outer edge by  $\frac{1}{8}$  or  $\frac{1}{4}$  of an inch (3 to 6 mm.) will sometimes throw the weight more on the outer border and correct the deformity, but this may produce corns. The most useful method of correction is a graduated pad of leather or felt incorporated in an insole which raises the arch and holds the foot on the outer border. In the severest cases some pull on the inner malleolus is required. A steel plate jointed at the ankle to an upright running on the outer side of the leg to the upper part of the calf is necessary. The child should be drilled in use of the muscles and correct standing. [H.M.]

3.—See *American Medicine*, Vol. IV, No. 18, p. 689.

4.—Ethyl Bromid.—According to A. R. Solenberger, for the brief anesthesia of ethyl bromid all of the forked guillotines and the old patterns of McKenzie are too slow and clumsy, and those intended for the associate use of vulsellum and cold snare are not practical. To make ethyl bromid thoroughly effective it must be limited to selected cases and the use of a guillotine whose fenestrum can be opened with one hand, and whose blade and fenestrum ring are as thin as adequate strength will permit, and which allows of a grasp so firm that the tonsil can be crowded into the fenestrum to its fullest extent with a precision and quickness commensurate with the evanescence of the anesthetic. The writer describes a modification of the McKenzie guillotine intended to fill these indications. Three children's sizes are necessary. When anesthesia is complete 45 seconds are required to excise the tonsils, leaving one minute of unconsciousness to clear the vault. If the operator has not the dexterity necessary to complete both operations in this time there may be two sittings with bromid of ethyl. [H.M.]

6.—Accessory Pancreas.—G. F. Ruediger reviews the

literature and reports a case of recent occurrence in which the mass was located in the wall of the jejunum. He discusses the investigations as to the development of the pancreas from the intestinal tract and believes we are justified in concluding that it is formed from three embryonal matrices, one dorsal and two ventral. If one of the original diverticulums fails to unite with the others we can understand how it would give rise to an accessory pancreas. Abnormalities of the duct may occasionally be a factor in causing hemorrhagic pancreatitis from impaction of gallstones in the ampulla of Vater. Annular pancreas may so constrict the bowel as to cause marked dilation above the point of constriction. Diverticula of the intestine may be produced by continuous traction. The anomaly may at times be the starting point of carcinoma. Obstruction to the movements of the intestinal contents may be caused. [H.M.]

**7.—Poisoned Wounds.**—L. A. La Garde finds that although the composition and manufacture of ammunition, with the exception of the wad, rather negative the presence of bacteria in original packages observations show contamination in the explosive in 12% and in the ball in 47%, and this is increased by handling. The wad and wadding materials are always contaminated. Bacteria are not destroyed by the heat generated in firing. When placed in the barrel they can be recovered by shooting into culture media or animals. This has been demonstrated by anthrax placed on bullets and in black and smokeless gunpowder. Tetanus has been transmitted with fatal results when placed anywhere from the powder to the point of impact on the skin. It follows that all forms of bacterial life can be transmitted by portable firearms. Hematoma confer a special predisposition to infection, and gunshot lesions are of this nature, the lacerations and other injuries leading to a condition of necrosis beside, making them still more susceptible. The necrosis caused by burning is another factor, manifested in toy pistol tetanus. Vegetable poisons like curare and ricin and animal poisons like snake venom can be conveyed in the same way. Clean incised wounds absorb poison more readily than other wounds. In all criminal attempts a chemic and bacteriologic examination of weapon and ammunition and of the point of impact should be made. [H.M.]

**8.—Transplantation of the Omentum.**—E. J. Senn concludes from a review of literature and clinical and experimental work which he reports that transplantation of omentum over defects in the stomach is an established operation. He recommends it in intestinal defects, but it is still in the developmental stage; the most favorable portion of the intestinal tract is the cecum. Transplantation of omentum over defects in the small intestine should be preceded by fixation of the segment of intestine to the abdominal wall. Gauze drainage should be resorted to, excluding the general peritoneal cavity. [H.M.]

**9.—Fibrosis of Larynx and Trachea.**—R. W. Seiss finds meager attention given to this type of disease in the textbooks. The progressive sclerosis is unexplained. Stiffening of the muscles, changes in the epithelium, and the close adherence of the mucus give rise to inability to use the larynx in a normal manner for longer than a few minutes at a time. There is extreme vulnerability to acute inflammation. Spasmodic asthma is found in 10% of cases. The treatment should be stimulating—chlorotone, volatile oils, carbolic acid, and iodine are most useful, with alkalies for dissolving the mucus. Massage may be cautiously attempted, or may be combined with faradism. Breathing and vocal exercises often do good. Climatic change sometimes arrests the process. [H.M.]

**10.—Pathology After Nonsurgical Treatment of Peritonitis.**—H. D. Niles believes that absorbed in our efforts to avert immediate sepsis we forget the sufferings and deaths from recurrent attacks and from adhesions, dangers vastly greater than those occurring in primary attacks of acute peritonitis. Just how much general absorption may occur from a low-grade infection of appendix, gallbladder, or fallopian tube is impossible to determine. Febrile and circulatory disturbances, gastrointestinal disorders, headaches, fugitive pains, etc., may be due to such toxemia. Rheumatism is a not infrequent result of the nonsurgical treatment of peritonitis. Adhesions are more reliable evidence of infection than any available microscopic or bacteriologic proof. With adhesions gastric symptoms are

rarely absent, the dragging gives rise to ulcers, and the regions in which adhesions are most likely to occur are also the most frequent sites of malignant disease. In deciding for or against operation this pathology must be taken into the strictest account. [H.M.]

11.—See *American Medicine*, Vol. III, No. 25, p. 1054.

**12.—Prescription Repetition.**—W. C. Alpers believes the physician should be considered the owner of the prescription. The laws as to ownership differ in different States. The renewal of prescriptions is an evil. Physicians should bring enough influence to bear on legislation to prevent it. [H.M.]

### Boston Medical and Surgical Journal.

April 16, 1903. [Vol. CXLVIII, No. 16.]

1. A Case of Interscapulothoracic Amputation for Sarcoma of the Brachial Plexus. F. B. LUND.
2. The Diagnosis of Gonorrhoeal Urethritis. ALFRED H. GOULD.
3. Cream for the Home Modification of Milk. CHARLES W. TOWNSEND.
4. Variation in the Composition of Human Milk. PHILIP P. SHARPLES and EUGENE A. DARLING.

**1.—Interscapulothoracic Amputation for Sarcoma of the Brachial Plexus.**—F. B. Lund reports the case. A man of 40, 11 months previous to the report, was struck by a falling case of goods. The left arm in the region of the deltoid and the left knee were the seats of injury. The knee was put on a splint and retained there for 11 weeks; it is yet somewhat stiff. The arm in the region of the deltoid was bruised and painful, but otherwise attracted no great attention. It steadily grew worse, with darting pain in the radial side of the forearm and hand, and the latter has become weak, with shrinking of the thenar eminence. The left arm became atrophied, nearly completely paralyzed and anesthetic in the median nerve distribution. Treatment was unavailing. Later a hard, movable, tender tumor appeared in the left axilla. Operation was undertaken for removal of the tumor which appeared, on being exposed, to have its principal point of origin in the median nerve. In removing the tumor the axillary vein was torn. It was at once closed by three fine silk sutures. Not all of the tumor could be removed, and a month later, the remaining portion having greatly increased in size, interscapulothoracic amputation was done. Recovery was prompt, and as yet (three months) there is no evidence of recurrence. Microscopic examination showed the tumor to be a sarcoma, and the author is of opinion that it began in the brachial plexus of nerves. A point in amputation which is advocated by the author is ligation of the artery, then elevation of the hand and arm to return the venous blood, after which ligation of the vein. [A.B.C.]

**2.—Diagnosis of Gonorrhoeal Urethritis.**—A. H. Gould calls attention to the frequent tetrad arrangement of the gonococci as seen under the microscope, especially in the early stages. The organism decolorizes by Gram's method but absolute proof that the cocci seen are the gonococci can be determined only by culture. In the earliest stages the gonococci are extracellular, but the presence of pus at once gives them an unlimited medium in which to proliferate. They invade or are taken up by the pus cells where they rapidly multiply. The leukocyte at once begins to show degenerative changes, the nuclei increase in size and stain less perfectly. As the organisms multiply they invade the cell nucleus, which may in this way be completely destroyed and the entire cell be disintegrated by the rapidly multiplying germs. With this destruction the clump of gonococci are liberated and are free to attack other cells. When the germs seek the deeper structures in the urethra the pus becomes thin and the subacute stage is reached, this gives way to a more or less chronic condition and shreds are noticed in the urine. The amount of shreds floating in the urine indicates fairly well the amount of pus in suspension. The gonococci are rarely found in the shreds but in the pus cells floating in the urine. [A.B.C.]

**3.—Cream.**—C. W. Townsend concludes from his analyses that centrifugal cream is probably less desirable for infant feeding than gravity cream. As obtained from dealers it is often far from accurate in percentage. Siphonage is accurate but requires skill. Dipping off the top milk is accurate, if care is used. Pouring off the top is accurate and extremely simple. By this method it is possible to obtain cream of any desired

percentage. The upper 3 oz. gives 22%, the upper 6 oz. 14%, the upper 8 oz. 10%, the upper 12 oz. 8%, and the upper 16 oz. 6%. To ensure perfect accuracy frequent examinations with the Babcock machine are required; but for practical purposes this is not necessary, provided the mixed milk from a well-regulated dairy is obtained. [H.M.]

4.—Variation in Human Milk.—P. P. Sharples and E. A. Darling endeavored to collect samples under as uniform conditions as possible, 1 oz. being drawn by the breast-pump after the child had sucked for a few minutes in the morning. One hundred and seventeen analyses show the average composition to be: Fat, 2.91; sugar, 7.01; proteids, 1.34; ash, 0.13; total solids, 11.39; solids not fat, 8.48. There are wide variations from the average in milk from the same individual at different times and from different individuals. The average composition does not vary to any marked extent at different periods of lactation. During the first lactation the milk on the average is weaker in fat and proteids but stronger in sugar than in subsequent lactations. These differences may or may not be due to age. [H.M.]

**Medical Record.**

April 18, 1903. [Vol. 63, No. 16.]

1. A Report of Final Results in Two Cases of Polyarthrits in Children of the Type First Described by Still, Together with Remarks on Rheumatoid Arthritis. ROYAL WHITMAN.
2. "Eye-strain" in Youth and Its Modern Treatment. AMBROSE L. RANNEY.
3. Tuberculous (Basilar) Cerebrospinal Meningitis and Delusional Insanity Complicating Pulmonary and Laryngeal Tuberculosis. HENRY LEVIEN.
4. Resection of Intestine, with Report of Three Interesting Cases. A. E. ISAACS.

1.—Polyarthrits in Children.—R. Whitman reports two cases, differing in some particulars from those described by Still. In one there was complete recovery, of which Still records no instance. He mentions enlargement of the spleen only, yet in both these the liver was enlarged, in one ending in amyloid degeneration. In Still's cases the joints of the fingers and toes were exempt, while the spine was involved at an early period of the disease. In one of these all the small joints were diseased, while in neither was the spine affected. Still mentions slight pitting of the cartilage in one case that came to autopsy, while the writer's examination shows that such erosion is inevitable. The case in which recovery occurred was treated by daily exposure of the naked body to heat and light supplied by numerous electric lights beneath a tent-like covering. The cure was apparently completed by an attack of scarlet fever. The writer classes this disease as an atrophic form of rheumatoid arthritis, considering it as distinct from osteoarthritis or the hypertrophic form of arthritis deformans. It is the common form in early life. The symptoms simulate tuberculosis so closely that diagnosis is impossible until extension to other joints shows the true character. The appearances suggest the effect of a continuous feeble irritation within the joint and a feeble reaction. This indicates the removal of depressing influences, proper nourishment and stimulation of local nutrition. Deformity should be prevented and corrected and there should be local support to relieve painful motion. The cause of the disease is obscure. [H.M.]

2.—Eye-strain.—A. L. Ranney emphasizes the statement that too much stress cannot be laid upon the fact that severe types of eye-strain often exist in connection with eyes that have the most acute vision and that cause no apparent discomfort. He cites his own case, in which atropin cycloplegia revealed the cause of terrific headaches, uncontrollable vomiting, and extreme nervous debility after his eyes had been examined by three oculists without discovery of a latent refractive error. He deplors the use of the ophthalmoscope for determination of refractive errors. It is unfortunate that very careless refractive work is constantly done by oculists of international reputation. Some refractive errors enhance the acuteness of vision. It is gross injustice to the patient to omit any measure that may throw light on the diagnosis. He suggests methods by which parents and teachers may test visual acuity and muscle imbalance, and calls professional attention to the diagnostic importance of certain facial expressions and peculiar attitudes that tell of visual perplexities, illustrating these by cuts. No child

should begin education till its eyes are properly fitted for the work. Legislative enactment should compel examination. Test of muscle imbalance should be made as thoroughly as for refractive errors. A knowledge of the effects of eye-strain should be widely disseminated. The modern methods of testing are the only ones that furnish accurate information. [H.M.]

3.—Tuberculous Cerebrospinal Meningitis.—H. Levien reports these two cases because meningitis in adults is rather uncommon and because they corroborate the opinion that the disease affects men oftener than women. The symptoms in one case pointed to positive organic lesions in the brain substance, in the other the disorders were apparently only functional. [H.M.]

4.—Resection of Intestine.—A. E. Isaacs reports three interesting cases. A man of 52 suffered from an attack of apparent appendicitis. In addition to the symptoms of appendicitis there was absolute constipation. Refusal on the part of the patient delayed operation 24 hours. Laparotomy showed a normal appendix, but a mass of adhering intestines in the right iliac fossa. The origin of the trouble lay in the presence of a band passing apparently from the bladder to some structure in the region of the cecum. The desperate condition prevented this being ascertained definitely. A loop of intestine had slipped under this band, become strangulated and gangrenous. Some 23 inches of the gut was resected, anastomosis accomplished with a Murphy button, which passed on the ninth day. Recovery was complete. The second case was that of a boy of 9 years, who suffered from all the symptoms of acute appendicitis. A mass could be palpated in the region of the appendix. Operation showed a lumbar abscess, which instead of following the psoas muscle or pointing posteriorly, had worked its way forward and pointed in the usual site of an appendiceal abscess. The normal appendix was removed and the wound closed with drainage. The patient did well for three weeks, when he developed all the symptoms of acute intestinal obstruction. The abdomen was opened in the median line, the intestine quickly opened and an artificial anus established. Natural bowel movements being reestablished a third operation was done to close the artificial anus. This was but partially successful, and later a fourth operation was done, several inches of the gut being resected and anastomosis accomplished. The stump of the removed appendix failed to unite, producing a fistula at this situation. A fifth operation was done to effect its obliteration. The patient finally recovered, having been under treatment for nearly six months. The third case was one of strangulated femoral hernia, occurring in a woman of 56. Six inches of gangrenous gut was resected and the patient recovered. [A.B.C.]

4. Food and Nutrition in Disease. L. H. WATSON.
5. Methods which Render Some Therapeutic Agents More Palatable. SAMUEL E. EARP.

1.—See *American Medicine*, Vol. IV, No. 18, p. 690.

2.—Silver Sulfoichthyolate.—H. C. Wood, Jr., has made some experiments to determine the physiologic action of ichthargan. He finds that it is rapidly precipitated by the alkalis, the chlorids, and the albumens of the body, and that it is therefore unabsorbable as the sulfoichthyolate if given by the mouth. It can be absorbed after its hypodermic administration only with the greatest slowness. He failed to obtain in the rabbit any sign of its action from subcutaneous injection, except locally, with doses reaching as high as 1.4 grams to the kilo of body weight. The injection of ichthargan into the posterior lymph sac of a frog caused motor weakness and finally complete paralysis. This palsy was associated, if the dose was very large, with diminution in the irritability of the motor nerve, but was not entirely dependent on changes in the nerve or muscle, as the experiments show. The paralysis was chiefly central in origin. When injected into a vein there occurred an immediate fall of the blood-pressure which, if the

dose was sufficient, progressed steadily until death. After death the lungs were found filled with a frothy fluid and markedly congested at the bases. [C.A.O.]

**3.—Intubation for Croup.**—F. L. Taylor gives some practical points on intubation of the larynx for croup and reports 36 cases. In 2 cases the Klebs-Loeffler bacillus could not be found, leaving 34 cases of laryngeal diphtheria with 10 deaths. In 4 cases the patients already had marked evidences of bronchial diphtheria when intubated. He prefers the hard rubber tubes, as they do not become incrustated in spots with calcium carbonate. Some of the dangers mentioned are: Asphyxia from too prolonged attempts to introduce the tube; making a false passage and pushing down false membrane. Sometimes it will be found that the patient can inspire, but that expiration is impeded or impossible. This is due to valvular action of a piece of partially detached membrane at the lower orifice of the tube. In such cases if the tube is suddenly withdrawn, after giving a teaspoonful of brandy to produce cough, the false membrane will be expelled. If this is ineffectual the short O'Dwyer foreign body tubes may be used or tracheotomy may be performed. [C.A.O.]

**4.—Food and nutrition in disease** is discussed by L. H. Watson. Protein, fats, carbohydrates, mineral salts, etc., are taken up in order. The most important of these is protein, which for the sick is usually selected from the meat foods, milk and eggs, on account of their more perfect digestibility. The carbohydrates act as heat producers and spacers of protein. Bulk for bulk with protein food, they contain much less nourishment, furnish a larger refuse, and are not so easily digested, but they supply fuel to the body and protect it from waste, allowing the albuminoids to build up tissue and furnish secretions. The fuel value of protein and the carbohydrates is about the same. In speaking of milk the author says that when cooked with rice it furnishes the most easily digested food, with the largest amount of nutrients contained in moderate bulk of any combination of foods known to him. [C.A.O.]

**5.—Palatable Therapeutic Agents.**—S. E. Earp calls attention to some methods which render some therapeutic agents more palatable. To give castor-oil in one dose as a purgative the best method is to put in the bottom of the glass a small quantity of glycerin, then the oil, lastly half an ounce of sherry wine, and take at one draught. This will also apply to a simple dose of codliver-oil. In case either agent is dispensed in quantities an emulsion in which the flavor of cinnamon or gaultheria predominates generally serves the purpose. A glass of soda is a good vehicle for Epsom salts, but the ordinary "soda pop" is better. Chocolate, yerba santa, and licorice in the form of a heavy syrup may be used to disguise quinin, but the author believes that one grain of tannic acid to each three grains of quinin in a vehicle of syrup of tolu is better. Potassium iodid and potassium bromid and salicylic acid may be given in milk, which also prevents gastric irritation. In case copaiba and turpentine are not used in gelatin capsule form an emulsion flavored with gaultheria comes next in order. Equal parts of peppermint water and simple syrup make a good solution for sodium salicylate. If the mouth is flushed quickly with a small quantity of whisky the medicinal oils may be taken immediately afterward and the disagreeable taste is not so perceptible. [C.A.O.]

5. Itching: Its Occurrence Both as a Concomitant and as a Cure of Disease. EDWARD BENNET BRONSON.
6. The Röntgen Ray: Its Mechanics, Physics, Physiology, and Pathology. EDEN V. DELPHEY.
7. The Congenital Criminal. ROBERT T. IRVINE.

**1.—Intestinal Indigestion.**—J. C. Hemmeter considers first dystrypsia due to stomach disease. Chymaze in the gastric secretion does not digest food, but accelerates the action of the

ferments of the pancreatic secretion. The most efficient means of counteracting pancreatic insufficiency is to bring about a healthy appetite. The mistake of older experimenters was that they ignored psychic secretion, under which a more effective juice is formed than that secreted under purely chemical stimulation of the food. Psychic secretion may be due to a special ferment in the saliva. The stomach detects the composition of foods, regulating its secretion accordingly, even distinguishing between various organic acids. The writer has discovered a ferment in saliva, which, if added to gastric juice accelerates its digestive power, and proposes the name salivary secretion for it. He limits himself to the discussion of dys-trypsia due to abnormalities in diet. Excess of carbohydrates causing formation of acetic and lactic acids interferes with the alkalinity needed by the pancreatic secretion. This is the most frequent cause of infantile diarrheas. The abnormal peristalsis excited hurries on the jejunal chyme rich in mucin. Catarrhal stools exhibit epithelia and round cells, absent in jejunal stools. The latter are rich in bile pigment, have only slight fecal odor, and are generally acid. Starch may not be demonstrated by Lugol's solution because decomposed by fermentation, not digested. Starch residues signify intestinal disturbance, and starch should be excluded from the diet in quantities graduated by the iodine reaction. Muscle nuclei show insufficient pancreatic secretion. Excessive connective tissue points to abnormal gastric secretion. Treatment is principally dietary, indicated by the stools, together with general hygiene. The author gives a number of drug formulas for special symptoms. [H.M.]

**2.—Etiology of Intestinal Dyspepsia.**—E. F. Smith discusses the predisposing factors, and among the exciting causes anatomic alterations, deficiency of bile and pancreatic juice, irregularities of diet, abnormal bacterial activity, abnormal gastric chemistry, neurasthenia intestinalis, abnormal substances in the blood, intestinal parasites (exclusive of bacteria), and hyperperistalsis due to motor, sensory or secretory neuroses. [H.M.]

**3.—Tetanus Treated by Spinal Subarachnoid Injections of Antitetanic Serum.**—W. H. Lockett gives a brief synopsis of various treatments introduced for tetanus, and our present belief as to the pathology of the disease, viz., that the toxin of tetanus appears to have a special action on the cells of the anterior cornua of the gray matter in the spinal cord. He reports a case occurring in a boy of 12, who six days after a blank cartridge pistol wound in the hand developed marked symptoms of tetanus and died, after the ordinary symptomatic treatment, especially with bromids and chloral had been employed. In contrast with this case, two others are reported. A boy of 12 likewise received a blank cartridge pistol wound in the left hand. On the seventh day symptoms of tetanus were manifested, and they became violent. Lumbar puncture was made between the third and fourth lumbar vertebrae, a few drops of the cerebrospinal fluid withdrawn, and 8 cc. (2 drams) of antitetanic serum injected. This was soon followed by cessation of the violent symptoms, which cessation lasted some six hours, when convulsions, etc., returned. On the following day another injection (of 11 cc.) of antitetanic serum was given with a similar result. This treatment was continued, subarachnoid injections being given each day for 12 days, when the patient was considered out of danger. The doses of antitetanic serum ranged from 8 cc. (2 drams) on the first day to 15 cc. (4 drams) on the last day, a total of 92 cc. (23 drams) being given, and a total of 161 drops of cerebrospinal fluid being withdrawn. Another patient, a boy of 10, developed tetanus five days after being cut on the wrist with dirty glass. Daily subarachnoid spinal injections of antitetanic serum were given for five days, when all symptoms abated and recovery was complete. A total of 605 drops of the cerebrospinal fluid was withdrawn and 59 cc. (15 drams) of antitetanic serum injected. The author believes the rational treatment of tetanus lies in the withdrawal of a portion of the toxic cerebrospinal fluid, and the subarachnoid spinal injection of antitetanic serum. [A.B.C.]

**4.—Staphylococcus Aureus in the Blood.**—E. Libman reports in some detail 23 cases in which he found *Staphylococcus aureus* in the blood during life. Five of the 23 recovered.

In each case which came to postmortem the bacteriologic findings confirmed the findings before death. The relative number of bacteria found appeared to bear no definite relation to the malignancy of the case, this number depending much on the time at which the examination is made. In the series of cases there are a number of osteomyelitis, and this is especially true in those cases in which children were the victims; that is, children with systemic *Staphylococcus aureus* infection are apt to have the bones involved, whereas adults with a similar infection are more apt to have other forms of metastatic lesions. [A.B.C.]

**5.—Itching.**—E. B. Bronson believes it is the disturbance of the sense of contact which causes itching. It accompanies only those skin diseases in which there are changes in the superficial layer. Like pain, smarting is antipathic to itching and tends to extinguish it. Pruritus associated with vasomotor affections is frequently due to urticaria. In a number of pruriginous diseases hypertrophy of the arrectors is present. Pruritic affections are commoner in the hairy regions than elsewhere. The distinctive feature in eczema is vesiculation in the prickle cell layer, atrophic change, and the essential cause of the itching. At a higher level, as in sudamina, itching is absent. When skin changes occur slowly itching is generally absent. Itching without obvious disease is called *Pruritus essentialis*. In pruritus hiemalis the intermediary may be the motor disturbance. Itching is sometimes a pure neurosis, a symptom of hysteria or neurasthenia. It may be due to suggestion. In pruriginous papular diseases it is not the papule which causes the itching, but *vice versa*. In all pruriginous affections measures directed to the relief of itching are of the first importance. The first case is to avoid irritating contacts. The substitution of another sensation for that of itching is the rationale of many antipruritics used. Menthol, one of the most valuable, substitutes temperature sense. Some remedies, as hot water, relieve through sedative action. Carbolic and bichlorid solutions are anesthetic. General sedatives and motor depressants are sometimes indicated, and in toxic urticarias, antiseptics. In pruritus senilis, faradism, cannabis indica and strychnin are valuable. Bath pruritus may be mitigated by regulation of the temperature and amount of soap, or by adding salt. Heat, carbolic acid, and menthol are often efficient in pruritus vulvæ and a conical plug of bone will sometimes relieve pruritus ani. [H.M.]

**6.—The Röntgen Rays.**—E. V. Delphy describes in some detail the mechanism of the Röntgen ray apparatus, gives briefly a review of the literature bearing on the physiologic and pathologic effects of the rays—dealing largely in theory. Little that is of value clinically is added. Having reference to the pathologic and physiologic effects, he gives Beck's summary, as follows: (1) The Röntgen ray causes slow degeneration. The connective tissue, the elastic fibers, musculature and the bones are not at all or but slightly affected, and only suffer secondarily to inflammatory action. The first change is a degeneration of the epithelia. There were also localized masses of the cells of the glandular organs, of bloodvessels, of muscles and of connective tissues which show degeneration. This degeneration is both of the cell body and nucleus; (2) as soon as the inflammatory reaction has reached a sufficient degree, there is increased vessel dilation with serous effusion, infiltration of cells and emigration of leukocytes until the structure is lost in a mass of infiltration. [A.B.C.]

**7.—The Congenital Criminal.**—R. T. Irvine notes that only the physician knows how often moral insanity and epilepsy are associated with high grade intellectuality, and how difficult these forms of mental alienation are to verify. The primary data in the study of the criminal are his ancestry. A predisposition to destroy human life may be due to the mother having contemplated destruction of the child during gestation. The type of a species is more clearly represented in the female, and her greater longevity means a proportionate increase in criminal progeny. Proofs of hereditary predisposition will always be scientifically unsatisfactory. It is a mere matter of probability in a given case. The possibility of improving the race depends on increasing the productivity of the best stock. Brain cells will not proliferate after birth. The

problem is to seek means by which the cells may avoid atrophy or morbid change. [H.M.]

### Philadelphia Medical Journal.

April 18, 1903. [Vol. XI, No. 16.]

1. The Syphilitic Nature of Tabes and General Paralysis. DR. LEREDDE.
2. Pulmonary Abscess Producing Dextrocardia: A Case Report. THOMAS L. COLEY.
3. Methods of Röntgen-ray Treatment of Malignant Diseases of the Uterus, Rectum, and Bladder, with Description of Tabes. MARGARET A. CLEAVES.
4. The Surgical Treatment of Tuberculous Peritonitis. D. S. FAIRCHILD.
5. The Operative Treatment of Laryngeal Tuberculosis. LORENZO B. LOCKARD.
6. Pernicious Anemia Following Thyroid Enlargement. V. S. MERRITT.

**1.—The Syphilitic Nature of Tabes and General Paralysis.**—Leredde believes that the lesions of tabes and general paralysis may be syphilitic in nature, omitting secondary degenerative lesions which are only of syphilitic origin, to which no objection can be made on account of the absence of the usual histologic lesions of syphilis, a fact formerly insisted upon. The meningitis accompanying these lesions, minutely studied in tabes at least, may be found to markedly resemble ordinary syphilitic meningitis, in accord with Nageotte. In many cases of general paralysis, also at autopsy, classic lesions of syphilis, gummas, have been noted, besides the lesions of the disease. Further, lesions of tabes have been found coinciding with gummas of the meninges. If there is any affection of the nervous system, the nature of which can be decided by mercury, that affection is syphilitic in origin. The word recovery in tabes and general paralysis means, for the physician, nothing but arrest of the disease. Numerous cases are quoted which have been reported as recoveries from general paralysis and tabes. The existence of the cases cannot be denied; the only thing left is to attempt to find some other interpretation of them than the conclusions drawn by their writers. Leredde thinks of but one possible diagnosis outside of the diagnosis of true tabes and true general paralysis: syphilitic tabes or abortive tabes, and syphilitic pseudogeneral paralysis or abortive general paralysis. True general paralysis is incurable, pseudogeneral paralysis is not often cured, but recovery is not impossible. As the diagnosis is impossible all cases of general paralysis should be treated from the beginning of the disease with mercury; those of syphilitic origin are curable upon injections of large doses of mercury. [F.C.H.]

**2.—Pulmonary Abscess.**—T. L. Coley details a case of pulmonary abscess following pneumonia in a farm hand of 24, who was admitted to the Methodist Hospital, cyanosed and pulseless with intensely foul-smelling pus pouring from the mouth and nose; death occurred on the sixteenth day. The case is noteworthy in that the patient worked daily throughout his initial attack of pneumonia, and until a few hours before the rupture of the abscess; on account of the abscess and the complete dextrocardia produced by it; and from the point of view of differential diagnosis. The dextrocardia was readily accounted for by the massive pulmonary abscess. The pressure symptoms produced aphonia, stridor, loss of power in the left arm and a clinical picture similar to that so frequently seen in cases of aortic aneurysm. [F.C.H.]

**3.—Röntgen-ray Treatment of Malignant Diseases of the Uterus, Rectum and Bladder.**—External applications of the Röntgen ray to malignant growths, approachable by accessible mucous cavities, and especially when the natural course of drainage is such as to prevent, to a very great extent, the danger of systemic absorption, as in the female pelvis, should not be made. From clinical observations in extensive and inoperable malignant growths of the uterus, adnexa and adjacent organs in women, M. A. Cleaves believes that the danger of the establishment of metastases in the liver and peritoneum, as well as a general toxemia, is very great from external applications, and that the approach should be by way of the accessible mucous cavities, just so far as it is possible to devise the means of conveying the Röntgen ray energy within these cavities. The writer describes the tubes which she has so successfully employed for this purpose. [F.C.H.]

4.—**The Surgical Treatment of Tuberculous Peritonitis.**—D. S. Fairchild concludes as follows: If an intraabdominal focus of tuberculosis is diagnosed or is suspected, an abdominal section should be made with the view of efficient treatment; if a chronic tuberculosis of the peritoneum with ascites is diagnosed or believed to exist, laparotomy is indicated as soon as it is found that medical and hygienic treatment has failed; in fibrous tuberculosis of the peritoneum the same course should be pursued, and if cheesy degeneration has not commenced or progressed too far, a certain percentage of recoveries will follow. In acute tuberculous peritonitis with ascites and high temperature, laparotomy is useless. In extensive adhesive tuberculosis with matting of the intestines, laparotomy is useless, and the attempt to separate the adhesions is dangerous in its immediate results. [F.C.H.]

5.—**The Operative Treatment of Laryngeal Tuberculosis.**—L. B. Lockard concludes as follows: The treatment of tuberculous laryngitis usually should be the same as that for tuberculosis of the tongue, bones or skin, complete removal of the affected parts at the earliest possible moment, provided a conscientious trial has been given the more conservative methods. [F.C.H.]

6.—**Pernicious Anemia Following Thyroid Enlargement.**—V. S. Merritt details the case of a married woman 43 years of age, terminating in death. The interesting points are fright as a possible etiologic factor; coexisting goiter, which became less pronounced as the disease progressed, and menstruation again established after two months' cessation. The treatment was Fowler's solution in ascending doses, together with beef extracts. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

### EDITORIAL COMMENT

**The Dietary of the Laboring Classes in Edinburgh.**—Some interesting sociologic data are contained in the report of D. N. Paton, J. C. Dunlop and E. Inglis on the Diet of the Laboring Classes of Edinburgh.<sup>1</sup> Taking as a standard the recognized requirements of an economical diet for an adult (viz., 3,500 calories, consisting of: Proteids, 130 grams, yielding 533 calories; carbohydrates, 800 grams, 2,050 calories; fats, 100 grams, 930 calories), we find that a typical laborer's diet in Edinburgh is deficient, for it has the following composition: Proteids, 107.74; fats, 88.44, and carbohydrates, 479.42, yielding an energy value of 3,228 calories. Such a diet costs 7.29d. (about 15 cents). In this country the statistics of the Department of Agriculture show the following figures among families in the poorest districts of different cities:

	Families.	Grams of proteid.	Caloric value of food.
Chicago .....	29	119	3,425
Philadelphia .....	26	109	3,235
New York.....	19	106	3,030

Paton, Dunlop, and Inglis believe that the energy value and the proteid value of the Edinburgh diet, especially the latter, are too small. To improve the dietary of the laboring classes, the following principles should be instilled into them: 1. That a diet of tea and bread, or of tea, bread and butter (the lazy diet) is faulty. 2. That the faults of the tea and bread diet may be corrected by the free use of eggs, meat or other animal food, but this mode of correction is expensive. 3. That these faults may also be corrected by the free use of oatmeal with milk, or of peas or beans, without extra cost. 4. That to correct the faults of a tea and bread diet, either money spent on animal food, or labor spent on the cooking of vegetable food is necessary. If the people have not the money they must give the labor of properly cooking more nutritive food.

<sup>1</sup> Reports from the Laboratory of the Royal College of Physicians of Edinburgh, Vol. viii, 1903.

## REVIEW OF LITERATURE

**Typhoid Pericarditis.**—Gandy and Gouraud<sup>1</sup> report the following case: A woman of 30 entered the hospital on the eighth day of a benign typhoid fever. Examination showed the presence of a distinct pericardial friction, without any enlargement of the area of cardiac dulness. A diagnosis of dry pericarditis was made. The patient's condition steadily improved; and when seen on the morning of the twenty-fifth day of her illness she stated that since the beginning of her illness she had not passed such a good night. Shortly afterward, just as the bed linen had been changed, she uttered a loud cry and fell over dead. No autopsy was permitted, but a puncture of the pericardium was made and 90 cc. of a lemon-yellow, serofibrinous fluid were drawn off. This was centrifuged, and the sediment was found to contain red corpuscles and an almost equal number of lymphocytes, with a few polymorphonuclear cells. An exhaustive study of the history of typhoid pericarditis is appended to this report. The condition is very rare, and presents itself under two forms: that of a fibrinous and that of a purulent pericarditis, the former being the more frequent. Sometimes the pericarditis exists alone, and sometimes it has associated with it endocarditis, myocarditis, or bronchopulmonary lesions. The etiology is as yet not definitely known. The purulent form is due to a secondary infection; while for the fibrinous form the typhoid bacillus is probably responsible. [D.R.]

**Hypertrophic Cirrhosis of the Liver With Splenomegaly.**—The case reported by Eshner<sup>2</sup> is that of a young man of 19, presenting jaundice, enlargement of the liver and spleen, and a history of periodic excessive indulgence in alcohol and of chills and fever. There was no enlargement of the axillary, inguinal, supraclavicular, cervical, or epitrochlear glands. Blood examination showed red cells, 4,100,000; leukocytes, 3,000; hemoglobin, 73%. Of the leukocytes there were large mononuclear, 9.2%; small mononuclear, 15.2%; polymorphonuclear, 62.8%; transitional, 3.2%; eosinophile, 2.5%; myelocytes, 4; mast cells, 2.8%. Malarial plasmodia of the quartan type were present but disappeared under quinin injections. The case is considered as one of hypertrophic cirrhosis of the liver with splenomegaly, though it exhibits many of the features of so-called splenic anemia, the symptoms of that disease which are lacking being hemorrhages and ascites. In the absence of urgent or alarming symptoms, splenectomy has not been recommended. [A.G.E.]

### REVIEW OF LITERATURE

**A Case of Salivary Fistula.**—This condition is infrequent but obdurate. No less than 30 different methods have been recommended for its cure, and yet it often becomes necessary in spite of them all to treat the fistula radically by ligating the glandular duct, or even by extirpating the gland itself. A. N. Zimin<sup>3</sup> reports a case occurring in a girl 19 years old. The fistula existed since the age of 3 years, and followed a "boil" in the masseter region. The boil led to an ulcer, and the ulcer healed, leaving a dimpled scar with a central opening through which saliva was discharging drop by drop. After futile attempts to cure the fistula with silver nitrate and the paquelin, an operation was performed. By freshening the fistular area and cutting through the cheek into the mouth, an internal fistula was formed, the freshened edges having been united with sutures and the artificial inner tract packed with gauze. However, the wound soon began to suppurate, the sutures were removed, and the original fistula returned to its former state. A second attempt was now made by burning a hole through the cheek with the paquelin and inserting a rubber tube 3-4 millimeters in diameter in this canal. On the eleventh day the tube could be removed. The granulating fistular surface was covered with an ointment of silver nitrate. About four weeks

<sup>1</sup> Gaz des Hôp., March 28, 1903.

<sup>3</sup> Chirurgia, February, 1903.

later the salivary discharge gradually came to a stop, and a cure was thus finally obtained. [L.J.]

**Is Rupture of the Aortic Valve an Accident?**—This question having arisen in connection with the application under the Workmen's Compensation Act for benefit due to those holding policies payable as compensation for accident was described in the *British Medical Journal* for January 3. Theodore Fisher<sup>1</sup> holds that it would be difficult to prove that rupture occurred in a healthy aortic valve. In the many reports which have been made of such rupture necropsy has in each of the reported cases shown that there was disease of the aortic valves prior to rupture. This disease of the aortic valve, as is well known, may arise in any of the diseases which attack bloodvessels and the endocardium. He states that it is possible for a healthy valve to rupture as the result of severe muscular strain, but he apparently believes it highly improbable. The rupture of the valve almost presupposes a diseased condition of the aorta. [A.B.C.]

**Syphilis and Life Insurance.**—J. J. G. Brown<sup>2</sup> thinks the comparative lightness of the disease in connection with insurance work as compared with hospital experience is dependent on closer following of the rules of cleanliness and the prescribed treatment. Mortality is almost entirely limited to the tertiary period, resulting from cerebral or spinal syphilis, or from general paralysis or tabes. It is impossible to say to the end of life that syphilis has been cured. Fatal symptoms may develop after 50 years of abeyance, though tertiary and parasymphilitic manifestations generally show themselves within 12 or 15 years. This suggests an extra loading, nine-tenths of which to be removable at the end of the fifteenth year from infection, provided the health is then good. Conditions predisposing to the development of serious syphilitic symptoms are intercurrent tuberculous disease, immoderate use of stimulants, irregular habits, and infection late in life. Severe tertiary symptoms are more likely to occur when the primary and secondary manifestations were slight. A syphilitic has not a normal longevity and should not be insured at normal rates. If the health is otherwise good, habits steady, if the primary affection occurred at least four years before date of proposal and no secondary symptoms have appeared for a year and there is evidence of thorough treatment, a moderate loading—say five years for a man of 30—would cover the risk. Tertiary symptoms would make the life uninsurable. [H.M.]

**Calomel Injections in Leg Ulcers.**—A remarkable cure is reported by G. T. Meshtcherski.<sup>3</sup> The patient was a man of 61, who had for the past seven years undergone fruitless treatment for a crural ulcer of varicose origin. Elephantiasis complicated the condition. In view of the beneficial influence of calomel on elephantiasis, first noted by Pospelow, this remedy was administered hypodermically in conjunction with tight bandaging and fomentations with 3% boric acid solution. In all, four injections were given, one grain calomel each, according to Veisser's formula. The injections were made with weekly intervals, and the chronic ulcer healed completely at the end of four weeks. The edematous and thickened condition of the leg also disappeared almost entirely. This noteworthy result must be credited to the stimulating influence of calomel on granulations and epithelial cells. [L.J.]

**Dilation of Pylorus for Simple Stricture.**—H. P. Symonds<sup>4</sup> reports the case. The patient was a man of 40. He had been in comparatively poor health for a number of years. That the stomach was dilated could be easily ascertained. No tumor could be made out. There was no history of vomiting or of blood; this, together with the length of time which the symptoms had persisted, excluded malignant disease. Operation, however, was deemed justified. The pylorus was found stenosed by a benign growth. This was dilated by picking up a fold of the anterior wall of the stomach and invaginating it through the pyloric opening and causing dilation of this orifice. A tuck or fold of the stomach was then made upon its gastric wall. The portion of the stomach employed in the invaginating and dilating process was included in the tuck or fold. [A.B.C.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**To What Extent May the Female Genitals be Saved from Mutilation.**—J. H. Dowd<sup>1</sup> concludes as follows: Gonorrhoea in the female being curable in at least 95% to 98% of cases, it is only natural to make the bold statement, if the disease is healed rationally and until all danger of infection has been obliterated, the percentages of inflammation in the female genitals should be reduced to a minimum. The argument that the druggist treats three out of five cases of gonorrhoea in the male has no standing, for the reason that they do not stop the discharge in 1 out of 10, the remaining 9 being compelled sooner or later to consult a physician. [F.C.H.]

**Immediate Repair of the Soft Parts Following Labor.**—C. E. Congdon<sup>1</sup> advocates the immediate repair of lacerations of the cervix, vulva, and vagina, and firmly believes that if the sutures are properly introduced, and the tissues brought into perfect apposition, primary union will almost invariably be secured; if the repair work has been properly executed, the after treatment is of little moment. [F.C.H.]

**Clinical Thermometer in the Bladder of a Woman.**—This case, seen in consultation, is reported by M. Tixier.<sup>2</sup> The patient was a woman of 40. The vaginal temperature being desired, the attending physician inserted the thermometer without exposing the patient. When, after a sufficient lapse of time, an attempt was made to remove the thermometer, it could not be found. Examination revealed that it was in the bladder where it caused the patient but little discomfort. After slight dilation of the urethra the thermometer, unbroken, was removed from the bladder by means of forceps. The only explanation of the easy passage of the instrument, which was 8 cm. (3½ inches) long, into the urethra was that an operation two years before for prolapse and cystocele had left the anterior vaginal wall with the meatus unduly prominent. [A.G.E.]

### EDITORIAL COMMENT

**Substitutes for Salicylic Acid.**—The number of organic compounds of salicylic acid which have been put upon the market is so large as to forbid even a casual notice of them all. We shall therefore limit this article to the consideration of those which are employed chiefly for the relief of rheumatism, excluding the antiseptic preparations of salicylic acid and those in which through the union of a more powerful antipyretic, as in salipyrin and saliphenin, the salicylic acid becomes of secondary importance. We shall also omit any consideration of salicin, salol, the oils of wintergreen or of birch and synthetic methyl salicylate, as these are so well known that any note of them is superfluous.

**Aspirin.**—By far the most important substitute for the ordinary salicylates is aspirin. This substance, which is chemically a diacetyler of salicylic acid, has indeed achieved in the few years in which it has been before the profession such an important place among practical remedies that those who use it, use it almost to the exclusion of the other salicylates. It is impossible to review in detail even a percentage of the literature which has accumulated upon this drug, but as all those who use it are in accord, and as our own experience with it agrees with that of other observers, we shall simply recite the advantages and methods of using this compound. Being practically insoluble in water the powder has little taste, such as there is being that of acetic acid; the unpleasant nauseating taste of the salicylates is entirely absent. On account of its insolubility it has practically no irritant effect upon the stomach, and although we have used it in large doses in a great

<sup>1</sup> Buffalo Medical Journal, January, 1903.

<sup>2</sup> Lyon Medical, March 22, 1903.

number of cases, we have seen but one case in which it caused any nausea, and we know of no instance in literature of any untoward effects upon the digestion. It was originally asserted that the drug would not produce symptoms of salicylism. This, however, is not strictly true, for although comparatively large amounts of it are well borne we have seen typical symptoms of salicylism produced by small doses. Aspirin is slowly decomposed in the stomach with the liberation of free salicylic acid; in the intestines, however, it is broken up much more rapidly. Hill<sup>1</sup> found the salicylic reaction in the urine within 20 minutes after the ingestion of aspirin. According to this same experimenter the reaction persists for 20 hours after a single dose of 15 grains. Aspirin may be used in almost every condition in which sodium salicylate has been found useful. It is of equal merit with the salicylates in acute articular rheumatism and various forms of muscular and subacute rheumatism as lumbago and in the treatment of rheumatic neuralgia, as sciatica. Like the salicylates it is of less value in gouty and gonorrhoeal rheumatism than in true rheumatism. It always exerts some antipyretic effect, but when this is manifested in a decided manner the result should be considered as a demand for greater care in the use of the drug. It is best administered in the gelatin capsules, and in most cases may be given in doses of 5 to 15 grains three or four times a day or as often as may be necessary. Nevertheless, there are cases in which it produces untoward effects—cardiac weakness and even collapse, and sometimes these symptoms follow the use of comparatively small doses. This is especially apt to be the case in depressing infections, as scarlatina and influenza. Care and caution must therefore be observed in every instance, and full doses should never be given until the susceptibility of the individual has been ascertained.

**Mesotan.**—Mesotan, the methyloxymethylester of salicylic acid, is a clear, yellowish fluid. It is used by dermal absorption. According to Reichmann,<sup>2</sup> a weak salicylic reaction occurs in the urine within a half hour after painting the skin with this drug. That enough of it is absorbed through the skin to have an effect is shown by the results which he has achieved in various rheumatic and febrile conditions. For practical use it may be diluted by the addition of 10% to 20% of either olive or castor-oil. Roeder<sup>3</sup> has also used it pure. Reichmann believes that there is a local as well as a systemic effect and advises therefore the painting of the preparation directly over the affected part. Floret<sup>4</sup> has found it especially useful in muscular and aponeurotic rheumatism and also in cases of rheumatic neuritis, including torticollis and sciatica. It is usually advised that the application should be covered with some impenetrable covering, as parchment, paper or oiled silk, which should be allowed to remain in place for two days. According to Roeder, however, this is unnecessary so far as the therapeutic effects are concerned, although some sort of covering is desirable as a protection to the parts. The quantity of mesotan employed at a single application varies from 6 to 14 cubic cm. (1 to 2 drams).

**Ulmaren.**—Ulmaren, which is recommended especially as a substitute for oil of wintergreen and methyl salicylate, is a mixture of ethyl and amyl salicylates. It is an orange-colored fluid with a faint odor recalling that of salol, boiling point 237 to 240, soluble in alcohol and insoluble in water. It represents, according to Hibert,<sup>5</sup> 75% of salicylic acid. Animal experimentation<sup>6</sup> showed that in moderate dose it is well taken, but if given in large doses by the mouth it causes in the dog vomiting and purging and in the rabbit a dose of 0.07 gm. per kilo intraperitoneally injected caused death from asphyxia. It is recommended to be used as an external application

in rheumatic neuralgia diseases as well as in gout, either to be painted on the part or used in the form of an ointment made up with lanolin, in which case it should be present in the proportion of 30%. After epidermatic application the salicylic reaction may be demonstrated in the urine in three hours and lasts for three days.

**Salophen.**—Salophen is closely allied to salol. It differs from the latter, however, in that the carbolic acid it contains is so bound up in an organic radical as to be practically nontoxic. It is insoluble in water but soluble in alkaline solutions as shown by Sieben.<sup>1</sup> In the intestines it is broken up into its constituent parts, paramidophenol and salicylic acid, liberating about 50% of each. It has been extensively employed in various rheumatic and neuralgic conditions with good results. Like salol, however, it finds its chief value in chronic types of the disease being generally considered less useful in acute rheumatism than the other salicylates. Audebert<sup>2</sup> has found it useful in the after-pains of parturient women. Jacobi<sup>3</sup> has found it of marked service in influenza, especially of a nervous type. It has also been used as an intestinal antiseptic. It may be given in doses of 15 to 30 grains, two or three times a day. Ghetti<sup>4</sup> has obtained good results in sciatica by the injection into the gluteal muscles of 10% solution in sterile alkaline water.

**Salacetol.**—This is another substitute for salol; in it the toxic phenol has been replaced by an acetone radical. It does not seem to have achieved so much popularity as salophen. The dose is 30 to 45 grains.

#### REVIEW OF LITERATURE

**Aconite the Toxic Agent in Aino Arrow-poison.**—Anno Noki is the arrow-poison used by the Ainu, a tribe of about 17,000 inhabiting Yezo, an island belonging to Japan. Very little is known concerning this poison. Owing to a Japanese law forbidding its preparation, it can be made only surreptitiously and obtained only with great difficulty. Dr. H. M. Hiller, during his recent travels in the East, procured a fresh specimen, which he presented to Dr. S. Weir Mitchell, from whom Dr. E. T. Reichert<sup>5</sup> obtained it for study. The specimen is in the form of a short cylinder with rounded ends, 35 mm. long and 26 mm. in diameter, supported on a stick 150 mm. long. When fresh, it weighed about 50 grams. When rubbed up with water, a gelatinous mixture was formed which gave the starch reaction with iodine. Both the aqueous and the aqueous-alcoholic filtrates were poisonous. It was found by Eldredge, of Yokohama, that the killing power of this poison depends upon aconite; and experiments made by Reichert upon dogs leave no doubt that the toxic agent is aconite. The symptoms caused by subcutaneously injecting an aqueous or an aqueous-alcoholic filtrate did not differ in any important particular from those following the injection of the official tincture of aconite root. Reichert found no evidence of the presence of tobacco, capsicum, venom, or any other poison than aconite. [D.R.]

**Atropin Hypodermically in Spasmodic Torticollis.**—C. S. Potts<sup>6</sup> reports the cure of a case of spasmodic torticollis by means of hypodermic injections of atropin. The patient was 30 years of age and had been afflicted for a year. The injection was made directly into the affected sternocleidomastoid. It at first consisted of .3 mg. ( $\frac{2}{100}$  grain) and was made daily into the muscle and into the back of the neck alternately. The dose was gradually increased until at the end of three weeks 1 mg. ( $\frac{1}{100}$  grain) was used. Throughout this period electricity was also given. The patient was comparatively well for four months after this. There was then some return. Treatment was therefore recommenced and was continued, though not daily, for three months longer. The patient was then able to return to work. More than 1 mg. ( $\frac{1}{100}$  grain) could not be tolerated. [D.R.]

## OPHTHALMOLOGY

WALTER L. PYLE

## EDITORIAL COMMENT

**Misuse of the Word Lorgnette.**—With due deference to the authority of common usage, there seems good reason for believing that the ordinary interpretation of the word lorgnette, as used in American ophthalmic practice, is not correct. The word is derived from the French *lorgnier*, to spy or peep; perhaps allied to *loren* of German dialect. In all the standard French dictionaries the word *lorgnette* is distinctly defined as an operaglass or a spyglass, while the word *lorgnon* is used to indicate an eyeglass or eyeglasses mounted on a handle, or, to be more explicit, a quizzing glass. *Lorgnon à deux branches* is a double eyeglass. There is, however, the French term *lorgnette de spectacle*. Worcester defines lorgnette as an operaglass, giving Spiers as the authority. The last edition of Webster interprets lorgnette as an operaglass; *pl.* elaborate double eyeglasses. The Century dictionary defines lorgnette first as an operaglass, but gives a second definition as an equivalent to lorgnon. Lorgnon is described as an eyeglass or a pair of eyeglasses shutting into a frame, which, when in use, serves as a handle intended for examining objects at a little distance. This is a perfect description of the common American acceptance of the word lorgnette.

"She raises to her eyes of blue  
Her lorgnon, as she looks at you."  
—*The Atlantic*, lxiii, 649.

It is also stated in the Century that lorgnon is sometimes used synonymously with operaglass or lorgnette. The definitions of lorgnette in the Standard dictionary are: 1. A pair of eyeglasses carried on a long ornamental handle, into which glasses shut when not in use. 2. An operaglass, especially one with a long handle. Lorgnon is made synonymous with lorgnette and is also defined as a monocle.

**The Ocular Signs of Hysteria.**—Among the ocular affections observed in hysteria are disorders of accommodation, anomalies of convergence, profound asthenopia, disturbances of the external ocular muscles, polyopia, monocular diplopia, micropsia, megalopsia, hemianopsia, central scotoma, and monolateral blindness. As a rule the pupillary reflexes are preserved, an important point in differential diagnosis. Disorders of sensation, such as the so-called "islands of anesthesia in the skin, and anesthesia of the mucous membranes," particularly of the pharynx and conjunctiva, are also important distinguishing associate symptoms. The study of the visual fields likely affords the greatest opportunity for accurate diagnosis. A common phenomenon is concentric, or almost concentric, contraction, often modified by exciting the skin as by pin-pricks. Sometimes continuous irritation of the skin will be followed by a marked restoration of the fields. Associated with the contraction is often found dyschromatopsia, with perhaps inversion of the fields for colors. In such cases the fields for red and green may be distinctly larger than that for blue. Recently Greef and others have called attention to the tubular form of the visual fields in hysteria, and insist on the importance of testing for this phenomenon in suspected cases. In ordinary projection of the visual fields on perimetric charts, the farther the fixation point is from the eye the larger will be the field. It is now affirmed that in hysterical patients the outlines of the fields on the chart may have nearly the same dimensions whether taken with a standard perimeter or at several times the usual perimetric distance, but of course still within the range of distinct vision. Repeated observations of the tubular fields are being reported, and it is likely that they may be added authoritatively to the other significant ocular signs of hysteria.

**Photographing the Ocular Fundus.**—The difficulties of photographing the intraocular picture are many, and heretofore efforts in this direction have met with little success. The retina must be illumined from without through the small pupillary aperture, and the rays of light must traverse all the media twice. Again, the dark red of the ocular fundus is a very poor photographic color, and the photograph must be taken almost instantaneously. However, Dimmer has recently exhibited at Gratz some very satisfactory photographs of both normal and diseased eye-grounds. One-half of the pupil was utilized for illumination with a special mirror covering only that half, while through the other half a photograph of the corresponding side of the retina was made. The pupil was dilated *ad maximum* and the patient was instructed to fix one eye upon a bright point while the camera was directed toward its fellow.

**Division of the Anterior Ciliary Arteries in Chronic Simple Glaucoma.**—In cases of chronic glaucoma in which there is greatly diminished vision and increase of tension, but no acute symptoms, it is generally supposed that the condition is due either to closure of the canal of Schlemm or to an increased secretion from ciliary congestion, either active or passive. The condition is so desperate that some vigorous treatment is indicated. After 20 years' experience in the treatment of these cases H. B. Chandler<sup>1</sup> is of the opinion that very little benefit is derived from iridectomy. He believes that the ultimate results are the same whether or not this operation is performed, and in fact he has personally observed equal loss of vision in several cases in which one eye was operated on and the other left untouched. In these doubtful cases for the past two years he has divided the anterior ciliary arteries before they perforate the sclera and in every instance satisfactory results have followed. Tension has been lowered, vision improved, and pain when present relieved. In comment on this procedure Standish remarks that in the cases so treated that he has seen there was not so marked dilation of the pupil as there was increase of tension. The latter was diminished in fifteen minutes and there was instant relief of pain. While not committing himself as to the ultimate outcome of these cases, Standish is profoundly impressed by the immediate results of the operation and adds that in all events hereafter in hopeless cases of glaucoma ordinarily indicating such a radical procedure as enucleation he shall always first resort to division of the ciliary arteries.

**The Wernicke Hemianopic Pupillary Reaction.**—According to Vossius,<sup>2</sup> the leading ophthalmologists are about equally divided in their belief of Wernicke's teaching relative to the diagnostic import of certain pupillary phenomena. Some deny the existence of the hemianopic reaction, and others the possibility of producing it. The examination should be made in a dark room with the patient's eye fixed on an object 5 or 6 meters distant. Drs. v. Fragstein and Kemper, of Wiesbaden, Germany, have devised an instrument to facilitate the examination of pupillary reflexes, and Kipp has recently reported<sup>3</sup> its successful employment in eliciting the Wernicke sign in an interesting case of unilateral hemianopia following head injury, in which he believed that the left optic tract had been torn or otherwise injured, and that the left optic nerve had been torn or compressed in the optic foramen, perhaps by fracture of the bone, or that the chiasm was torn in the median line. Vossius makes a plea for more careful observation and for the publication of every case in which the hemianopic inaction or rather the hemianopic pupillary reaction is observed. Reports of such observations are very rare in medical literature, due partly to careless or hurried

<sup>1</sup>Trans. American Ophthalmological Society, Vol. ix, 1902, p. 461.

<sup>2</sup>Ueber die hemianopische Pupillenstarre, Halle, 1901.

<sup>3</sup>Trans. American Ophthalmological Society, Vol. ix, 1902, p. 678.

examination, but largely, as pointed out by Kipp, to the infrequency of the fundamental causal condition—basal affection of the chiasm and of the optic tracts, and complete interruption of the conductivity.

**Arthritis Accompanying Gonorrhoeal Conjunctivitis in the Newborn.**—We are indebted to R. Clement Lucas<sup>1</sup> for the recognition of joint-complications associated with ophthalmia neonatorum. His first report, in 1885, was greatly criticised, and suggestions were freely made that his case might have been one of epiphysitis or syphilitic synovitis. With the exception of a case by R. G. Fendick, no parallel case was recorded in Great Britain for 13 years. When in 1899 Lucas again introduced the subject a search through European medical literature had resulted in the discovery of only 23 cases. Since 1890 A. E. Garrod, J. Mitchell Bruce, Sydney Stephenson, and L. Vernon-Jones have called attention to the joint affections complicating ophthalmia neonatorum, and quite recently C. O. Hawthorne<sup>2</sup> reports a case confirming the results of the earlier observations, more especially as regards the possibly quiet nature of the arthritis and the prompt and thorough restoration of the efficiency of the affected joints. Unfortunately there was no bacteriologic examination in this case, although there was positive medical testimony that both father and mother had been infected with gonorrhoea shortly before the child was born, and the child began to suffer purulent ophthalmia on the second day. It may be added, however, that in several other instances on record there was undoubted bacteriologic diagnosis of gonococcus infection in both the conjunctival discharge and the synovial effusion. In this connection Lucas defines two varieties of arthritis, viz.: (1) A very acute form with features suggesting a tendency to suppuration, and (2) a milder form accompanied by a great deal of effusion and pain on movement, but with little or no surface redness. Hawthorne's case adapts itself exactly to this latter form. The promptness and completeness of the restoration of the joints to normal is in pleasing contrast to the obstinate nature of the ordinary gonorrhoeal arthritis. The explanation is doubtless to be found in the comparative ease with which the conjunctival discharge may be checked, and as noted by Hawthorne, this fact lends emphasis to the statement that the cure of the urethral or vaginal discharge is of first importance in treating cases of gonorrhoeal arthritis.

#### REVIEW OF LITERATURE.

**Permanent Left Hemianopia Following Puerperal Eclampsia.**—Woods<sup>3</sup> reports a case of this nature in a woman of 33, in good health save for the ocular condition and with perfect central vision in each eye. He believes that the poisonous substance in the circulation in eclampsia may produce thrombi of the smaller vessels, lead to areas of necrosis, and thus bring about permanent defect. Profound transient blindness is the rule in cases of eclampsia. In such cases there is no organic change, the effects cease with the elimination of the poison, but in a few cases thrombosis destroys a limited area, and if this area happens to be a part of the cerebrum having important function there is irreparable loss of that function, as in the case reported.

**An Interesting Case of High Astigmatism.**—Millikin<sup>4</sup> reports a case of mixed astigmatism, in which during 11 years of observation there was an increase in the right eye from a total of 17 D. to 26.5 D., and in the left from a total of 10 D. to 14.5 D., the vision after each correction being  $\frac{5}{6}$  in the right and nearly  $\frac{5}{6}$  in the left eye. During this period the axis in the right eye changed from 90° to 100°. There were no gross pathologic conditions in either eye-ground, and the patient was able to use his eyes without discomfort at close work until five years ago,

<sup>1</sup> British Medical Journal, 1885, 1, 429; 11, 57, 699, 773.

<sup>2</sup> Reports of the Society for the Study of Children, Vol. 11, London, 1902.

<sup>3</sup> Trans. American Ophthalmological Society, Vol. 1x, 1902, p. 659.

<sup>4</sup> Trans. American Ophthalmological Society, Vol. 1x, 1902, p. 657.

in the incessant visual strain of bookkeeping. He is very careful to keep his lens frames accurately adjusted, and for his presbyopia he uses convex lenses in eyeglass frames to wear over his distance lenses.

**Trachoma in Egypt.**—The following is an abstract of Dr. Mohammed Eloni Bey's conclusions:<sup>1</sup> (1) Granular ophthalmia is diminishing in Egypt; (2) three forms of trachoma are to be recognized—the typical granulomatous, the papillogranulomatous, and the simple papillary (false granulations); (3) the last named is the only one which leaves no stigmata; (4) none of these is connected with purulent ophthalmia, but they may be related to tuberculosis; (5) they are propagated by flies, dust, and uncleanness; (6) they are only contagious in the secreting stage; (7) they may be contracted at any age, but half the cases occur between the ages of 1 and 3 years; (8) they should be treated at once, and the eyes of all children in Egypt should be inspected half-yearly between the ages of 1 and 5.

**Paraffin Injections After Enucleation of the Eyeball.**—As there are on record cases in which after the injection of paraffin into the tissues the patient died from embolism of the pulmonary artery, and others in which sight was lost through the formation of an embolism in the central artery of the retina, it was subsequently suggested that in order to avoid these risks the paraffin should be injected into the capsule of Tenon after the eyeball had been removed. Ramsay<sup>2</sup> reports great cosmetic value with this method in 22 cases, and describes the operation as follows: The patient having been placed fully under the influence of chloroform the eyelids are separated and kept apart by a spring speculum. The conjunctiva is divided as close as possible to the corneal margin, each rectus muscle is caught up on a strabismus hook and sutured to the overlying conjunctiva with a strand of catgut, the tendons of the recti muscles are cut at their insertion into the sclerotic, and thereafter the operation for the removal of the eyeball is completed in the ordinary manner. If adrenalin chlorid solution be freely used the amount of bleeding is very slight, and the hemorrhage is easily stopped by douching the socket with hot sterilized water. The capsule of Tenon is packed with gauze till a strong black silk purse suture has been passed round the conjunctival margin, and then, the packing being removed, the melted paraffin is injected with a carefully sterilized glass syringe, the capsule being opened to its utmost capacity by holding the recti muscles on the stretch by means of the four catgut sutures and filled to overflowing. The purse suture is then tightened (care being taken to hold the patient's head steady and to relax the tension on the recti muscles) and is securely fixed by a double knot, and the catgut sutures are tied, the superior rectus muscle being approximated to the inferior and the internal to the external. The paraffin is thus induced to mold itself in the socket and to form a stump, to which the divided muscles readily attach themselves. The excess is wiped away, and after the conjunctival surface has been carefully bathed with boric solution a compress and bandage are applied. This operation is followed by very little inflammatory reaction and, as a rule, causes the patient hardly any more discomfort than simple enucleation does. The purse suture is kept in place for a fortnight, and when it is removed at the end of that time there will be found over the freely movable paraffin stump a clean, nondischarging surface of conjunctiva. A week later an artificial eye can be adjusted, the ordinary shell proving, as a rule, quite satisfactory, though sometimes better results may be obtained from the use of the form recommended by Snellen. Care needs to be taken that this is not too large, otherwise the paraffin stump will move behind the prosthesis. To insure success two points require special attention: First, the operation must be carried out with every precaution against sepsis, and so it must not be attempted in cases where the eyeball is in a state of active suppuration; and, secondly, the sutures must hold the conjunctiva in accurate position over the paraffin.

**The Conjunctival Flap in Cataract Extraction.**—Wilson and Miles,<sup>3</sup> after an extensive bibliographic and clinical study of this subject, conclude that notwithstanding the arguments to

<sup>1</sup> British Medical Journal, 1903, 1, 263.

<sup>2</sup> Lancet, 1903, 1, 299.

<sup>3</sup> Trans. American Ophthalmological Society, Vol. 1x, 1902, p. 503.

the contrary the conjunctival flap deserves consideration, because it exerts a very positive and easily demonstrated influence in preventing the reopening of the wound. Although the iris prolapses as often, if not a little oftener, it does not fall outside of the wound. The chief disadvantages are the ensuing hemorrhage and the increased difficulty in performing iridectomy, and in removing loose masses of cortical matter after extraction of the cataract proper.

**Postoperative History of 50 Cases of Simple Chronic Glaucoma.**—C. S. Bull<sup>1</sup> offers the following brief review of his observations after iridectomy on 94 eyes. In 7 cases under observation for a period ranging from 15 months to 11 years the fields remained as they were at the time of operation. In 6 of these cases the vision grew slowly worse, and in 1 case the vision was somewhat improved. In 5 cases the vision remained as it was at the time of operation, or improved, while the fields grew narrower. Age, in itself, did not seem to exercise any definitely bad effects, for some of the most satisfactory results occurred in patients past 70 years. The best results as to ultimate vision occurred in the cases in which the central vision was best and the fields were the least encroached upon at the time of operation; or, in other words, as soon as the diagnosis was established. Bull also believes that better results are obtained by simultaneous operation upon both eyes when bilateral affection is undoubtedly present, and in all cases early operations are the most effective.

**The Cause of Sympathetic Ocular Disturbance.**—After describing the lesions in a series of eyes which produced various types of so-called sympathetic disturbance in the fellow eye, de Schweinitz and Shumway<sup>2</sup> comment on the failure of the theories of ciliary reflex and direct bacterial migration to satisfactorily explain the phenomena, and remark that it is possible that future investigations will confirm a recent theory that not the microorganisms but their metabolic products are the etiologic factors in these cases, or, in other words, that a toxin is liberated by them which acts as the exciting agent. Panas believes that these cases of sympathetic ophthalmitis furnish examples of autoinfection, not in the sense of a migratory ophthalmitis, but, as Hubbell has said, "in the sense that the uveal tract of the sound eye, by reason of a lowering of its vital tone through the extreme reflex and vasomotor disturbances, kept up by a foreign body in or injury to the other eye, becomes truly poisoned or infected by materials in the general circulation to the extent of inducing a most obstinate and uncontrollable inflammation." The authors point out that these observers do not entirely escape from the reflex theory, or sympathetic theory, which in our day of pathologic research does not seem to be a scientific one. They conclude that the best that can be said at the present time is that an eye so wounded that a plastic iridocyclitis or uveitis appears sometimes sets up in the opposite eye an analogous inflammation, to which we give the name sympathetic ophthalmitis, and that in all probability this depends upon an infection of the so-called sympathizing eye by some form of bacteria or some form of toxin which they liberate, but that sometimes exactly analogous lesions will produce only an irritation which promptly disappears on removal of the originally injured eye, and disappears, moreover, without leaving a trace of organic change, and that it would further seem that some undiscovered, perhaps constitutional, perhaps local, condition determines on the one hand the inflammation and on the other hand the temporary so-called irritation.

**Ligation of the Canaliculi to Prevent Infection.**—Buller<sup>3</sup> advocates ligation of the canaliculi before operation on cases in which infection through the tear-passages is feared. He also recalls cases in which continuous infection of corneal lesions has been prevented by this means. He passes a No. 2 iron-dyed silk ligature around the canal a little to the inner side of the puncta, tying it as tightly as the silk will allow. Vision allowed by a stouter thread might cause it to cut through the tissues. Perfect occlusion can be effected for some days without impairment of continuity. After the removal of the ligatures, in one instance after two weeks, there was no dif-

ficulty in passing a small probe into the sac. The slight swelling and reaction caused by the ligature are of little importance, and rather increase the desired effect.

**Concerning Scintillating Scotoma and Migraine.**—Jolly<sup>1</sup> when 9 years of age lost an eye by an accident, and since then he has been subject to attacks of scintillating scotoma and migraine. He made careful observations both of his own condition and that of a large number of other patients. The attacks usually occurred after fatigue, long reading and hunger. They occurred once or twice a month, and occasionally only once every three months. A premonitory symptom of an oncoming attack was a desire to rub the eyes, which, however, gave no relief. The attack was followed by headache and at times accompanied by vertigo, nausea and aphasia. The headache was usually on the side opposite to the affected eye. Jolly discusses the etiology of the scotoma. He concludes that the hemianoptic form of scintillating scotoma originates in the optic tract or in the region of the external geniculate body. The binocular variety originates in the neighborhood of the optic chiasm, while the purely one-eyed scotoma is caused by a defect in the optic nerve or in the retina. He offers no treatment for this condition, yet he believes that since the origin of the trouble has been determined a proper treatment will soon be forthcoming. [W.E.R.]

**The Action of Radium Rays on the Eye.**—The radium rays make all the layers of the eye phosphorescent, thus producing a light which seems to fill the entire visual field. The Röntgen rays, on the other hand, must impinge directly on the retina. Javal and Curie<sup>2</sup> have made numerous studies with a very active radium salt, placing it into a covered glass vessel, and this into a dense pasteboard box through which no ordinary light could pass. Two absolutely blind men, one as the result of optic nerve atrophy, the other through glaucoma, did not perceive the presence of the light at all. A third individual, afflicted with prolapse of the retina, retained light perception in a small portion of his visual field. When exposed to the radium rays he announced at once the appearance of a light and precisely in that part of his visual field which corresponded to the inviolate portions of his retina. A fourth individual, blinded by ophthalmia neonatorum, had thick corneal scars, form perception was completely lost, color perception was present to a slight degree. Exposed to the radium rays he at once noticed a lighting up of his visual field, even after the eye was covered with both hands; were it possible to make his cornea transparent he could be given perfectly satisfactory vision. In a fifth case the eye had become glaucomatous after an iridectomy, and all form perception was lost, light perception was retained; later the lens became cataractous, and light perception also failed. A consultant blaming the light blindness on the cataract, wanted to operate. Knowing that the sensitive retina would have perceived the approach of the radium light, we could inform him that the removal of the cataract would not be of the least service in this case. [E.L.]

**Retinal Arteriosclerosis.**—Beard<sup>3</sup> speaks of the distribution and accessibility to inspection of the retinal vessels and their importance in the study of certain brain disorders. The ophthalmoscopic evidences of arteriosclerosis are considered in detail. In speaking of the condition that has been named, embolism of the central retinal artery, Beard states that true embolism of that artery is an exceedingly rare condition, Haab having found 12 cases diagnosed among 60,000 patients. Of these 12 only 2 were found to be undoubted emboli. A case of spastic ischemia of the retina, occurring in a physician, is mentioned. In connection with thrombosis of the choroid, attention is called to a condition that Beard believes has never before been mentioned. This is a peculiar pigmented spot or scar that always remains at the site of thrombosis. The outline is either round or quite irregularly oval and the pigment is arranged in whorls through which the white of the sclera shows. The appearance suggests that of knots in pine boards. Active thrombosis and one or more of these old scars have been seen together in the same eye. [A.G.E.]

**Changes in the Medical Corps of the U. S. Army for the week ended April 18, 1903:**

TEN EYCK, Major BENJAMIN L., surgeon, is granted leave for one month.

The following named medical officers are detailed to represent the medical department of the Army at the annual meeting of the American Medical Association to be held in New Orleans, La., from May 5 to 8, 1903: Major Louis A. La Garde, surgeon; Major Charles F. Mason, surgeon; First Lieutenant James Carroll, assistant surgeon. The officers named will proceed to New Orleans at such time as will enable them to reach that place on or before May 5, and upon the adjournment of the association will return to their proper stations.

MCADORY, ROBERT J., contract surgeon, is granted leave for one month. Upon the expiration thereof, will report by letter to the surgeon-general of the Army for annulment of contract.

RAMSAY, GEO. D., contract surgeon, is granted leave for two months to take effect upon the arrival at Fort Adams of another medical officer.

HEPBURN, JAMES H., contract surgeon, is granted leave for one month on surgeon's certificate, with permission to apply for an extension of one month.

The following named medical officers are detailed to represent the medical department of the Army at the Interstate National Guard Association to be held at Columbus, O., May 4 to 6, 1903: Captain Merritt W. Ireland, assistant surgeon; Captain Frederick P. Reynolds, assistant surgeon. The officers named will proceed to Columbus, O., in time to reach that place on or before May 4, and upon the adjournment of the association will return to their proper stations.

PEASE, F. D., contract surgeon, leave granted is extended one month.

FISHER, WILLIAM C., contract dental surgeon, is granted leave for twenty days, from about April 25.

KENNEDY, Captain JAMES M., assistant surgeon, having completed the duty for which he was ordered to Washington, D. C., will upon the expiration of his present leave proceed to Allentown, Pa.; New York City; Boston, Mass.; West Point, N. Y.; Buffalo, N. Y.; Cleveland, O.; Chicago, Ill.; and St. Louis, Mo., on business pertaining to the medical department of the Army, and upon the completion of this duty will rejoin his proper station at the Presidio.

So much of orders of March 27 as direct First Lieutenant John R. Devereux, assistant surgeon, to proceed to Fort Columbus, is amended so as to direct him to proceed to Fort Snelling, Minn., for duty.

GILCHRIST, First Lieutenant HARRY L., assistant surgeon, will proceed to Philadelphia, Pa., and New York City on business pertaining to the medical department of the Army.

MILLER, EDWARD W., contract surgeon, will report to the commanding officer, Fourteenth Battalion, Field Artillery, in camp at the Presidio, for duty therewith en route to Fort Sheridan, and upon the completion of this duty will proceed to his home, Chicago, Ill., for annulment of contract.

BLANCHARD, First Lieutenant ROBERT M., assistant surgeon, is granted leave for seven days.

**Changes in the Medical Corps of the U. S. Navy for the week ended April 18, 1903:**

HARRIS, H. N. T., surgeon, detached from the Monocacy and ordered to the Glacier at Manila, P. I.—April 11.

DRAKE, N. H., surgeon, detached from the Solace and ordered to the New York as fleet surgeon of the Pacific Station—April 15.

RUSSELL, A. C. H., surgeon, detached from the Naval Museum of Hygiene and Medical School, and ordered to the Newark as fleet surgeon, South Atlantic Station—April 15.

CORDEIRO, F. J. B., surgeon, detached from the Naval Training Station, Newport, R. I., and ordered to the Solace—April 15.

BARBER, G. H., surgeon, detached from the Monongahela and ordered to the Training Station, Newport, R. I.—April 15.

LANGHORNE, C. D., passed assistant surgeon, detached from the Naval Hospital, Port Royal, S. C., and ordered to the Monongahela—April 15.

**Changes in the Public Health and Marine-Hospital Service for the week ended April 16, 1903:**

WILLIAMS, L. L., assistant surgeon-general, granted leave of absence for seven days from April 11—April 11, 1903. Granted extension of leave of absence for one day—April 15, 1903.

IRWIN, FAIRFAX, surgeon, to proceed to Washington, D. C., for special temporary duty—April 13, 1903.

WICKES, H. W., passed assistant surgeon, granted leave of absence for one day—April 14, 1903.

RUSSELL, H. C., assistant surgeon, relieved from temporary duty at the Immigration Depot, and directed to rejoin his station at Stapleton, N. Y.—April 15, 1903.

BILLINGS, W. C., assistant surgeon, to proceed to Quebec, Canada, for duty in the office of the U. S. Commissioner of Immigration—April 16, 1903.

WARREN, B. S., assistant surgeon, granted leave of absence for five days from April 16—April 15, 1903.

FOSTER, A. D., assistant surgeon, to proceed to Southport, N. C., and assume temporary command of the station at that port during absence, on leave, of Assistant Surgeon B. S. Warren—April 15, 1903.

DEVEREAUX, JOHN, acting assistant surgeon, granted leave of absence for twenty-three days from April 2—April 9, 1903.

MCCONNELL, A. P., acting assistant surgeon, granted leave of absence for three days from April 20—April 16, 1903.

MCCONNELL, E. F., acting assistant surgeon, granted leave of absence on account of sickness, for thirty days—April 9, 1903.

SLAUGHTER, A. W., acting assistant surgeon, granted leave of absence for six days from May 5—April 10, 1903.

WALKER, R. T., acting assistant surgeon, granted leave of absence for thirty days from April 8—April 9, 1903.

**A Momentous Discovery.**—In the discovery of the infecting organism of variola, announcement of which we have been authorized to make by Prof. W. T. Councilman, of Harvard University, medicine has made a most important advance. The search for this organism has been the labor of years, and the failure to demonstrate it a stronghold of those opposing the theory of the bacterial origin of disease. Since in vaccination there is such a proved prophylactic for the ravages of the disease, the discovery has not the clinical interest attaching to the identification of the bacillus of diphtheria and the consequent perfecting of the diphtheria antitoxin; yet it will doubtless eventually lead to an absolute demonstration of the process by which vaccination confers immunity, and thus end much of the opposition to that measure. Prof. Councilman states that the organism is a protozoan, at present unclassified, and that its life cycle has been demonstrated. We congratulate research workers in general, and Prof. Councilman in particular, upon the results of his work as evidencing the value of such labors not only to the profession, but to the race.

**Accuracy and uniformity in reporting the causes of death** is one of the most important duties of physicians, as the value of statistics depends upon such precision. The United States Census Office is making an earnest and commendable effort to secure such uniformity, which, now that the office is organized upon a permanent basis, becomes all the more necessary. Figures according to an old proverb are great liars, but we know, of course, that the lying is done by the ignorant, or unscrupulous, or careless figurer. No physician is unaware of the vast importance of the facts of vital statistics, for it is upon them and their accuracy that science, and especially medical science, largely rests. Hence the appeal of the Census Office comes to us as citizens, but especially as officers of the law, and agents of the government, which we in truth are, in the gathering and reporting of the facts of mortality. The Census Office has issued five pamphlets that should be in the hands of every physician in the United States. These pamphlets should be carefully read, and preserved for constant reference. They bear the titles given as headings of the following editorial paragraphs.

**Legislative Requirements for Registration of Vital Statistics.**—With the organization of the Census Office upon a permanent basis, and the provision for annual reports relating to vital statistics in registration areas, a possibility is now presented that the vital statistics of the United States may be brought up to a higher standard of completeness and accuracy. But there can be no complete statistics of this kind for the United States, as a whole, until comprehensive registration laws are enacted and effectively enforced, in a uniform manner, in all of the States. A movement for the extension of registration legislation and methods upon such lines as practical experience has demonstrated to be necessary has been initiated by the Census Office in conjunction with the American Public Health Association, after a thorough study of all of the local laws in effect and a complete knowledge of the good and bad features of each. This movement has now been approved by the Congress of the United States in a resolution which recites the necessity for it, and requests the favorable consideration and action of the State authorities, to the end that the United States may attain a complete and uniform system of registration. The resolution, as passed by Congress, together with a report made by the Census Committee of the House of Representatives, also resolutions passed by the American Public Health Association at the annual meeting at New Orleans in December, 1902, are given in this circular. The report of the House Committee contains a paper on the subject prepared by the experienced vital statisticians and registration officials constituting the committee on "Demography and Statistics in their Sanitary Relation" of the Association. A specimen form of a law for the registration of deaths is given as an illustration of construction to meet the requirements indicated by the committee, including provisions for its proper administration and the maintenance of an effective system.

**Relation of Physicians to Mortality Statistics.**—The circular with this caption is issued for the use and benefit of physicians who have to make out certificates of death in compliance with registration laws, by acquainting them with the scope and requirements of the international classification, which has been adopted by all of the registration States and by most of the principal registration cities for the compilation of their mor-

tality statistics. Such statistics, to be comparable, must be uniform; and to be valuable for scientific purposes they must be accurate. Their chief value is in the distribution of deaths *by causes*, but the cause of death must be properly *stated* before it can be properly *classified*. In this particular the entire value of the statistics depends solely upon the lucidity and certainty with which the physicians supply the information. In all statistics of deaths by causes there is much too large a proportion of unknown or indefinite items for which the physicians alone are directly responsible and which they alone can remedy. It is probable that the defect in this particular is largely due to the fact that there has heretofore been no general and comprehensive plan to direct the attention of all physicians to the use of their certificates for statistical purposes, and to exhibit the necessities and requirements in this respect by explaining the classification used and by specifying wherein certain returns are incomplete, indefinite, or unsatisfactory. This circular is designed to furnish such information. It should be considered that the classification, in itself, is but a selection and arrangement of *titles only*, under which deaths reported in thousands of different ways must be compiled, and that the assignment of any death to the proper title requires a definite statement of the course of disease or the sequence of causes resulting in the death. A copy of the list of indefinite returns given will be sent to every local registrar in the United States with the suggestion that no certificate containing only these or similar terms be accepted, and no burial permit be issued, until the cause of death is accurately specified, in accordance with the explanatory notes, or a satisfactory explanation made. There will undoubtedly be cases in which the exact cause can not be ascertained and others in which an accurate diagnosis is impossible, but an observance of the suggestions made in this circular will very largely reduce the number of deaths that must necessarily be classed as unknown or ill-defined.

**The Manual of International Classification of Causes of Death**, issued by the United States Census Office, should be a part of the literary armamentarium of every physician's office. It is designed to present a detailed statement of the general arrangement of the international classification of causes of death, showing the inclusion of the terms reported by physicians as compiled under each title, in a form that will render it of practical use to registration offices in this country. The use of a classification of causes of death is imperative in the compilation and study of mortality statistics embracing any considerable number of deaths. The causes of death as assigned by physicians are so extremely numerous that it would be wholly impracticable to present them individually, and if it were possible to do this, and the causes, exactly as returned, were arranged in purely alphabetical order, the resulting compilation would be of very little use to the sanitarian or other student of mortality statistics, for he could not tell, except by a very laborious examination of the entire table, whether he had obtained the total number of deaths from any given disease or not. In other words, he would be obliged to do for himself, at a prohibitive

expenditure of time and effort, what it is the province of any fairly well devised classification of causes of death to do for him. The selection of the international classification by the Census Office for the compilation of the mortality statistics derived from registration areas for the calendar year 1900 and subsequent years is based chiefly upon the fact that this action will render the data directly comparable with the individual reports of the States chiefly composing the registration area, all of which have adopted this system, as well as tend to promote the uniformity and comparability of the mortality statistics of the United States with those of other countries.

**Practical Registration Methods.**—The Standard Certificate of Death, as printed by the Census Office, was prepared in conjunction with the Committee on Demography of the American Public Health Association, after conferring with many of the principal registration officials and after a study of all forms in use, as a part of the movement for uniformity in registration laws and methods, initiated by the publication of Circular No. 71 by the Census Office. This form of certificate has been adopted by the States of Colorado, Illinois, Indiana, Michigan, New York, and Vermont, and the authorities in other registration States and cities have approved it and announced their intention to adopt and put it into use as soon as the change can conveniently be made. This is an important step toward securing uniformity in returns and results. The form covers all of the information generally required under an advanced system of registration, but if other items are necessary for local purposes they may be added. It is, however, best to avoid increasing the number, unless further details are absolutely necessary under local laws or to meet very unusual conditions. As presented, the form is adapted to use in a State where returns are made under State laws, applicable in all parts and in which the certificates (or copies) are sent to a central office. In such cases the best results are obtained when the central office prints and supplies the blank forms of certificates and all other forms of records used. Where the form is adopted by any city in a nonregistration State the heading may be changed to correspond. The size of the form given is  $7\frac{1}{2}$  by  $8\frac{1}{2}$  inches. This makes it compact and convenient to handle, and when bound the certificates occupy but little space. This size of blank may be cut from ordinary stock paper, 22 by 34 inches, without any waste.

**Medical Education in Vital Statistics.**—In spite of the complaint of overcrowding the medical course, it is plain that our medical colleges must undertake definite courses of instruction in the detail work of observing, formulating, and reporting the facts of vital statistics as required by law, and also of doing it in the spirit of science which our profession demands. Such a course should be made to include a general review of the origin and development of the modern system of boards of health and the basis of their operations; utility and application of reports of disease, particularly of communicable diseases; registration of data relating to births

and deaths; importance of recorded data, (1) to individuals, (2) to the general public; relation of vital statistics to sociologic questions; relation of mortality statistics to advancement in medical science and public hygiene; duties and obligations of physicians, (1) to patients, (2) to the profession, and the public, through proper registration of births and deaths; legal liabilities; necessity for uniformity in forms and methods; the "Standard Certificate of Death;" relation of sex, age, color, or race, conjugal condition, parent nativity, occupation, and other factors (see certificate) to the mortality from different causes; necessity for complete returns; classification of causes; explanation of the international classification; meaning of titles in statistical tables; indefinite titles; provisions for revision; precision in statement of causes of death as essential to proper classification and elimination of indefinite titles; and all other matters germane to a thorough knowledge of the subject. Instruction in these lines should be supplemented by practical work in the classification of causes of death and in the tabulation of statistics. As a corollary to this proposition medical examining boards should see that applicants for license to practise medicine are interrogated upon these points, and that a proper knowledge and appreciation of the duties and obligations of physicians in the premises be made a condition precedent to granting licenses.

**An Execrable Governor.**—In our issue of April 4 we spoke of the admirable medical practice bill which Dr. Van Meter and his fellow workers had drafted and by great exertion had secured the passage of through the Legislature of Colorado. No one could have supposed that the demagog in the Governor's chair would have proved such an enemy to his people and State as to veto the measure. At the demands of populists, osteopaths, and the combined antis, he has done so, and every physician and honorable citizen of the State should see to it that he get his reward. The ground of complaint was, of course, the old criminal lie that the proposed law was "a vicious trust measure." The ignoramuses and quacks who secured the Governor's veto were, of course, not actuated by the financial reasons which they ascribed to the medical profession! The fact is terrible in what it reveals of the mental and moral condition of so many citizens of the State. When one remembers that the only demands made by the proposed law were really for education of a primary character in the fundamental branches of medical science, the exclusion of the abortionists, dishonorables, etc., and that the best sectarian "schools" were recognized and accepted the requirements—then the full measure of the shame is seen. In other words, the quacks of the worst sort have more influence over a demagog politician than all the educated and decent people of the State. That is a powerful inducement to offer settlers! The lovers of ignorance, immorality and disease in charge of the banner sanitarium State—this is Colorado's advertisement to all the seekers after health and wealth of the United States! That of course cannot long be so. Even every commercial interest must see that this is suicide. "At them again, comrades!"

**Plague Situation at San Francisco.**—Infected rats were first discovered in San Francisco in November, 1902, but none have been found during the past four months. The last human case in 1902 was that of a white man who died on December 11. An interval of 95 days passed before a fresh case appeared, that of a Japanese woman, who died on March 16, 1903. Since March, 1900, there have been four periods exceeding 60 days, two of them exceeding 90 days, of apparent subsidence of plague. According to accepted views these intervals must have been bridged by unobserved or unreported cases. More than six months have now elapsed since the last reported case of plague among the Chinese and it is a pity that this circumstance may not be accepted at its face value. Plague experience has given us a great respect for the elusiveness of John Chinaman. Surgeon-General Wyman said at New Haven in October last, and he repeated the statement at the Washington conference in January, that three years' work would be required to make sure of the eradication of plague from Chinatown. Two years ago (June, 1901), during one of the periods of quiescence of plague, Dr. John Williamson said in his official report: "The future will demonstrate what the past has shown, that while the Chinese are permitted to inhabit their present quarters, . . . San Francisco harbors a constant peril. . . . The day has passed when a progressive city like San Francisco should feel compelled to tolerate in its midst a foreign community perpetuated in filth for the curiosity of tourists, the cupidity of lawyers, and the adoration of artists." So far as this wide country is concerned there is nothing disquieting in the opinion of Dr. Wyman or in the more positive statement of Dr. Williamson. Even in San Francisco the occurrence of a few cases of plague need not excite alarm so long as capable and honest health officials are free in the exercise of their lawful powers. California has subdued, for the present at least, an infection more blighting than plague. Part of the penalty for her misguided policy in the past is that we at a distance fear a recrudescence of the pest of liars. If she is secure against this terrible contingency plague cannot prevent California from reestablishing her credit.

**The New State Board of Health of California.**—Governor Pardee has appointed to the State Board of Health a group of men whose reputations lead us to expect a good repair of the mischief done by their predecessors. A week after its organization the new State Board of Health suffered the loss of its president, Dr. Matthew Gardner, who died of appendicitis on April 18. Dr. Gardner was for a time one of those who disputed the existence of plague. He was sent by Governor Pardee as a delegate to the conference at Washington on January 19. He there confessed his own abandoned error, repudiated the conduct of those who deluded the people of San Francisco, and made a very able plea in extenuation of San Francisco's failure to deal effectively with plague. Returning to San Francisco he began at once a determined effort to subdue the hostility of the press, the politicians, and the commercial bodies. He endeavored with the utmost vigor and earnestness to

have the commercial bodies admit in their recent manifesto the existence of plague. But they had no such courage as Dr. Gardner had, and though he brought them to the point of contrition they would not confess. Apparently he failed also to induce his associates in the State Board of Health to utter this essential truth; for the State Board of Health addressed on April 10 to the other State Boards of Health in the country a brief statement, which promises that California will soon present "the cleanest bill of health of any in the sisterhood of States," but containing no mention of plague or any other infectious disease. A better chance to win confidence and good-will was never lost. One's mind cannot be coerced into a favorable interpretation of this letter of April 10. Men who shy at a word are not expected to be steadfast in action. Such is the inevitable corollary to the first utterance of the new State Board of Health of California.

**We are killing fewer babies, at least in some cities, notably in Chicago, says the *Bulletin of Health* of that city:**

During the six years preceding the present administration of the department there had been 66,003 deaths of those under five years of age; during the six years of the present administration, 1896-1902, there have been only 51,046 such deaths, or 14,957 fewer than in the first period. But this tells only part of the story. The population of the city increased, according to the United States census, 5.4% per annum between 1890 and 1900, and it is fair to assume that the under-five-years population increased in at least the same ratio. It follows that if the deathrate of the earlier period had been continued during the last six years there would have been 87,387 under-five-years-of-age deaths instead of the 51,046 that did actually occur. Chicago's present population is therefore more than 36,000 greater than it would have been, and there are that many fewer little graves in the city cemeteries.

There is no more encouraging demonstration of medical progress and of advance in true civilization than these figures show. The dragging-out of life at the tail-end of it, and the multiplication and lengthening of the lives of so many of the useless has been too large a part of the results of sanitation and preventive medicine. These results were not, of course, bad, and were certainly good. However they were not the best good possible. It did not lessen the labor of the producer, or better his condition. It rather increased his load and kept him down. While doing all this we continue to kill the babies at the old heathen rate. To add to the number of children growing to maturity was and remains the all-important thing to do. The proof that at last we are doing it is most significant, not only to medicine but for the future of the nation.

"Physical Culture's" exposé of the Koch consumption-cure frauds—of the "Thirteen Koch Lung-cure Institutes," of "Dr. Koch's Sanitarium, Incorporated," and of the "Koch Sanitarium"—by Gerald Keating is a capital bit of work. It is a pity that the profession has left such a job to be done by a lay magazine, but we feel gratitude for the help, whencesoever it comes. For similar crusades against the "Electric Belt," the Elixir-of-life, and the "Woman! why-in-the-world-will-you-suffer-any-longer?" frauds we must also be thankful. The antidote goes straight

to the poisoned patient. We wish we had space to reproduce the details of the abominable business of the much-advertised and many-branched "Koch cures" and "Koch Institutes," how they originated and are carried on, etc., as given by the writer of the article in *Physical Culture*. To our readers, of course, it would only be indirectly useful in the possible education of some of their patients, the poor dupes who are fleeced by the scamps whom the law also seems powerless to touch.

**Patent Medicine Testimonialists.**—We suggest that our subscribers should invest ten cents in the current number of *Physical Culture*, a popular magazine which in its way is doing a deal of good as regards some "curers"—at least in this number. This advice is given in order that our colleagues may have some "ammunition" for their patients who are addicted to the "Celery Compound" and "Peruna" forms of alcoholism. The career of Supreme Court Judge and Member of Congress H. Henry Powers as a taker and endorser of the popular tipples called patent medicines is entertaining. Facsimiles of the advertisements and portraits of Powers and of other notabilities appearing in the great yellow dailies are given. Mr. Iller, in *Physical Culture*, says:

Although cured by Paine's Celery Compound Powers was still a long way from being a healthy man. He had taken so much of Celery Compound that he was literally full of "Pains." He decided in favor of Greene's Nervura. On the prominence gained by this second testimonial he was elected to the United States Congress. On his arrival in Washington, D. C. he found that this body no longer existed, and that it had long been replaced by the Peruna Congress. The majority of the congressmen and senators put forth their best efforts in trying to establish Peruna as the national tonic. Powers soon discovered that the cause of Nervura was a lost cause, and he promptly set about digging up a new crop of pains in his multicured anatomy to fit the regulation Peruna testimonial. Pitted in Congress against the Peruna faction was the Malt Extract party, which was led by the invincible Chauncey Depew. The Peruna faction was led by Amos Cummings, who was completely cured by Peruna, but died shortly afterward. Having been cured more frequently and by more varied remedies than any other congressman, Powers was the most eligible candidate for leader, and was accordingly unanimously elected. Under his leadership the Peruna party made wonderful strides forward but, strange anomaly, the more the congressmen professed being cured the more feeble they grew, and stimulated by the example of Mr. Powers, there are now over fifty "active" members in the party taking the cure. Powers' term expired in 1901, and his constituents failed to return him to Congress. They claimed that a man may have some pains all the time, that he may get rid of all the pains some of the time, but they doubted Powers when he got cured of all his pains all the time.

**A Little Bad Weather Killed at Least Seventy-five People in One City.**—The Chicago Health Department finds that as a result of the blizzard of April 3 there were seventy-five more deaths the following week than in that preceding the storm. If these in a short week and in one city were the consequences discoverable by the statisticians, the untabulated deaths were of course many times as great. The fact shows how near many lives are constantly running to the death line and how small a thing will push them over it. The weather adds, therefore, an important element to the physician's solicitude and work.

## BOOK REVIEWS

**Manual of Antenatal Pathology and Hygiene.**—J. W. BALLANTYNE. Edinburgh: William Green & Sons, 1902.

It is possible that some investigators of fetal pathology have had more material at their disposal than Dr. Ballantyne, but certainly no one has used it to better advantage. Personal observation of nearly 300 specimens of fetal disease during a period of 18 years forms the basis of his studies. That this material has been thoroughly studied is indicated by the author's personal bibliography of 228 publications, nearly all of which deal with the subject of fetal pathology. With such preparation one is not surprised that this volume of about 500 pages devoted to the physiology and pathology of the fetus is a most complete and masterly exposition of the subject. Dr. Ballantyne promises to take up in a second volume teratology and morbid heredity. Such a work in English is sadly needed, and in combination with the present volume will constitute a valuable contribution to a much neglected field of pathology. The present volume is of such general excellence that it is almost impossible to select particular chapters as of more importance than others. The following brief summary indicates the scope of the work. The introductory chapters treat of the relation of antenatal pathology to postnatal pathology. The injuries which the fetus may suffer during the intranatal stage or period of birth are then discussed. These include the traumatism, as hematoma, paralysis, fracture, dislocation, etc.; the infections, as ophthalmia, mastitis, etc. Then follows the neonatal period, or period of physiologic readjustment, corresponding practically to the mother's puerperium. Hemoglobinuria, icterus, melena, néonatorum, etc., are described, as well as the infections that may occur at this time. Four chapters are then devoted to the anatomy and physiology of the fetus. Transmitted fetal diseases are treated most thoroughly; the discussion of variola, tuberculosis, typhoid, and syphilis being especially noteworthy. A most interesting chapter is that devoted to the discussion of the possibility of the transmission of mineral and vegetable poisons to the fetus. Seven chapters are devoted to the idiopathic diseases of the fetus, one to changes in the cord and placenta, one to intrauterine death, and two to the hygiene and therapeutics of the fetus. The author believes antenatal pathology to be the most essential and simplest form of preventive medicine, and offers interesting suggestions concerning the possibility of the practical development of such a hygiene. To sum up, it may be said that the book is one of the most important of the past year, and of value not alone to the obstetrician or pathologist, but to the student of medicine in the broader sense. The illustrations are uniformly good and some of them unusual. The publishers' work is excellent.

**The New International Encyclopedia, Vol. VIII.**—Dodd, Mead & Co., New York.

This runs from Fuller's Earth to Halitherium. The principal medical and semimedical subjects included are:

Fusel Oil	Glaucoma
Galbanum	Glioma
Gallic Acid	Glossitis
Galvanic Battery	Goa Powder
Garbage Disposal	Goiter
Gas (Sanitary Aspects)	Gonorrhœa
Gastritis	Gout
Gastroenteritis	Grape Cure
Gastrostomy	Gualacum
Gastrotomy	Guarana
Gelsemium	Gunshot Wound
Gentian	Hematemesis
Glanders	Hemophilia
Glanber's Salt	Hemoptysis

Among closely related biologic articles, to which a larger amount of space is given, are:

Function Change	Hair
Gestation	Hematin
Glycogen	Hemoglobin
Growth	

Under "Function" the physiologic processes receive an exposition covering a third of a column, while nearly three

columns are devoted to the mathematic use of the term. Glycosuria is defined as a symptom of diabetes mellitus, with no allusion to its occurrence as a physiologic phenomenon. Vegetable germs are described, but the anatomic structures, together with their diseases, are completely ignored, and skin grafting is omitted under Grafting. The articles on Gout and Gonorrhœa are well written. Gangrene is treated with relative inadequacy. Among subjects which are omitted entirely or to which there is no cross-reference are:

Funis	Genu Valgum and Varum
Furuncle	Germicides
Gait	Gingivitis
Galactagogs	Glycyrrhiza
Galium	Granatum
Gastric Neuroses	Hand (Diseases of)
Gavage	Handkerchief Dressings

Between 40 and 50 physicians are noted biographically, though some as distinguished as Thomas Gray, the anatomist, are left out. It seems strangely inconsistent that members of other professions, some of whom are new to fame and little known, should receive mention, and medical men of international repute, like Fuchs, Haig, Gowers, DaCosta, Fenger, and a hundred others, are passed by in silence.

**Progressive Medicine: A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences.**—Edited by HOBART AMORY HARE, M.D., assisted by H. R. M. LANDIS, M.D. Vol. I, March, 1903. Lea Brothers & Co., Philadelphia and New York, 1903.

The first volume for 1903 of this wellknown and deservedly popular review of the progress of medicine comprises a critical digest of recent literature on the surgery of the head, neck, and chest, by Dr. Charles H. Frazier; of infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by Dr. James B. Herrick; of the diseases of children, by Dr. Floyd M. Crandall; of pathology, by Dr. Ludvig Hektoen; of laryngology and rhinology, by Dr. A. Logan Turner; and of otology, by Dr. Robert L. Randolph. In the excellence and trustworthiness of its contents the volume fully sustains the reputation of its predecessors.

**Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition.**—By Dr. CARL VON NOORDEN, Senior Physician to the City Hospital in Frankfurt a/M. Authorized American edition translated under the direction of BOARDMAN REED, M.D., Philadelphia. Part I.—Obesity. Part II.—Nephritis. Part III.—Colitis. New York: E. B. Treat & Co., 1903.

We heartily concur with the statement of the American editor that the English reading physicians of the world are to be congratulated upon the publication here, simultaneously with their appearance in Berlin, of these monographs by Dr. von Noorden. They are concise statements of facts gleaned from the experience of a master clinician and investigator. The arrangement of these facts may be judged from the statement that the text is so brief and methodic that the reviewer is tempted to furnish an abstract of each volume. Every physician should read them.

**PART I.**—Deals wholly with indications for reduction cures of obesity and not with methods. The indications are grouped under two heads: First, simple obesity in otherwise healthy subjects, and second, when complicated by other diseases. The author places himself on record as opposing the frequently expressed view that reduction cures are a weakening procedure. They are not weakening if really indicated and properly carried out.

**PART II.**—The author uses as a text the customary therapy of kidney diseases and then proceeds to annihilate utterly many of these traditional methods. No structure is torn down, however, without being replaced by a finished substitute that is accompanied by reasons for its building. Protective therapy of the kidney is the keynote of this monograph which states the facts of metabolism as a basis for the dietary regulations to be adopted in kidney disease. Various substances are considered according to the ease or difficulty with which they are excreted. The principles underlying the dietetic and physical treatment of acute nephritis and of contracted kidney are sep-

arately discussed. The theory that milk is the best diet in all cases of nephritis is questioned, if indeed it is not actually disproved. In many cases the ingestion of fluids needs to be greatly restricted. The fallacy of the belief in the value of light meats over dark is clearly shown. The generally good work of the publishers of these volumes is marred in this one by the appearance on the front cover of the author's name as *von Norden* and by the transposition in the text of the headings of Chapters IV and V.

**PART III.**—This deals entirely with membranous catarrh of the intestine (*colica mucosa*), pathology and treatment being the topics considered. As to the cause of this condition, von Noorden states that "neither constipation alone nor neurasthenia alone nor the common combination of these states can produce *colica mucosa* unless at the same time there is some involvement of the nervous apparatus that governs the secretion of mucus in the large intestine." A general outline of the diet recommended in the treatment of this condition is given. Drs. von Noorden and Carl Dapper, who aided in the preparation of this volume, have treated in all 76 cases of *colica mucosa* by the methods they present and in 79% they obtained complete and permanent cure.

**The Malarial Fevers of British Malaya.**—By HAMILTON WRIGHT, M.D. Studies from the Institute for Medical Research, Federated Malay States. Vol. I, No. 1, 1902.

This contribution by the director of the Institute is a summary of the preliminary study of problems concerning the malaria of Malaya. While it is not an extensive work, and although the greater portion of the publication is devoted to detailed descriptions of cases, reproduction of charts, etc., the many interesting observations which are made indicate that Malaya offers a very valuable field for research in malaria. Two hundred and fifty-one cases were studied which, according to the type of parasite found, are divided into malignant tertian 93, benign tertian 78, quartan 56, pigmented quotidian 22, unpigmented quotidian 2. This may be considered as an index of the various types of malaria in British Malaya. Multiple infections were the rule. The European quarters of large centers of population were practically free from malaria despite the presence of large numbers of anopheles. In these localities, however, the anopheles were seldom infected. Infection of Europeans usually resulted from visits to the jungles, outstations, native quarters, etc., all of which are foci of infection. The majority of infections occurred among the natives (Tamis, Chinese and Malays). This is explained by their mode of living, bad hygienic environment and their neglect of prophylactic measures. They usually live in gangs at railway and irrigation stations, quarries and mines, in most of which localities infected anopheles are found. Dysentery and ankylostomiasis commonly accompanied the malaria. "Black-water fever" was not observed. The age limits were three and sixty-three years. The common form of Anopheles found were *A. sinensis*, *superpictus*, *A. species a* and *b*, and an unidentified form. The rarer forms were *A. costalis* and *A. rossii*. For the extermination of malaria Dr. Wright suggests clearing, drainage and cultivation of the ground in the neighborhood of large communities, the use of mosquito netting and administration of quinin. The use of oil is not feasible on account of the heavy rains. He is not optimistic about prophylactic measures, on account of the ignorance of the natives who use their own remedies and neglect all rules of hygiene.

#### BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

**Anatomy of the Brain and Spinal Cord.**—By HARRIS E. SANTEE, M.D., Ph.D., Professor of Anatomy in the College of Physicians and Surgeons, Medical Department, University of Illinois; Professor of Anatomy in Harvey Medical College, Chicago. With a preface by WILLIAM T. ECKLEY, M.D., Professor of Anatomy in the Medical and Dental Departments, University of Illinois. Third edition; revised and enlarged. Price, \$2.00 net. E. H. Colegrove, Chicago, 1903.

**The International Medical Annual: A Year-book of Treatment and Practitioners' Index.** E. B. Treat & Co., New York, 1903.

**Transactions of the American Climatological Association:** Vol. xviii, 1902.

**Bacteria in Milk and Its Products.**—By H. W. CONN, Ph.D., Professor of Biology, Wesleyan University. With 43 illustrations. P. Blakiston's Son & Co., Philadelphia, 1903. Price, \$1.25 net.

**A Pocketbook of Infant and Childhood Diets.**—By A. B. SPÖCH, A.M., M.D., Instructor in Medicine, Medical Department of the University of Illinois. E. H. Colegrove, Chicago. Price, 50 cents net.

**Hygiene and Public Health.**—By LOUIS PARKES, M.D., D.P.H., London University, Fellow of the Sanitary Institute and member of the Board of Examiners; Lecturer on Public Health at St. George's Hospital Medical School, etc. And HENRY KENWOOD, M.B., D.P.H., F.C.S., Fellow of the Sanitary Institute, and member of the Board of Examiners; Assistant Professor of Public Health at University College, London, etc. Illustrated. P. Blakiston's Son & Co., Philadelphia, 1902. Price, \$3.00 net.

**Essays on Clinical Medicine:** Being reprints of papers published at various times in the *American Journal of the Medical Sciences.*—By BEVERLEY ROBINSON, A.M., M.D. (Paris), Clinical Professor of Medicine at University and Bellevue Hospital Medical College, etc. William J. Dornan, Philadelphia, 1903.

**State Board of Health:** Sixteenth Annual Report, Year Ending October 31, 1901. Fred. J. Heer, Columbus, Ohio, 1903.

**American Edition of Notlingel's Practice:** Diseases of the Pancreas, Diseases of the Suprarenal Capsules, and Diseases of the Liver.—By Dr. L. OSER, of Vienna; Dr. E. NEUSSER, of Vienna; and Drs. H. QUINCKE and G. HOPPE-SEYLER, of Kiel. The entire volume edited, with additions, by FREDERICK A. PACKARD, M.D., late Physician to the Philadelphia and to the Children's Hospitals, Philadelphia; and REGINALD H. FITZ, M.D., Hersey Professor of the Theory and Practice of Physic, Harvard University Medical School, Boston. Handsome octavo of 918 pages, illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$5.00 net; half morocco, \$6.00.

**American Edition of Notlingel's Practice:** Diseases of the Stomach.—By Dr. F. RIEGEL, of Giessen. Edited, with additions, by CHARLES G. STOCKTON, M.D., Professor of Medicine in the University of Buffalo. Handsome octavo volume of 835 pages, illustrated, including 6 full-page plates. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$5.00 net; half morocco, \$6.00 net.

**How to Succeed as a Physician.**—The Church Publishing Company, Meriden, Conn., 1902.

**Care and Feeding of Children.**—By L. EMMETT HOLT, M.D., LL.D., Professor of Diseases of Children in the College of Physicians and Surgeons (Columbia University). Third edition, revised and enlarged. D. Appleton & Co., New York and London, 1903.

**Handbook of Climatology.**—By JULIUS HANN, M.D., Professor of Cosmical Physics in the University of Vienna, etc. Part I. General Climatology. Translated from the second revised and enlarged German edition, with additional references and notes, by ROBERT DE COURCY WARD, Assistant Professor of Climatology in Harvard University. Price, \$3.00 net. Macmillan Company, New York, 1903.

**The Care of the Baby:** A Manual for Mothers and Nurses, Containing Practical Directions for the Management of Infancy and Childhood in Health and in Disease.—By J. P. CROZER GRIFFITH, M.D., Clinical Professor of Diseases of Children, in the Hospital of the University of Pennsylvania; Physician to the Children's Hospital, Philadelphia. Third edition, thoroughly revised. Handsome 12mo volume of 436 pages, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$1.50 net.

**Practical Points in Nursing:** For Nurses in Private Practice. With an Appendix Containing Rules for Feeding the Sick; Recipes for Invalid Food and Beverages; Weights and Measures; Dose List; and a full Glossary of Medical Terms and Nursing Treatment.—By EMILY A. M. STONEY, late Superintendent of the Training School for Nurses, Carney Hospital, South Boston, Mass. Third edition, thoroughly revised. Handsome 12mo of 458 pages, fully illustrated, including 8 colored and half-tone plates. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$1.75 net.

**Materia Medica for Nurses.**—By JOHN E. GROFF, PH.G., Apothecary in the Rhode Island Hospital, Professor of Materia Medica, Botany and Pharmacognosy in the Rhode Island College of Pharmacy. Second edition, revised and rewritten. P. Blakiston's Son & Co., Philadelphia, 1903. Price, \$1.25 net.

**Bacteria in Milk and Its Products.**—By H. W. CONN, Ph.D., Professor of Biology, Wesleyan University, etc. With 43 illustrations. P. Blakiston's Son & Co., Philadelphia, 1903. Price, \$1.25 net.

**Twelfth Report of State Board of Health of the State of Maine** for the two years ending December 31, 1901.

**Weekly Public Health Reports.** Vol. xvii. Part I, Nos. 1 to 26. Part II, Nos. 27 to 52.

**A Textbook of Legal Medicine and Toxicology.**—Edited by FREDERICK PETERSON, M.D., Chief of Clinic, Nervous Department of the College of Physicians and Surgeons, New York; and WALTER S. HAINES, M.D., Professor of Chemistry, Pharmacy, and Toxicology, Rush Medical College, in affiliation with the University of Chicago. Two imperial octavo volumes of about 750 pages each, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Per volume: Cloth, \$5.00 net; sheep or half morocco, \$6.00 net.

**Diseases of the Heart and Arterial System.**—By ROBERT H. BABCOCK, A.M., M.D., Professor of Clinical Medicine and Diseases of the Chest, College of Physicians and Surgeons (Medical Department of the Illinois State University), Chicago; Attending Physician to Cook County Hospital and Cook County Hospital for Consumptives, etc. With three colored plates and 139 illustrations. D. Appleton & Co., New York and London, 1903.

**Medical Jurisprudence, Insanity, and Toxicology.**—By HENRY C. CHAPMAN, M.D., Professor of Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College, Philadelphia. Third edition, thoroughly revised, greatly enlarged, and entirely reset. Handsome 12mo volume of 329 pages, fully illustrated, including four colored plates. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$1.75 net.

**Tuberculosis:** Recast from Lectures Delivered at Rush Medical College, in affiliation with the University of Chicago.—By NORMAN BRIDGE, A.M., M.D., Emeritus Professor of Medicine in Rush Medical College; Member of the Association of American Physicians. Handsome 12mo volume of 302 pages, illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Cloth, \$1.50 net.

## AMERICAN NEWS AND NOTES.

## GENERAL.

**The National Association of the United States Pension Examining Surgeons** will hold its second annual meeting in Washington, D. C., May 13, 14, 1903.

**Eddyites.**—The *Baltimore Underwriter* says: Christian Scientists can't be Foresters, and all life insurance companies might as well shut the door in the faces of such cranks.

**Gift to National Museums.**—Surgeon Edgar Means, of the Army, has given a wonderful collection of rats to the national museum. It is said to be the most complete collection in existence, and contains specimens of all known varieties of rats. Surgeon Means has been a lifetime in making his collection, which has the merit of being novel at least.

**Fourth Pan-American Medical Congress.**—At a meeting of the International Executive Committee of the Pan-American Medical Congress held April 1, 1903, it was decided to accept the proposal of the Argentine Republic to hold the Fourth Pan-American Congress in Buenos Ayres in 1905 instead of 1903, as had been announced in their invitation of February, 1901.

**New Quarantine Rules and Plague.**—Regulations to gauge the admission of plague to the United States are emphasized in the new quarantine regulations. A vessel in quarantine for plague will not hereafter be allowed to anchor near enough to shore to allow rats to swim ashore, and the sweepings of the decks even are to be burned and not thrown overboard. Fumigation for the destruction of rats and all forms of vermin is prescribed. The regulations are the most specific and explicit on all subjects ever issued.

**New Quarantine Rules and Mosquitos.**—The new quarantine regulations drawn by Surgeon-General Wyman are the first which have been issued since 1899. They contain, beside all the laws relating to the subject, 185 specific regulations governing the subject. The mosquito is mentioned in several of these regulations for the first time. Definite instructions are given for the destruction of mosquitos on board ships leaving foreign ports for the United States, particularly if the ship is leaving a country in which yellow fever is prevalent.

**To Prevent the Spread of Yellow Fever.**—Surgeon-General Wyman, of the Marine-Hospital Service, has assigned a number of surgeons attached to that service to the fruit ports of Central and South America for the purpose of inspecting the vessels, crews, and cargoes of vessels leaving those ports bound for the United States. This step is taken as a precaution against the introduction into this country of yellow fever. In a letter of instruction to his assistants Surgeon-General Wyman says: "Your attention is called to the spread of yellow fever through the agency of the mosquito known as the *Stegomyia fasciata*, and special precautions should be taken to prevent their presence aboard vessels. Should yellow fever break out at your port you are requested to immediately cable the bureau."

**Leprosy in the Army.**—A soldier who while serving in the Philippines contracted leprosy is still nominally retained in the service and is isolated at a point in South Carolina where he is being observed by the Army surgeons, with a view of determining something more definite with reference to the etiology of the disease, its course, and treatment. Efforts are being made to ascertain some form of curative treatment for this hitherto hopeless disease. Although he receives the pay of an ordinary soldier, the question has arisen as to the advisability of permitting the soldier to sign the pay-roll and other papers necessary for receiving his check from the government. It has been settled by permitting an agent with the power of attorney to sign the pay-roll in the presence of the physicians and nurses.

## EASTERN STATES.

**Noise an Element of Damage.**—The Supreme Court of Massachusetts has confirmed the ruling of the Chief Justice of the Superior Court that noise is an element of damage. The question arose through the operation of the Boston Elevated Railway, leading to the institution of various suits along its line for damages due to noise. The full text of the decision is of very great interest in relation to this matter, which naturally affects directly a large number of persons and indirectly the entire community.

**To Recover Damages for Autopsy.**—Suit has been brought against a number of physicians connected with the Massachusetts General Hospital to recover \$2,000 because of the alleged autopsy performed on the body of a patient who died at that institution. Relatives of the deceased claimed that the autopsy was performed without their knowledge or consent, and for this reason the body could not be buried according to the Jewish rites. Judge Sullivan, before whom the case was tried, found a verdict in favor of the defendants, because as testified by them the autopsy was performed in the belief that the consent for the necropsy had been given by a relative.

## NEW YORK.

**For the Adult Blind.**—A bill creating a commission to investigate the condition of the adult blind of the State passed the Assembly. Its main purpose is to provide methods whereby the adult blind of the State may be taught trades.

**Lunacy Bill is Vetoed.**—Governor Odell, of New York, has vetoed the bill providing for a treasurer and a purchasing agent for the State hospitals. The Governor's objection to the measure was the unnecessary creation of new departments with expense incident thereto, the placing in the hands of the treasurer provided for in the act power to make drafts upon the Comptroller for quarterly estimates of funds necessary for the maintenance of the hospitals, and the practical replacing of the stewards of the various institutions by a single agent vested with the plenary power.

**Child Labor Bills Passed.**—The General Assembly of New York has passed the last of the bills promulgated by the Child Labor Committee. The bill amends the penal code, so as to provide severe penalties for false statements in reference to age, etc., in connection with the employment of children. The first offense involves a fine of from \$20 to \$100; the second a fine of \$50 to \$250, or 30 days' imprisonment; and the third, a minimum fine of \$250 or 30 days' imprisonment, or both. The importance of this bill lies in the fact that the three bills all depend for efficiency upon the certificates of age.

**Sanitary Control of the Water Source.**—Since the reorganization of the City Water Department of New York on January 1, the Commissioner and Chief Engineer have introduced new features and methods for the inspection and patrol of the source of supply. An assistant engineer and a force of four men are to be kept constantly in the field for this purpose. Sanitary maps of the entire water-shed with its various villages are to be made and all nuisances are to be located. Such maps are to be filed in the Commissioner's office with exact and complete information pertaining to the water-shed. Each nuisance as reported by the patrol is entered in a book, with a record of the notice sent out for its abatement. Plans for the disposal of the sewage of all villages of the water-shed are to be kept in the Commissioner's office for inspection. It is believed that by this means the quality of water supplied to the city will be materially improved.

**No Camps for Consumptives.**—A bill was passed by the New York Assembly, but vetoed by the Governor, prohibiting the erection of any camp or hospital for the treatment of patients suffering from pulmonary tuberculosis in any county of the State without first securing the consent of the Board of Supervisors and the Town Board. If the city of New York desired to give her tuberculous poor the benefit of open-air treatment she would have been prevented from establishing camps in the mountainous portions of the State for this purpose. The bill was strongly favored by representatives from the districts where such camps would naturally be located except for the law. Persons living in such districts are naturally opposed to the location of camps in their midst, since they are regarded as a source of contagion.

## PHILADELPHIA, PENNSYLVANIA, ETC.

**Frederick A. Packard.**—An eloquent memorial address on the late Frederick A. Packard, delivered by Samuel McC. Hamill before the Philadelphia Pediatric Society, has just been issued in pamphlet form. It is a graceful and sympathetic tribute to one of the noblest men of our brotherhood.

**Disinfection for Schools.**—A bill passed by the Legislature and signed by the Governor of Pennsylvania makes it the duty of school directors, trustees, or other persons having control of any school or college building to adopt and immediately put into operation a modern method and system of disinfection.

**Ray Bill Fails to Pass Senate.**—The Ray bill, designed to raise the standard of education among physicians in Pennsylvania, has been shelved by the State Senate after passing the House by a vote of 126 to 13. It is claimed that some of the lower standard medical schools, through their political influence, succeeded in killing the bill.

**Home for Dying Consumptives.**—The Phipps Institute for the treatment of tuberculosis will establish a home for dying consumptives in this city. The plan for such a home is being carried out, and a number of gifts in money have been received for its consummation. A distressing feature which renders the establishment of such a home urgent is the fact that poor consumptives are refused admission into the hospitals of the city.

**Improved Sanitation in Tenement Houses.**—A delegation representing the Octavia Hill Association has called on the Director of Public Safety to ask his assistance in the improvement of the sanitary condition of tenement houses in the congested portions of the southern section of the city. They suggested that inspectors be delegated from the Board of Health or that officials of the association be empowered to make frequent inspections. The director took the matter under consideration.

**An Old German Midwife's Records.**—Susanna Müller practised midwifery in Providence township, Lancaster county, Pa., at the close of the eighteenth and in the early part of the nineteenth century. From her records, covering the years from 1791 to 1815, which have recently been edited by M. D. Learned and C. F. Brede, it appears that she confined a total of 1,667 cases, an average of 69 a year. The editors believe that this is by no means the entire number attended by her, though it is the one given on her simple tombstone. Her journal was kept in Pennsylvania German, the spelling of English names being strictly phonetic. Thus the little infant, Billy Woods, appears as "bile wuds." Susanna was very successful, and had the confidence of the best physicians in the city of Lancaster.

**Professor Hans Kehr, of Germany,** who comes to Philadelphia on next Tuesday will be the guest of Dr. Max J. Stern, of the Philadelphia Polyclinic. The trustees of that institution, taking advantage of this fact, have arranged for a series of clinics at the Polyclinic to which the medical profession will be invited. Professor Kehr, although one of the most expert abdominal surgeons of Europe, has confined his published works more particularly to the surgery of the biliary system, the pancreas and spleen. He has operated on over 800 cases of gallstones alone. It is desired that physicians having cases suitable for clinical material communicate at once by telegraph with the Polyclinic, or with Dr. Stern, and an endeavor will be made to have Professor Kehr see and relieve as many as may be in his power. Clinics will be held at the Polyclinic Hospital on May 6 and 7, and probably on the 8th.

#### SOUTHERN STATES.

**The West Virginia State Medical Association** will hold its thirty-sixth annual meeting at Charleston, W. Va., May 26, 27, 28, 1903.

**Health Statistics.**—In the health statistics for Washington, D. C., for the week ended April 18, there were 90 deaths as compared with 85 in the previous week and 118 in the corresponding period of last year. Of the decedents 50 were white, representing a deathrate of 12.5, and 40 colored, the deathrate being 22.8. For all the deaths the rate was 15.7; for the former week, 14.3; and for the corresponding period of last year, 20.

**New Hospital.**—Contracts have been awarded for the construction of a new hospital for contagious diseases in Jacksonville, Fla. It is stated that the city is in much need of a modern hospital for this purpose. It was agreed by the State Board of Health to undertake the erection of the hospital on condition that the county should provide the land. The new building is to be put up in the same locality as the present pesthouse.

#### WESTERN STATES.

**Refused Vaccination: Smallpox and Death.**—The health department officials of Minneapolis are pointing to the death of Charles Stevens as a signal instance of the fallacy of the anti-vaccination position. As secretary of the Antivaccination League of that city, Mr. Stevens had steadfastly refused to be vaccinated. It is regarded as a significant fact that the attack to which he succumbed was the most malignant case of smallpox on record in that city. From the first the physicians entertained scarcely a hope of saving him. Mr. Stevens had frequently denounced vaccination as a barbarous practice, entirely without efficacy in either preventing or staying the progress of smallpox.

**California State Board of Health.**—The Governor of California has entirely reorganized the State Board of Health by appointing the following: Dr. M. Gardner, San Francisco, president; Dr. W. A. Briggs, Sacramento; Dr. O. Stanbury, Chico; Dr. M. Regensburger, San Francisco; Dr. A. C. Hart, Sacramento; Dr. W. LeMoyné Wills, Los Angeles; and Dr. N. K. Foster, Oakland, secretary. The Legislature appropriated and placed in the hands of Governor Pardee (who is himself a physician) \$100,000 as a "contagious disease fund," to be used at his discretion. This board, together with the several local boards, are working in complete harmony with the United States Public Health and Marine-Hospital Service, and the result of united scientific effort can already be seen. Dr. Gardner's death last week is of importance, but it is trusted that his successor will continue on the lines already in operation.

**Charges Against Health Department.**—The Bureau of Charities in Chicago has made charges against the Health Department of the city. These will be investigated by the city authorities. The charges are as follows: That consumptive patients are allowed to live in lodging houses in direct violation of the law. That "double-decker" beds have been restored in a large number of lodging houses, the Health Department making no attempt to enforce the ordinance against them. That in scarlet fever cases the department often neglects fumigation, and in a large number of instances makes only a faulty fumigation of the house. That typhoid fever in the course of a few years often wipes out whole families, the origin of the disease being laid to unsanitary conditions of which the Health Department has repeatedly been advised. That fruitless attempts to

obtain reform from the department has led the bureau superintendents to resort to private means for a regeneration of unsanitary conditions.

## FOREIGN NEWS AND NOTES

### GENERAL.

**Pasteur Institute.**—It is stated that Dr. Emile Roux, who is subdirector of the Pasteur Institute, will present the Osiris Prize of \$20,000, which has lately been awarded to him, to the Pasteur Institute. This prize was founded by M. Daniel Osiris, a wealthy Parisian, to be awarded to the person that the Institute of France considered the most worthy to be thus awarded.

**A New Bacillus.**—An epidemic disease has been discovered among the eels in the small lakes at Obertello, in the vicinity of Rome, and Dr. F. Inghilleri has discovered in his investigations of this disease a new bacillus, as is announced in a published paper in the *Atti di Lincei*. The disease is known as "red plague," and the author considers it unsafe for eels thus attacked to be used as food.

**Emperor William to Stop Ill Treatment of Soldiers.**—In his instructions to officers in the Army, Emperor William says: "Officers must explain frequently to the soldiers that it is neither the wish of his Majesty, and their other superiors, nor does it correspond with the reasonable feeling of self-respect of privates, that they silently tolerate ill treatment. If soldiers do not report ill treatment it is well-nigh impossible for their superiors to take steps for their protection, and call to responsibility the officers guilty of cruelties. Soldiers really encourage, through their silence, the rough treatment given them contrary to the rules, and in the course of time this becomes force of habit."

**Juvenile Smokers.**—The *London Chronicle* states that the proposed bill penalizing juvenile smokers is interesting in that 20 years ago the prohibition of tobacco to children under 16 was proposed in France, but not brought into force. In several other countries, however, juvenile smoking is restricted by law. The nearest instance is Norway, where the sale of tobacco to any boy under 16 is forbidden, except on an order signed by an adult relative or employer. The penalizing fine varies from 2s. to £5. In nearly all the American States there are similar laws, with penalties also for the youthful consumer. It is the same in Canada, and the Government of Victoria is leading the way in Australia. A clause in the licenses of tobacco dealers forbids them to trade with children under the age of 16. More than two years ago the House of Keys discussed a similar law for the Isle of Man.

**Women Physicians.**—The number of female physicians is increasing every year in all civilized countries of the world. Madame Dr. Melanie Lipinska, a Polish lady now living in Paris, in a recent article in a French contemporary, calls attention to the fact that the first prominent female physician was Florence Nightingale, now an old lady still living in London. The first European university admitting female medical students was Zurich, in 1864. Then followed Paris in 1868, and then London. In 1901 there were altogether 95 female physicians in France, chiefly in Paris. In 1900 there were 11 colleges in England where ladies could study medicine. During the same year there were 258 female physicians in England. There are, furthermore, 156 English female physicians in India, China, Egypt and other Oriental countries. In Switzerland there were in 1900 altogether 355 female medical students. Russian Poland had 90 female physicians in 1900, while in Italy, Portugal, Bulgaria, Roumania, Greece, Belgium, Holland, Sweden and Denmark the number of female physicians did not exceed 20. Up to the year 1890 no female medical students were admitted to any university in Austria-Hungary. Germany opened her universities to female medical students only in the year 1899, and in 1900 there were 406 female medical students at the various universities of the Empire. In 1893 there were already over 2,000 female physicians in the United States.

### GREAT BRITAIN.

**Suicides Increased.**—With the return of spring the increase in the number of suicides in the United Kingdom is again apparent. Recently there has been an epidemic of self-destruction. In the first seventeen days of April no fewer than 40 suicides have been committed in England, Wales, and Scotland. Of this number seven people ended their lives with revolvers, while the means adopted in other cases were as follows: Drowning, 7; hanging, 4; throat-cutting, 5; suicide on railway, 4; opening of artery, 1; poisoning, 4. One-third of the suicides were women.

### CONTINENTAL EUROPE.

**The Osiris Prize Awarded.**—The *Figaro* states that the Institute of France, at a secret meeting, decided to award to Dr. Emile Roux, Sub-Director of the Pasteur Institute, a prize of \$20,000, founded by M. Daniel Osiris for the person that the Institute considered the most worthy to be thus rewarded.

## OBITUARIES.

**William M. Griffith**, of Philadelphia, April 20, aged 54. He was graduated from the Hahnemann Medical College, Philadelphia, in 1872. He was a member of the Oxford Medical Club, the Philadelphia Homeopathic County Medical Society, and the State Homeopathic Medical Society.

**Edmund Ludlow**, of Paxton, Ill., died at Los Angeles, Cal., April 5. He was graduated from the Northwestern University Medical School, Chicago, in 1895 and had served as interne at St. Luke's Hospital, Chicago, and at the Central Indiana Hospital for the Insane at Indianapolis.

**George W. Westlake**, at Red Bluff, Cal., April 4, aged 59. He was graduated from the Medical College of Ohio, Cincinnati, in 1866. He was a member of the American Medical Association and was coroner and public administrator of Tehama county, California.

**John M. Allen**, of Chester, Pa., April 20, aged 84. He was graduated from the University of Pennsylvania in 1840. In 1861 he was appointed an army surgeon, joining the Fifty-fourth Pennsylvania Regiment.

**Guy B. Miller**, in Paris, France, April 7, aged 30. He was graduated from the College of Physicians and Surgeons, New York, in 1898 and had served as house physician at St. Luke's Hospital.

**Hugo Lupinski**, of Grand Rapids, Mich., April 7, aged 44. He was graduated from the University of Michigan, Ann Arbor, in 1882, and was a member of the American Medical Association.

**R. R. Brelsch**, in Ringtown, Pa., April 23. He was graduated from the Jefferson Medical College, Philadelphia, in 1881. He was a director of the First National Bank of Shenandoah.

**James B. Greeley**, of Merrimack, N. H., April 20, aged 73. During the Civil war he served as surgeon of the First Rhode Island Regiment and was wounded in the second battle of Bull Run.

**W. S. Robinson**, near Mount Hermon, Va., April 21, aged 73. For ten years he was resident physician at Red Sulphur Springs and two years at Phospho-Lithia Springs.

**F. W. Anderson**, in Salt Lake, Utah, April 20, aged 81. He was the first president of the Utah Medical Society and the oldest practicing physician in Utah.

**Frank B. Williams**, of Brooklyn, N. Y., April 19, aged 40. He was graduated from the New York Homeopathic Medical College and Hospital in 1884.

**J. W. Fink**, in Hillsboro, Ill., April 14, aged 79. He was graduated from the medical department of Washington University, St. Louis, Mo., in 1854.

**Samuel P. Timmons**, of Louisville, Ky., died at Graham, Tex., April 6, aged 38. He was graduated from the University of Louisville in 1896.

**William M. Carothers**, of Braddock, Pa., April 12, aged 45. He was graduated from the University of Pennsylvania, Philadelphia, in 1890.

**George M. Silvers**, in Chicago, Ill., April 15, aged 43. He was graduated from the College of Physicians and Surgeons, New York, in 1878.

**Gustave Sussdorf**, at San Francisco, Cal., April 4, aged 61. He was graduated from the Long Island College Hospital, Brooklyn, in 1866.

**Franklin A. Sherman**, in Ballston, N. Y., April 22, aged 75. He was graduated from the Castleton (Vt.) Medical College in 1850.

**John A. Evans**, in High Hill, Mo., April 8, aged 41. He was graduated from the Missouri Medical College, St. Louis, in 1882.

**Hugh Marshall**, in Monmouth, Ill., April 11, aged 77. He was graduated from the Rush Medical College, Chicago, in 1852.

**Samuel Kalghn**, at Leesburg, Va., April 13, aged 69. He was graduated from the Medical College of Ohio, Cincinnati, in 1866.

**Daniel H. S. Tutthill**, of Chicago, Ill., April 19, aged 43. He was graduated from the Rush Medical College, Chicago, in 1885.

**Charles A. Wunsch**, in Saranac, Mich., April 8, aged 77. He was graduated from the Cleveland Medical College in 1867.

**H. Cushman**, of Stromburg, Neb., April 8, aged 65. He was a member of the American Medical Association.

**Joel J. Walker**, in Hot Springs, Ark., April 9. He was graduated from the Louisville Medical College in 1878.

**James M. Brown**, of Philadelphia, April 11. He was graduated from the Jefferson Medical College in 1875.

**J. H. Clopton**, of Huntsville, Ala., April 24. He was graduated from the New York University in 1867.

**James M. Tomlinson**, in Indianapolis, Ind., April 9, aged 81.

**L. H. Gebhard**, at Grand View, Texas, April 3, aged 74.

**Albert Wyckoff**, in Belvidere, N. J., April 13, aged 53.

**George H. Welles**, of Reading, Pa., April 14, aged 70.

**Samuel L. Foulke**, of Stroudsburg, Pa., April 18.

**T. W. Keith**, in Downing, Tex., April 14, aged 36.

**E. Gallaupe**, at Santa Ana, Cal., April 5, aged 83.

**H. N. Coomer**, of Ashley, Ohio, April 1, aged 70.

**L. M. Bray**, of Toone, Tenn., April 11, aged 75.

**N. P. Givens**, of Bowie, Tex., April 5, aged 60.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## DOSE MEASURES.

BY

M. I. WILBERT,  
of Philadelphia.

Apothecary at the German Hospital, Philadelphia.

The opinions expressed in an editorial on this subject in *American Medicine*, April 4, 1903, would appear to indicate that the majority of medical practitioners do not quite appreciate the trend of recent discussions on dose measures, or the ease with which many of the existing errors could be corrected. While it is true that a discrepancy of a few cubic centimeters either way would be of little importance when the dose of a liquid medicine is a tablespoonful, or a wineglassful, it does matter very materially when the dose to be given is but a half or one teaspoonful. It is this particular feature in the discrepancy of dose measures that is usually lost sight of by the majority of physicians; in fact, many do not even realize that it exists. To illustrate, we will suppose that a physician wishes to administer a comparatively large dose of a potent remedy in solution. With the average medicine glass, that is otherwise correctly graduated, the probable error at the tablespoonful mark is about 3 cc. either way, making the possible variation from 12 cc. to 18 cc., estimating that a tablespoonful is the approximate equivalent of 15 cc. If, however, the prescribed dose is one teaspoonful, the ratio of error is entirely different. With medicine glasses, as usually sold, the actual error in measuring is as great at the teaspoonful as it is at the tablespoonful mark. Estimating 5 cc. as being the equivalent of a teaspoonful, we would have a possible variation of from 2 cc. to 8 cc. as the quantity measured out by different people, or at different times. It will readily be seen that while the variation in the case of the tablespoonful is of comparatively small moment, with the teaspoonful dose the maximum may readily be four or five times that of the minimum quantity measured out. In practice this discrepancy has actually been found to exist, and with the higher priced medicine glasses it is even more exaggerated. The reason for this will become self-apparent when we find that the diameter of these medicine glasses at the teaspoonful mark is from 10 to 20 times that of the height; a very slight difference in reading, therefore, would give us a comparatively great difference in the quantity measured. In addition to this, many of the available medicine glasses are not graduated correctly, particularly for the smaller quantities, making an additional element of possible error to be taken into consideration. Paradoxical as it may seem, the household utensils, from which doses of liquid medicines take their names, do not differ so much in actual capacity as medicine glasses. The different spoons do, however, differ in capacity from the quantities usually accepted as their equivalents. The actual capacity of the average teaspoon, for instance, has been found to be much nearer 5 cc. than one dram, the usually accepted equivalent. An average dessertspoon is the equivalent of two teaspoons, while an ordinary tablespoon very seldom or never holds more than the equivalent of three teaspoonfuls.

The supposed variation in the capacity of these various spoons appears to depend largely, if not entirely, on the amount that can be heaped on the spoon above its normal capacity.

Drops are even more uncertain and variable as dose measures. It is possible, for instance, to vary the number of drops of distilled water that are necessary to weigh one gram from 8 to 50, or even more. This difference in the size and weight of drops becomes even more marked when we compare drops of mixtures containing a variable amount of alcohol, or a solution of salts.

From what has been said, it will be seen that there is considerable room for improvement in the measuring out and administration of liquid medicines. That liquid medicines are more efficient as well as more reliable than pills, powders or compressed tablets will readily be acknowledged by all that

have ever given the subject of absorption and assimilation even cursory consideration. Accepting these statements as being based on fact, it would certainly appear as though some concerted action should be taken to improve, if only in a slight degree, the existing haphazard methods of measuring out doses.

A careful consideration of the set of resolutions adopted at a pharmaceutical meeting held at the Philadelphia College of Pharmacy, and later endorsed by the American Pharmaceutical Association, should convince every thinking physician that present methods of measuring out doses of liquid medicines can be improved on without the undue expenditure of either time or money.

These resolutions, with the preamble, are as follow:

WHEREAS, It is desirable to secure greater accuracy and more uniformity in the measuring out or administration of doses of liquid medicines; therefore be it

*Resolved*, That we, members of the Philadelphia College of Pharmacy, assembled at this pharmaceutical meeting, recommend the use of accurately graduated glass dose measures; these measures to be constructed so that the height of the contained liquid, at a spoonful mark, is greater than its diameter.

*Resolved*, That for use in connection with spoons as dose measures we recommend the promulgation of the following definition taken from the French Codex:

"A spoon is full when the liquid it contains comes up to, but does not show a curve above the upper edge or rim of the bowl."

*Resolved*, That for use in connection with the metric system of weights and measures, we recommend the adoption of the following approximate equivalents of spoonfuls:

One teaspoonful equals 5 cc.

One dessertspoonful equals 2 teaspoonfuls or 10 cc.

One tablespoonful equals 3 teaspoonfuls or 15 cc.

That these resolutions are reasonable cannot be gainsaid, that they are practicable has been averred by many. So far no reasonable objection has been raised to any portion of them, but it will depend entirely on the willingness of the medical practitioners of the country to make them effective.

[The contention of our correspondent for greater accuracy in the measurement of doses of potent drugs is proper and worthy, but until some method is devised by which patients can be standardized, we fear that uncertainty regarding the idiosyncrasy of the patient will render of little avail the greater certainty as to the exact dose. If every patient was built on the normal, decinormal or centinormal plan, then we could by means of an indicator of some sort gauge our doses to the cubic millimeter.

The physiologic susceptibility of the patient to any given drug being to a degree an unknown factor it matters little that the dose vary within narrow limits.]

## SOCIAL PROGRESS AND THE EXTINCTION OF TUBERCULOSIS.<sup>1</sup>

BY

EMMA L. BILSTEIN, M.D.,

of Canton, Ga.

*To the Editor of American Medicine*:—In a recent journey from Florida to north Georgia among other small signs of the times I noted in a "curio" shop in St. Augustine an indecent toy for the amusement or disgust of the tourist, who doubtless is oftener amused than disgusted or the toy would not be exhibited. On a druggist's window in the same town appears the inscription, "Alleopathic and Homeopathic Pharmacy," the broad-minded composer of which possessed an ear for rhyme if not an eye for spelling. Conspicuous along the way were osteopathic and eddyopathic signs.

In the "white waiting-room" of the railway station at Marietta, Ga., a notice on the wall reads, "Please do not spit on the floor or stove," which must be very perplexing to the "mountain hoosiers," for if not on the floor or stove where shall they spit? Spit they must. Spitting is the distinctively masculine accomplishment. The tiny boy, while still in petti-

coats and pinafores, begins to practice spitting in imitation of his father, who incessantly sprays saliva round about wherever he goes or stands, with an air of pride in the dangerous, filthy habit. But the spirit of social progress has penetrated even these mountain backwoods. In the coaches of the Atlanta, Knoxville and Northern Railway Company there is an educative notice conspicuously posted that "spitting on the floor tends to spread disease and is otherwise objectionable"—a laudable and intelligent endeavor to teach him who can read that "*malum* and *morbus* are often the same." However, not all the benighted beggars with backwoods behavior belong to the South. Daytona, where I spent five months, was a *noticeably* tidy town until the winter visitors came. Then the parkage was constantly littered and defiled with scraps of paper, skins of fruit, ends of cigars, and other refuse, while notices against spitting and smoking in public buildings, against wheel-riding on the sidewalks, and so forth—*notices* intended for the safety and comfort of all—were daily disregarded, doubtless chiefly by eddyites in the third degree, in which mortal mind disappears, and by followers of Mrs. Post, who obediently "assert the I" and are above (or beneath?) obedience in all else.

On the whole, these occidental mystics, professed and otherwise, with their neglected and misused opportunities for knowing better, are inferior in morals and manners to the simple mountain hoosiers.

## THE NUTRITIVE VALUE OF DESICCATED VEGETABLES.

BY

EDWARD R. GREGG, M.D.,

of Pittsburg, Pa.

*To the Editor of American Medicine*:—In your journal for April 4 I notice an editorial comment on "The Nutritive Value of Desiccated Vegetables." I know something of them from two years' experience with them while in Alaska. On the Pacific Coast one can buy all the desiccated or evaporated potatoes and onions one desires. While other vegetables are also prepared in this way, these two are the most satisfactory. Our party had no other kind of potatoes or onions for a year. We ate the potatoes every day, the onions two or three times a week. They are both palatable and nutritious, although, of course, they have not the full flavor of the fresh vegetable, and they are more fibrous. Even eggs are thus prepared, and go by the name of evaporated eggs. This preparation is put up in tins, and if kept dry does not spoil. The eggs are dried and then pulverized to about the consistency of sawdust, but when dissolved in cool water, beaten and cooked, make a really good omelet. Sweet potatoes and cabbage are put up in cans, and are quite acceptable. There is even a canned preparation of "beef-steak and onions." All of these are well known on the Pacific Coast, and large quantities are sold each year. Some of your Western readers will doubtless respond to your editorial, as these preparations are well known to many of them.

While I am reminiscent, I want to mention another matter. In December, 1898, at Rampart City, Alaska, I performed a laminectomy for fracture of the sixth cervical vertebra. The case did not fall into my hands until about two months after the injury. The classic symptoms of cord pressure were present; the patient was emaciated to the last degree, and had also two large bed sores. In spite of this he stood the operation well, the wound healed by primary union in 11 days and he recovered some motion of forearms and legs, and, in fact, all functions were improving until he died of hypostatic pneumonia about six weeks after the operation. Considering the time elapsing after the injury, I am tempted to count it a successful laminectomy. I have never had one before or since that showed so much improvement, and we have a few in western Pennsylvania. I am desirous of learning, however, if that operation could, by any possible chance, be the first laminectomy performed in Alaska, and if not, how many preceded it?

## THE TREATMENT OF THE ACUTE DIARRHEAS OF INFANCY.

BY

JOHN LOVETT MORSE, A.M., M.D.,

of Boston, Mass.

Instructor in Diseases of Children, Harvard Medical School; Assistant Visiting Physician at the City Hospital and at the Infants' Hospital, Boston.

The acute diarrheas of infancy may be divided, on the basis of etiology, into two main classes: those of nervous origin and those due to the action of microorganisms.

*Simple Diarrhea.*—The diarrheas of nervous origin are the result or manifestation of increased peristalsis. This increased peristalsis may be caused by various conditions acting through the central nervous system or by the mechanical action of undigested food. Among the most important of the conditions acting through the central nervous system are sudden changes in temperature, prolonged exposure to heat or cold, fright and fatigue. Food may fail of digestion either because it is unsuitable for digestion, or because the digestive power is functionally weak. In either case the food acts as a foreign body. The intestinal mucous membrane shows no pathologic lesions unless possibly a slight hyperemia. The number and fluidity of the dejections are increased. Except for the presence of more or less partially or entirely undigested food they are normal in character. Perhaps as good a term as any to apply to these cases of the nervous type is "simple diarrhea." They are rare in comparison with the other forms of diarrhea. Their chief danger lies in the increased susceptibility which they produce to invasion by microorganisms. It is this danger, rather than the severity of the disease itself, which demands appropriate, early and vigorous treatment, even in the mildest cases.

*Treatment of Simple Diarrhea.*—The first and most important method of treatment is the removal of the cause. This is usually easy when the cause is simply fright or fatigue. When the cause is atmospheric, however, a change of climate may be necessary. When the difficulty is due to undigested food this must be removed. This is best accomplished by castor-oil or calomel. As infants bear castor-oil proportionately better than adults it is usually advisable to give at least two teaspoonfuls. Calomel is best given in doses of 65 mg. ( $\frac{1}{10}$  grain) in combination with .065 gram (1 grain) of sodium bicarbonate every half hour or hour until .065 gram (1 grain) has been given. In rare instances it may also be wise to wash out the stomach and colon. The infant should be kept quiet in bed. After the cause has been removed the diarrheas usually ceases. If it does not the treatment should then be directed to the control of the excessive peristalsis. For this purpose opium and astringents may be used. This is, with rare exceptions, however, the only condition in which the use of these remedies is allowable. Opium is best given in the form of paregoric, the dose not exceeding a few drops. I have found tannigen or tannalbin, in doses of from .19 to .32 gram (3 to 5 grains), the best of the astringents. As the excessive peristalsis is in many instances merely the expression of general weakness, brandy in doses of a few drops, will often be more efficacious. It is best to withhold food for a few hours and then to begin with a rather dilute, highly alkaline, pasteurized milk.

*Infective Diarrhea.*—Microorganisms are the cause of the great majority of the acute diarrheas of infancy. These microorganisms may be the usual inhabitants of the intestines or forms not normally present there. The bacteria normally present in the intestines may as the result of abnormal local conditions develop pathogenic properties. These abnormal conditions are usually the result of disturbances of digestion. The bacilli of

the colon group are especially likely to become virulent. The abnormal forms of bacteria almost invariably enter the body with the food. They are chiefly the streptococcus, *Bacillus pyocyaneus* and *Bacillus proteus vulgaris*. Many other forms, chiefly saprophytic, are found, however. Shiga's bacillus and bacilli closely resembling it have recently been found in a number of cases of ileocolitis. Except in the comparatively few instances in which this group of bacilli has been found bacteriologic examinations of the stools have failed to show any very definite relation between any special form of bacteria and variety of diarrheas. Bacteriologic examination of the dejections at present, therefore, affords but little information of value as a basis for either diagnosis or treatment.

The intestines may show all grades of inflammation from simple catarrhal and simple follicular hyperplasia to follicular ulceration and the formation of false membrane. The severity of the symptoms is often no index of the degree of the pathologic changes.

The constitutional symptoms are due partly to the lack of nourishment and the abstraction of fluids, but chiefly to the absorption of toxins. These toxins may be formed within the body or taken in, already formed, with the food. Among the most striking of the symptoms of toxic absorption are reflex vomiting, hyperpyrexia, prostration with cardiac depression, and nervous excitement. The most common manifestations of nervous excitement are restlessness, incessant motion and sleeplessness.

The acute diarrheas due to microorganisms may be roughly divided into several classes which, to a certain extent, call for different lines of treatment. Certain general methods, however, are applicable to all. Among the most important of these is the prophylactic.

*Prophylaxis.*—This, while important at all times, is especially so in the summer, when these diseases are most common. Infants should be kept in the best possible hygienic surroundings, be given plenty of fresh air and bathed frequently. If feasible they should be sent to the country or seashore during the summer months. Care must be taken not to overfeed them, as less food is needed in warm weather than in cool. Moreover, owing to the depression produced by the heat, the child is less able to digest its food. The deficiency should be made up with water. Apparent hunger is often merely a manifestation of thirst. Much more water should be given, therefore, in warm weather than in cool. As these diarrheas are due to microorganisms, and as these microorganisms are very largely introduced with the food, it is evident that every effort should be made to give the child a fresh and sterile food. Too much care cannot be taken in obtaining, transporting, and preparing milk during the summer months. It must be remembered, moreover, that the sterilization or pasteurization of milk does not destroy toxins which may be present in it; it merely prevents the formation of more. The toxins present in milk before it is sterilized may well be sufficient to cause severe or fatal symptoms.

*Hygienic Treatment.*—While hygienic measures are of great importance in prophylaxis they are even more so in treatment. The infants should be kept quiet, given the greatest possible amount of fresh air, be lightly clothed and frequently bathed. The napkins should always be immediately disinfected in order to prevent reinfection. If the symptoms do not abate in a few days the children should, if possible, be given the benefit of a change of climate.

*Dangers of Opium and Astringents.*—Since, as has already been stated, the majority and the most serious of the symptoms are due to the absorption of toxins from the intestines, it is evident that any method of treatment which prevents the natural elimination of these poisonous products in the dejections is absolutely bad. The frequent discharges are nature's attempts to cure. Hence opium in any form is almost positively counterindicated. It can rarely do anything but harm.

Astringents are unsuitable for the same reason. They are less dangerous than opium only because they are less powerful. Opium and astringents should only be used in those rare cases in which peristalsis is excessive and in which the good results of the peristalsis are not commensurate with the worry and exhaustion which it causes, that is, in those cases in which a very large number of small movements containing little or no fecal matter keeps the child constantly excited, prevents him from sleeping and rapidly wears out his strength.

*Classification of Infective Diseases.*—As already stated the infective diarrheas may be roughly divided, largely on the basis of symptomatology but partly on that of pathology, into several main groups. These are known by various names, the best of which are fermental diarrhea, cholera infantum, and ileocolitis. Almost all of the summer diarrheas belong in the fermental class, ileocolitis being uncommon and cholera infantum exceptional. In making arbitrary divisions on the basis of symptomatology it must always be remembered, however, that in many cases there is absolutely no relation between the severity of the symptoms and that of the pathologic lesions, and that conclusions based on the symptoms alone may be entirely erroneous.

*Fermental Diarrhea.*—In brief, in fermental diarrhea the number of discharges is only moderate, not usually more than 10 or 12 in 24 hours. They vary in color from yellow and green through all shades of green. They are often watery or frothy, and may contain more or less curds and mucus, but rarely blood. The amount of the discharge is usually comparatively large. The odor is almost always offensive. In some cases it is markedly sour; in others, very foul. On this basis two main classes have been recognized, the acid fermentation and the albuminoid decomposition. It is supposed that in the first class the trouble is due to bacteria which thrive on sugars, and in the second to those which thrive on proteids. This division is, however, of but little practical use. Pain and tenesmus are less prominent symptoms than in ileocolitis. The various constitutional symptoms already spoken of are present in all cases in varying combinations and degrees. All grades of severity are seen, from the mild cases lasting a few days or weeks to those rapidly fatal in a few days or even hours. The pathologic changes are comparatively slight, rarely progressing beyond the stage of simple catarrhal inflammation.

*Treatment of Fermental Diarrhea.*—The first indication for treatment is to remove the cause, namely, the microorganisms and their toxic products. In mild cases a purge is often all that is necessary. Castor-oil is perhaps the most satisfactory when there is no vomiting, although calomel is applicable in all cases, and is altogether the best when there is vomiting. The dosage is the same as in simple diarrhea. A purge is always necessary, as it is the only way in which the small intestine can be reached. In the severe cases and in all cases in which vomiting is an important symptom, it is advisable to wash out the stomach. This is a simple procedure in infants, causing them but little discomfort or exhaustion. An ordinary soft rubber catheter makes a very satisfactory stomach-tube. Normal salt solution or a weak solution of sodium bicarbonate is somewhat better than plain water. If thirst is a prominent symptom it is well to leave a few ounces of water in the stomach. In the more severe cases it is also advisable to wash out the lower bowel. This is done by passing a rather large soft rubber catheter high into the bowel. Several quarts of liquid from a fountain syringe, not more than three feet above the patient, should be allowed to run in and out. Normal salt solution or a 1% or 2% solution of boric acid are most useful. The importance of thoroughly emptying the alimentary tract from both above and below, as well as by purging, can hardly be overestimated. While irrigation of the colon is most useful in the initial cleaning out in fermental

diarrhea, and may be repeated for a similar purpose later in the course of the disease, it is not indicated as a method of continued treatment. It does not reach the seat of the disease, and may by exciting the patient, especially if frequently repeated, do far more harm than good.

Unfortunately, it is impossible by the methods detailed above to entirely rid the alimentary tract of bacteria. Enough remain, if the conditions are favorable for their multiplication, to keep up or cause a recurrence of the trouble. The condition most favorable for their multiplication is the presence in the intestine of a suitable culture medium. This medium enters the intestine only through the mouth. Hence the next indication for treatment is to prevent the ingestion of any food which will provide such a suitable culture medium. For this reason it is best to cut off all food for at least 24 hours, giving only sterile water. Water is not counterindicated, although food is. In fact, on account of the losses in the dejections, more fluid is needed than under normal conditions. It also serves a useful purpose in favoring the elimination of toxins by the kidneys. An amount of water at least equal to that contained in the usual food supply should therefore be given. More is of advantage. The brilliant results claimed for barley water and rice water in the treatment of the early stages of these cases are probably to a considerable extent due to the fact that they contain so little beside water that their use amounts practically to starvation. (Barley water, as usually prepared, contains 1.5% or less of starch, and little else.)

Unfortunately, again, temporary starvation rarely suffices to diminish the number of bacteria to such an extent that they cannot cause trouble. The patient, however, demands and must have nourishment. The problem is to give it in the least harmful form. This is, of course, the form most unsuitable for the growth of the microorganisms causing the trouble. The odor of the stools, as being characteristic of acid fermentation or albuminoid decomposition, would seem to offer some means of assistance. Unfortunately, this distinction is rarely possible or reliable except in the case of the very sour stools. Here a proteid diet, with an almost complete exclusion of sugar, is indicated and gives satisfactory clinical results. In the majority of cases, however, the process seems to be a more complex one, and there is no indication for or against any special element of the food. It must, therefore, be selected on general principles.

There seems to be a very general feeling that milk in any form is unsuitable in these cases on the ground that the pathogenic microorganisms are usually originally introduced in milk and therefore should thrive better in it than in any other medium. This argument hardly seems sound, however. The bacteria enter in the milk simply because milk is the baby's food, not because it is the best culture medium. No one thinks of choosing milk as the medium on which to grow these same organisms in the laboratory; they choose rather preparations of meat or carbohydrates, the very materials from which the usual substitutes for milk in this disease are made. Clinically, nevertheless, these patients do seem to do better when they are fed for a time on something beside milk. There is much difference of opinion as to how long they should be kept off of milk. Some authorities think that a few days is all that is advisable, others that they should be kept off of milk until the stools are normal no matter how long this may be. This latter position is, I feel sure, a wrong one. It is almost always advisable to return to milk after a few days even if improvement has not been very marked, partly because the substitutes for milk are usually low in nutritive value and partly because the change provides a different soil for the bacteria. Few realize how dilute most of the substitutes for milk are and how little food value they have. Barley water as usually prepared analyzes about .05 of 1% of fat, .25 of 1% of proteids, and 1.56% of

starch. Rice water and arrowroot water are little, if any, stronger. The white of one egg is only equal in nutritive value to  $\frac{2}{3}$  of 1 ounce of milk. Beef-juice contains .6 of 1% of fat and 2.9% of proteids, giving a nutritive value, bulk for bulk, only one-quarter as great as milk. Broths contain only about 1% of proteids and hence have very little nutritive value. I feel, therefore, that the favorable results obtained from these substitutes for milk are to a certain extent due to the weakness of the foods. Milk preparations in a similarly dilute form will yield far different results from those obtained when they are given of the usual strengths. As already stated, however, there can be no doubt that these patients do better when milk is temporarily omitted.

Albumin water is best prepared by mixing the white of one egg with from four to eight ounces of water at a temperature of from 104° F. to 108° F. The egg should be mixed in carefully and not beaten. The shreds should be strained out.

Beef-juice is prepared by half-broiling a piece of round steak. The steak is then cut into small pieces and the juice expressed with a beef or lemon squeezer. It is better taken if salted, and may be given undiluted or diluted with warm water.

Barley water is made by boiling two teaspoonfuls of barley flour in a pint of water for 15 or 20 minutes. Water is then added until the amount of the mixture is again brought up to a pint. It is then strained through cheesecloth.

It is often very difficult to determine in a given case which of these preparations to use. If there is evidence of acid fermentation barley water and other cereal decoctions are counterindicated, while if there is evidence of albuminoid decomposition, broths, beef-juice and albumen water should not be given. It must also be remembered that the extractives in beef-juice and broth stimulate peristalsis and tend to keep up the diarrhea. Somatose given in .65 or .97 gram (10 or 15 grain) doses in water is often of service in those cases in which proteids are indicated. In those cases in which it is impossible to determine the nature of the pathologic process, and they make up the great majority, the cereal decoctions are more likely to agree than are preparations of animal proteids. In general, therefore, unless they are distinctly counterindicated, it is safer to begin with the cereal decoctions.

In beginning to feed with preparations of milk, whey is often most useful. It may be made from whole milk or skim milk. In either case it contains about 1% of proteids and 5% of sugar. When made from skim milk it contains almost no fat, while when made from whole milk it contains about 1%. It is prepared by adding a teaspoonful of essence of pepsin or liquid rennet, or a junket tablet to a pint of milk and heating it to from 100° F. to 110° F. until it coagulates. The mass is then broken up and strained through a napkin. If the patient is doing well the whey may be strengthened by the addition of small amounts of cream. If this is done the whey must be heated to 150° F., otherwise the ferment will make curds and whey of the cream also.

If whey is not used the infant should be given a modified milk prepared from fresh milk low in all percentages, highly alkaline and pasteurized. It is better to give small amounts frequently than large at long intervals. Experience only can teach just what percentages should be given in individual cases, barring those cases in which there are definite indications of acid fermentation or albuminoid decomposition. In general, the percentage of sugar may be comparatively high, while that of the proteids must be comparatively low. The fundamental principle, however, is to give a dilute food. As the patient improves the percentages may be increased, together or singly, and the intervals of feeding lengthened until the strength and intervals suitable for a normal infant of the given age are reached.

Breast feeding should not be forgotten in these cases.

After the initial periods of starvation and abstinence from milk it will sometimes result in cure in cases which otherwise seem hopeless. In very critical cases breast-milk may be given diluted with water.

As already stated, the first indication for treatment is to remove the cause. One way to do this is by destroying the cause. In this instance, however, the destruction of the cause involves the destruction of the patient. No germicides in doses large enough to be effectual can be used with safety. Drugs which limit to a certain extent the activity of the microorganisms can, nevertheless, be used to advantage. After a considerable and varied experience with many drugs, including many of the newer preparations, I have discarded all but bismuth. This is best given as the subnitrate or subgallate. Either to be of much use must be given in considerable doses, not less than 4 to 8 grams (1 or 2 drams) in 24 hours. Unfortunately, it is difficult to induce a sick infant to take this amount. About as much can be given in the form of powder, mixed with water or milk, as in any other way. It is often given suspended in chalk mixture or simple mucilage. Any form of mucilage decomposes very rapidly in warm weather, and after it has been kept 24 hours every teaspoonful brings a large reinforcement to the enemy already present in the intestine. The subnitrate of bismuth may be safely given in suspension, however, in the following way:

Ammonio-citrate of bismuth . . . . .	5 parts
Nitric acid . . . . .	30 drops
Water . . . . .	100 parts

The subnitrate formed in this way will remain in suspension for several days. The objection to this preparation is the strong taste of citric acid and the small number of grains to the teaspoon. It is possible to give this, however, when the dry powder will not be taken.

Zinc sulfocarbolate in doses of .010 to .016 gram ( $\frac{1}{4}$  to  $\frac{1}{2}$  of a grain) seems to diminish the formation of gas and to improve the odor of the stools. Stimulation is necessary on the same indications and along the same lines as in other diseases. Alcohol is counterindicated if there is much irritability of the stomach.

Certain special symptoms, due to toxic absorption, may require special treatment in addition to that for the removal of the cause. Excessive vomiting is best treated by stomach washing, and hyperpyrexia by cold bathing or packs. Extreme restlessness usually yields to bromids but morphin may be necessary. If it is used it is best given subcutaneously. Prostration and collapse require stimulation along the usual lines. Brandy and strychnin are most useful and must often be given under the skin.

All the symptoms due to toxic absorption are at times much relieved by subcutaneous injections of normal salt solution, which favor the elimination of the toxins through the kidneys and skin. Salt solution may also be given as an enema, although when given in this way it is not likely to be retained. Four to six ounces are sufficient for a single subcutaneous injection. The injections may be repeated every four or six hours. Prostration, collapse, and many nervous symptoms are often due to the loss of fluid in the stools and the consequent draining of the tissues. Subcutaneous injections of salt solution are of great value in these conditions and often give immediate relief.

*Ileocolitis.*—In ileocolitis are found the more severe pathologic lesions. They are usually most marked in the colon and in the lower part of the small intestine. The discharges are numerous, usually comparatively small in amount, contain much mucus, blood, and sometimes pus and membrane. The amount of fecal matter is usually small and often fairly well digested. The odor varies, being putrid when there is deep ulceration and sloughing, and almost *nil* when the discharge is composed principally of mucus. Pain and tenesmus are marked symptoms. The abdomen is often tender. Vomiting is usually not a prominent symptom.

*Treatment of Ileocolitis.*—The discovery of Shiga's

bacillus and allied bacilli in cases of this disease immediately suggested a specific treatment with injections of the serum of immunized animals. The few patients treated in this way have shown rather varied results. Too much cannot be expected from this method at present, however, when it is remembered that several different, although closely allied, organisms have been found in these cases and that each one calls for a different serum.

The treatment of ileocolitis must, therefore, be along the same lines as that of fermental diarrhea. Purgation, starvation and diet are as important in the one condition as in the other. It is important to give foods which are readily absorbed and which give but a small amount of residue. The inflamed colon is thus less exposed to irritation from masses of digested or undigested feces. For this reason milk, which has a large residue, is to a certain extent counterindicated. Whey, however, is not open to this objection and is most useful. Proteids are better borne in this condition than in fermental diarrhea and should make up a greater portion of the food. White of egg, beef-juice and somatose are especially useful. Fat is not as well borne, however, and should not be given except in very low percentages. Bismuth is even more useful than in fermental diarrhea, serving the double purpose of diminishing fermentation and of mechanically coating over the inflamed surfaces.

Owing to the location of the principal lesions in the large intestine it is possible to reach the seat of disease from below. Irrigation provides a means not only for removing the microorganisms and their toxic products, but also for cleansing the diseased surfaces and making local applications to them. Several quarts should always be used in irrigating the bowel, and as the chief object of irrigation is cleanliness, the liquid should be allowed to run until it returns clear. Normal salt solution and a 1% to 2% solution of boracic acid are most useful. Solutions of the stronger antiseptics are no more efficacious and may be dangerous. Irrigations may be used from one to three times in 24 hours. They should never be used oftener. It is a mistake to use them every hour or two, or after every movement, as is sometimes done. They always cause more or less exhaustion, even when the patient does not resist. If the patient resists a great deal, or is much excited or tired by them, they should be omitted. They should always be used with discretion, as while they often do much good, they may do great harm. In the more chronic cases irrigations of silver nitrate, in the proportion of 1 to 1,000, one in two or three days, seem to hasten recovery. A strong salt solution should always be at hand when this is used, in case it proves too irritating.

Suppositories of .006 to .010 gram ( $\frac{1}{10}$  to  $\frac{1}{8}$  grain) of cocain will often relieve tenesmus. Opium may sometimes be given in these cases when the peristalsis is excessive and is not serving a useful purpose. Other special symptoms should be treated as in fermental diarrhea.

*Cholera Infantum.*—This term should be applied only to those cases of diarrhea characterized by the most intense choleric symptoms. It is a very rare condition. The pathologic lesions are very slight, never progressing further than hyperemia and desquamative catarrh. The bacteria found usually belong to the proteus group.

Vomiting and diarrhea are constant, and both soon become almost entirely serous. As the result, all the tissues are rapidly deprived of their fluids. Thirst is marked. Wasting and prostration are extreme. The internal temperature is almost always high, although the surface temperature may be low. There is intense internal congestion. The disease is self-limited. The course is not more than two or three days, usually less. The termination is almost invariably in death, usually after marked nervous symptoms.

*Treatment of Cholera Infantum.*—In such a rapid and fatal disease it is evident that treatment, to be of avail,

must be immediate and vigorous. It is probable that there is a vasomotor paralysis of the gastrointestinal vessels. Hence food and drugs introduced into the alimentary canal cannot possibly be absorbed. They can do no good, and undoubtedly may do harm.

The main indications for treatment are: (1) To empty the stomach and bowels of their toxic contents; (2) to supply fluid to the tissues which are being so seriously drained; (3) to restore the surface circulation; (4) to reduce the temperature; (5) to keep the patient alive until the disease has run its course.

Purgatives act too slowly to be of much use in this disease and our chief reliance must be placed in stomach washing and intestinal irrigation. They must be used early and vigorously. It is useless to expect to supply fluids by the mouth. They are almost invariably vomited. Cold, sterile water in small amounts may be tried, however. The injection of normal salt solution into the cellular tissue is the only method of introducing fluid which can be depended upon. Not less than a pint should be given in 24 hours. This not only supplies fluid to the tissues but assists in eliminating the toxic substances in the blood and in restoring the surface circulation.

Irrigations of cold water tend to restore the surface circulation and also to reduce the temperature. The best methods for restoring the surface circulation are rubbing, mustard baths, and the warm pack. These procedures, however, are not those best fitted for the reduction of temperature. For this purpose cold, in the form of sponging, packs or baths, must be used. In the treatment of individual patients it is often necessary to determine whether it is the internal congestion or the high temperature which is doing the more harm, and then to treat the more serious condition. The relief of one, however, often aids the other also.

As food cannot be given, the patient must evidently be kept alive by stimulation. As drugs given by the mouth are not absorbed this stimulation must be given subcutaneously. The usual stimulants, alcohol and strychnin, are to be employed. Atropin is especially useful in these cases. It apparently has some special action antagonistic to that of the toxic products of the disease. It is to be used in doses of from .1 to .08 mg. ( $\frac{1}{500}$  to  $\frac{1}{300}$  grain) repeated every two or three hours as necessary. Morphin is indicated when the diarrhea and vomiting are extreme or when the nervous manifestations are very marked. Doses of .6 mg. ( $\frac{1}{100}$  grain) are usually sufficient; they should be given subcutaneously. Care must be taken not to give too much or to continue it too long.

In case improvement begins stimulants and water may be given by the mouth and soon after small amounts of food. It is safer to begin with barley water and later to give a pasteurized fresh milk of very low percentages.

#### SOME POINTS PERTAINING TO THE THERAPEUTIC MANAGEMENT OF THE UREMIC STATE.<sup>1</sup>

BY

HEINRICH STERN, PH.D., M.D.,  
of New York City.

The diversity of opinion as regards various procedures and medicinal agents in the treatment of uremia can be ascribed only to insufficient consideration of the original affection on the basis of which it has developed.

Uremia, an arbitrary designation comprising a multitude of phenomena often unlike in character and intensity in various patients and in the same patients at different periods, is not the exclusive result of one and the same causative factor in every instance. True enough, all uremic manifestations depend upon the condition of the blood, but while this exhibits some characteristics, which are in a measure common to all types of

<sup>1</sup>Read at the meeting of the Medical Society of the State of New York, at Albany, January 28, 1903.

uremia, the serum of every variety possesses some distinctive feature. Responsible for this is not only the different underlying renal condition, but also the specific material of the infectious disease in whose wake uremia may appear, and the decomposition products of the retained substances; the formation, quantity and specific state of which, are dependent upon duration of retention, oxidation and the physical condition of the serum.

In the large, white kidney, for instance, the passage of the watery constituent of the blood is seriously interfered with; in contracted kidney there is nothing to prevent its outflow. While at the approach of and during the uremic condition extremes in blood composition may not exist any longer, the sera of uremia on the basis of chronic parenchymatous nephritis are differently constituted in some major points from those of uremia due to interstitial nephritis. The tendency to convulsive phenomena in the one, and to a comatose state in the other variety, may well be explained by the different constitution and physicoelectric behavior of the respective sera.

It is not my intention to dwell upon all discrepant features of the various uremic sera on this occasion; however, in order to demonstrate the necessity of a different and more rational management of the various types of the attack I cannot refrain from briefly alluding to the retention nitrogen, a factor most conspicuous on account of its presence in large amounts in the uremic serum due to interstitial nephritis and by its occurrence in noticeably smaller quantities in the serum of uremia following chronic parenchymatous nephritis or the mixed form of the affection.

Under retention nitrogen in the blood is understood all the nitrogen remaining in the liquid after complete removal of the albuminous substances. The average amount of retention nitrogen<sup>1</sup> in 100 cc. of normal blood serum is between 25 and 30 mgs.; in chronic parenchymatous nephritis without uremia the average quantity amounts to 40 mgs. and in the presence of uremia to about 62 mgs. in 100 cc. blood-serum; in chronic interstitial nephritis without uremia a mean amount of 82 mgs. and when uremia prevailed 130 mgs. retention nitrogen were found in the average; in the mixed type of nephritis without uremia in the mean 51 mgs., and with uremia 120 mgs. retention nitrogen in 100 cc. blood-serum were demonstrated. These figures show that in the blood-serum of chronic parenchymatous nephritis about 35% more retention nitrogen is contained than in the normal liquid; that in interstitial nephritis the retention nitrogen in the blood-serum occurs in twice the amount as in parenchymatous nephritis, and that in the intermediate type of the affection there is contained more nitrogen than in parenchymatous and considerably less than in interstitial nephritis. They further evince that the amount of retention nitrogen is increased in the uremic conditions following the three forms of nephritis and that in the uremic serum in parenchymatous nephritis the amount of retention nitrogen occurs in about half the quantity it is found in the serum of uremia arising as the consequence of chronic interstitial nephritis.

The enormous quantities of retention nitrogen in the serum of chronic interstitial nephritis undoubtedly stand in causative relationship to the natural termination of this disease—uremia. In chronic parenchymatous nephritis uremia is not only a much rarer but also a less grave complication. In about 75% of the cases of uremia due to chronic parenchymatous nephritis which have come under my observation I have seen recovery from the first attack. The comparative infrequency and mildness of the uremic seizures due to chronic parenchymatous nephritis are explained by the fact of the relatively small amount of retention nitrogen.<sup>2</sup>

The inconsistency of pursuing the same plan of treatment throughout in cases of uremia so unlike in their manifestations and arising from two (or more) so markedly discrepant substrata is obvious. In the following it is neither my purpose to draw the outlines of a complete management of the various uremic states nor do I wish to introduce a new remedial factor, but I want to pass in review some of the therapeutic agents we are familiar with at the present hour, and to point out their particular field of usefulness.

*Sweating.*—Promotion of the activity of the sudoriferous glands to enhance the excretion of retentia is indicated under certain restrictions in every instance of acute uremia. It has proved of special value when employed soon after the onset of the uremic phenomena. When the attack has persisted for some time, or when a pronounced comatose condition has supervened, sweating, as a rule, is of little or no avail. For reasons already stated, its application has a greater salutary and more lasting effect in uremia having chronic parenchymatous nephritis at its foundation; it is essential that it should bring about the desired result in a short time; too long continued, particularly after marked symptoms of improvement have made their appearance, its beneficial influence at first noticeable, may cease, or it may become a directly harmful agent. That is, by free perspiration considerable amounts of excrementitious substances may be removed from the serum and the watery accumulations; the quantity of water, however, by the medium of which the solids are excreted, is in proportion larger than it exists in the blood. This is evinced by the molecular concentration of the blood-serum, which is most always higher than that of sweat. Withdrawal of indefinite (because unmeasurable) large amounts of water from the serum, in other words, tends to increase still further its hyperosmotic condition and to decrease its conductivity.

If sweating is kept up by active measures, enteroclysis with a weak sodium chloride solution, or hypodermoclysis with a hypotonic solution of NaCl should be performed at certain intervals.

*Venesection.*—Abstraction of blood is a therapeutic measure of transitory value mostly, but serving a good purpose in many instances of uremia. The most lasting results of bleeding are obtained in cases following acute nephritic conditions, that is in such instances in which the patient is still sthenic and in which the blood has not as yet attained that degree of admixture and impoverishment which it exhibits during the chronic renal affections. Furthermore, uremic manifestations on the basis of chronic parenchymatous nephritis yield more readily to venesection than those which are due to contracted kidney. In children, abstraction of 100 cc. to 250 cc. of blood often effects immediate improvement; in adults not less than from 150 cc. to 250 cc. and if the condition of the patient warrants it, 300, 400, or even 500 cc. of blood should be withdrawn. When the uremic symptoms do not abide after venesection, the procedure may be repeated on one and the same day, provided the patient (abstracting the uremic state) is yet in a comparatively fair condition and the uremic manifestations are the result of an acute renal disturbance. In asthenic and far advanced cases, on the other hand, abstraction of blood is not only useless as a rule but often even injurious.

The frequent salutary results of venesection in the properly selected cases cannot be ascribed to the abstraction of a few hundred cubic centimeters of blood and the proportionate quantity of retained nitrogenous material; furthermore, withdrawal of blood does not in the least interfere with the molecular concentration of the remaining blood nor does it tend to increase the electric conductivity of the blood-serum. We possess no definite information that after bloodletting oxidation is enhanced, a process by which the retentia could be transformed into innocuous substances. Such a transformation—if it really occurred—could probably reduce the

<sup>1</sup> The figures relating to the amount of retention N. were obtained by Strauss: Die chronischen Nierenentzündungen, etc., Berlin, 902.

<sup>2</sup> Those further interested in this subject I refer to my article: A Contribution to the Pathogenesis of the Uremic State: the Probability of its Physicoelectric Substratum, *Medical Record*, January 24, 1903.

"virulence" of uremic blood in a chemico-toxic sense but it would not materially alter its physico-toxicity. The improvement afforded by venesection is likely due to nothing else but the relief of the vasoconstriction in the kidneys or in the central nervous system or in both these places.

*Hypodermoclysis and Infusion.*—Subcutaneous or intravenous introduction of a weak solution of sodium chlorid dilutes the blood, produces diuresis and compensates for the amount of blood lost by venesection. The effects are more or less transitory in character, but may endure sufficiently long to bridge over a critical phase in the uremic attack. Intravenous injection, of course, acts more rapidly and vigorously than when the solution is introduced by hypodermoclysis, but its effects are correspondingly less lasting. A sodium chlorid solution which is isotonic to human blood contains 0.9% NaCl. It is the true physiologic salt solution and its intravenous injection after severe hemorrhage is followed by regeneration of the blood-plasma and restoration of the normal volume of blood. In uremia, however, it has been observed that an isotonic sodium chlorid solution does not act as efficiently as one which is hypotonic. For this reason a decinormal NaCl solution containing not quite 0.6% of the salt is usually employed in this condition. This is understood when we remember that the high osmotic tension of uremic serum is not so much due to its ionized as to its neutral molecules. To effect a more general ionization and conductivity water only is essential. We do not need additional electrolytes in the uremic serum which are introduced from without, but we should inject a solvent to facilitate dissociation of the electrolyte molecules existing in the blood. As plain water, however, may call forth too pronounced hypotonicity and as it is a poison to the erythrocytes producing their crenation, a weak solution of NaCl should be resorted to. I have used a 0.5% solution with the utmost benefit to the patient, especially in uremia due to chronic parenchymatous or acute nephritis. The comparatively small amount of nitrogenous retentia in the uremic serum in diffuse nephritis facilitates the reestablishment of its normal conductivity after subcutaneous or intravenous injection of the salt solution; on the other hand, in uremia having chronic interstitial nephritis at its foundation, when the retention nitrogen exists in enormous quantities, and when ion formation and ion movement are more or less paralyzed, not alone water but also goodly amounts of active molecules seem to be indicated. This, however, I wish to have understood as a hypothetic suggestion only, for it is an extraordinary fact that I cannot assign the improvement in a single case of uremia due to interstitial nephritis to the influence of the sodium chlorid solution alone, whether I administered it in hypotonic or isotonic solution, by hypodermoclysis or intravenously.

The minimum amount of the solution to be used should never be less than 125 cc. if injected intravenously, and 250 cc. when administered by hypodermoclysis. Smaller quantities, if at all, produce very limited and rapidly passing effects only. The maximum quantity of decinormal sodium chlorid solution which may be administered in the uremic state at one time should not exceed 750 cc. if employed subcutaneously, and not more than one-third of this if introduced by infusion. The procedure, however, may be repeated two, three, and more times during the 24 hours, especially when it directly precedes phlebotomy or if a considerable amount of blood has been abstracted.

As serum conductivity is enhanced by elevation of its temperature, more good will be accomplished if the saline solution when entering the organism exhibits a temperature above normal blood heat. If utilized by hypodermoclysis it should possess a temperature of from 40° to 41° C. at the moment it enters; injected by infusion it may safely be introduced into the vein at a temperature of from 45° to 48° C.

*Administration of Morphin.*—When after the employment of chloroform, vasoconstriction and convulsive phenomena do not diminish, small doses of morphin, although not exhibiting specific antidotal properties, may be resorted to. In uremia of acute nephritic states, more particularly, it may tend to bridge over a critical period, although it has never been proved to my satisfaction that the attacks would not have abated in case morphin had not been administered. Its eventual efficacy in controlling uremic convulsions may be due to its retarding the metabolic processes, thereby preventing further accumulation in the blood of katabolic substances, and to its augmentation of vascular tonicity. Convulsive manifestations arising on the basis of chronic parenchymatous nephritis also frequently decline in intensity or cease altogether after the injection of morphin; however, if we remember that about 75% of such cases (whether morphin was administered or not) recover from the first attack, we are forced to conclude that the influence of morphin cannot be a very potent one.

Uremia of chronic interstitial nephritis, characterized in almost every instance by a condition of tranquil coma, very rarely exhibits convulsive phenomena. In the absence of such manifestations there is no occasion at all to employ morphin, and the existence of a comatose state *a priori* precludes its administration.

While, therefore, morphin in small doses is innocuous in uremia of acute renal disease and chronic parenchymatous nephritis, and may possibly be a factor in effecting subsidence of convulsive symptoms, it is not indicated in uremia of chronic interstitial nephritis which presents an entirely different clinical picture, but being comagenous itself, may aggravate the existing comatose condition and hasten a fatal issue.

#### A CLINICAL AND STATISTICAL REVIEW OF 122 CASES OF ALBUMINURIA AND 48 CASES OF ECLAMPSIA OCCURRING IN THE MATERNITY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

BY

JOHN COOKE HIRST, M.D.,  
of Philadelphia.

Assistant Obstetrician, University Hospital.

There have been 122 cases of albuminuria and 48 cases of eclampsia in the University Maternity during the past 13 years. Our records show that 122 women developed albuminuria in the hospital while awaiting delivery. This was discovered by the usual tests for albumin—the test by boiling with acetic acid, and Esbach's albuminometer. Each woman in the Maternity has her urine examined once a week before delivery. Albuminuria is the most reliable indication of kidney insufficiency. The quantitative examination of urea is interesting, but not valuable as an indication of adequate renal action in pregnant women. A great deal has been written upon the importance of estimating the quantity of urea, and positive statements have been made that if the amount falls below 1% the woman is in danger, while the presence of albumin is of secondary importance. This statement is fallacious. To illustrate, recently the urine of eight women awaiting confinement in the University Maternity was examined on the same day and the quantity of urea estimated. The percentage of urea varied from .3 of 1% to 2.8%, and the total quantity excreted from 2.5 to 36 grams a day (the normal being 20 to 24 grams daily). With one exception these women were in perfect health, without a sign of toxemia. The one exception was a woman whose urea percentage was 2.2%, total quantity 30.97 grams in 24 hours, a quantity much above the normal. She had albumin in considerable quantities, and all the premonitory signs of an eclamptic attack—failing vision, spots in front of her eyes, nausea, intense and persistent

headache, etc.—and eclampsia was averted only by energetic treatment. In another series of 32 specimens of urine of women in the last month of pregnancy the percentage of urea varied from .1 of 1% to 3%, the total quantity in 24 hours being from 1.7 to 38 grams. All of these specimens were free from albumin, and the women had no symptoms of toxemia. A patient in private practice had, for the last two months of her pregnancy, never more than .3 of 1%, and usually .1 of 1% of urea, with a total quantity of urine of about 70 ounces a day. According to the advocates of the importance of urea, she was in a dangerous condition. She never had a single bad symptom, and when, merely as a precaution she was placed upon antitoxemic treatment, she became ill, but recovered promptly as soon as all treatment was stopped. She has since been safely delivered. Her urine contained no albumin. Two other patients in private practice excreted .1 of 1% and  $\frac{1}{2}$  of 1% urea respectively, far below the normal, and both were safely delivered without any symptoms of toxemia. Another patient was excreting 45 grams of urea a day, nearly 3%, and yet had a steadily increasing quantity of albumin with marked signs of toxemia, and finally labor was induced to avert eclampsia. Within the last few days a patient was admitted to the Maternity in violent eclampsia, with urine solid with albumin on boiling, but containing 1% of urea. She died six hours later. Very rarely albumin fails us as an indication of renal insufficiency, and our attention is first drawn to the woman's condition by the appearance of symptoms of toxemia. When such a patient is put on antitoxemic treatment, her symptoms steadily improve, while the percentage of urea often steadily diminishes in consequence of the milk diet. In view of these facts, which any one can observe in his own practice, it is inconceivable how men of clinical experience and average powers of observation can attach undue importance to the elimination of urea as an indication of toxemia.

When albumin is discovered in the urine of a patient awaiting delivery she is put to bed, her diet is restricted to milk, with addition of large draughts of water. Basham's mixture, in doses of 3ij four times a day, is prescribed, and her bowels are kept loose by means of Rochelle salts, Carlsbad water with Sprudel salts, or some other suitable cathartic. The total quantity of urine for each 24 hours is measured and daily examinations are made for specific gravity, albumin by Esbach's, urea by Doremus' apparatus, and casts and blood cells by the microscope. The majority of cases clear up entirely under this treatment without further complications. The albumin occasionally persists or increases in spite of treatment. In such a case the woman is actively purged by magnesium sulfate in concentrated solution, a dessertspoonful being given every 15 minutes until free catharsis is established. She is also given hot-air baths or hot packs every four hours, being kept in them for 30 minutes, with an ice-cup on her head, until she sweats profusely. In private practice the hot pack is almost always used, on account of the somewhat cumbersome apparatus needed for the proper administration of a hot-air bath. This hot pack can be made much more efficient by the following simple expedient: Eight bricks are heated on the kitchen stove till the hand cannot be borne on them. Each brick is wrapped in a crash bath towel. The bricks are then placed around the patient, and on each towel from four to five ounces of alcohol is poured. The patient is covered by a number of dry blankets. The alcohol is vaporized by the heat, and the woman usually sweats profusely. In hospital practice we usually administer salt solution by hypodermoclysis every four hours, alternating with the hot-air baths, a pint of the solution being introduced under each breast. The routine administration of salt solution in private practice is, as a rule, not practicable. This more energetic treatment must always be expected

to bring on labor, and in the vast majority of cases it will do so. If the symptoms do not show decided improvement inside of 48 hours and labor has not come on spontaneously, induction of labor is indicated, the best method being either the Champétier de Ribes bags, or Krause's method of flexible bougies. Under this treatment of our 122 cases of albuminuria, in which the amount of albumin varied from a trace to one-half by bulk on boiling, only eight, or 6.5%, developed eclampsia, a fact which speaks well for the efficacy of the treatment.

There were 48 cases of eclampsia, of these 15 patients died, or 31.2%; 8 developed in the hospital and 40 were brought to us in the ambulance.

This mortality does not fairly represent the success of treatment. Many of these patients came to us in a desperate condition, some of them moribund. They had had convulsions for 24 to 36 hours, and the deaths occurred within a few hours after their admission.

Excluding, therefore, the 10 patients who died in less than 12 hours after their admission, in whom any plan of treatment would have been unavailing, there is a mortality of 5 cases in 38, or 13.1%.

The number of children born was 50, there being two sets of twins. Seven children were born prematurely between the fifth and eighth months, and all died. Of the 43 children born at term, 17 were stillborn or died a few hours after birth, a mortality of 39.5%. One woman in this list had 5 attacks of eclampsia in 5 successive pregnancies, in all of which she was delivered prematurely. The number of convulsions in the mothers varied from 1 to 36. Of the patients who recovered, 3 had 19, 23 and 20 convulsions respectively. Winkel, of Munich, states that in his experience when a woman has more than 18 convulsions her case may be regarded as hopeless.

The amount of urine secreted during the attack was uniformly very small. Two of the women had complete anuria for 24 and 60 hours respectively, another is recorded as having passed 6 drams in 4 days, the largest amount noted was 6 ounces in the 24 hours. Albumin was invariably present both before and during the attacks. This is a most important clinical fact. The loose statement has been repeatedly made in textbooks and articles on the subject that quite a large proportion of eclamptic cases, some 16%, show no albumin before the onset of convulsions, though it is always present after the attack begins. This is one of the chief arguments of the men who attach such importance to the quantitative estimation of urea, and would have some weight were it true. It is not borne out by clinical evidence. I have knowledge of one such case of eclampsia which showed no albumin before the occurrence of the convulsions, and her urea percentage was almost 2%. In all cases in this report albumin was present in measurable quantity before the occurrence of convulsions. One woman was passing, the day before her convulsions appeared, 41 ounces of urine which contained a measurable trace of albumin, with a nearly normal percentage of urea; after the first convulsion her urine turned solid on boiling. The presence of albumin in the urine is therefore far the most reliable indication of renal insufficiency we possess; the excretion of urea is so variable as to furnish practically no guide to the patient's condition. The amount of albumin present after the convulsions began is recorded as from 10% by bulk to solid on boiling, the majority of the specimens turning solid.

When the kidneys begin to resume their functions the amount of urine excreted is sometimes very great. One of these patients within three days from the beginning of her treatment was passing 156 ounces a day. Seven of the women had albumin persisting after recovery, due to nephritis, while the remaining 26 were discharged with their urine entirely free from albumin.

Coma lasted from two hours to over three days in 17 women. The curious loss of memory we see in patients

with eclampsia who are to all appearances rational, and yet who remember nothing that occurred for some time preceding their first convulsion to some time after the last one, was present in all.

Two of the women had hyperpyrexia running above 110°, and both died.

Three patients were blind on admission. One of them stated that she could not tell when the gas was lighted in her room. All three recovered.

Three women became maniacal. One of these remained permanently insane and was removed to the Philadelphia Hospital, where she still remains. The other two became rational in four and eight days respectively; one of these relapsed for a few days some two weeks later, but ultimately recovered.

The time at which convulsions appeared is interesting:

		Per- cent.	Died.	Percent mortality.
Before labor (none afterward).....	27	56.25	5	19.2
During labor (none afterward).....	1	2.1	.....	.....
After labor (none before).....	11	22.9	7	63.6
Before labor and persisting afterward...	9	18.75	3	33.3
Totals.....	48	100.00	15	

The treatment adopted for eclampsia is as follows: The convulsions are controlled by chloroform, and during the convulsion it is usually necessary to use some form of mouth-gag to keep the patient from biting her tongue. Most of the women in this series sent to the hospital from outside came in with their tongues dreadfully bitten. In the hospital we use the regular form of mouth-gag; in private practice a toothbrush handle wrapped in a handkerchief answers every purpose. The woman is purged by the administration of Epsom salts in concentrated solution ʒij every 15 minutes until a free evacuation occurs. If she cannot swallow, croton-oil, two drops in a little sweet oil, on the back of the tongue, is substituted. If the pulse is very full and bounding, veratrum viride, m xv, is given hypodermically, and repeated in doses of 5 minims every two hours till the pulse softens. Very rarely venesection may be necessary. The patient is given a hot pack or hot-air bath in the manner already described, for 30 minutes every four hours. Hypodermoclysis of Oj of salt solution under each breast is given every four hours, alternating with the hot packs. If the patient is seen far advanced in labor, with the os dilated and the head well down, there is no question of the propriety of terminating the labor with forceps. Little or no anesthesia is required; if an anesthetic is necessary, chloroform should be selected. The question of the forcible termination of labor by rapid dilation of the cervix and version is one which is still undecided.

It will be seen from the foregoing table that over half the patients had convulsions before labor, ceasing directly after delivery. This is a strong argument in favor of the prompt evacuation of the uterus of an eclamptic woman, provided it can be done without too great violence. The force necessary in accouchement forcé has been the great objection heretofore to such a plan, a large proportion of patients dying of shock in consequence of their rapid and violent delivery. In this series of cases four were delivered by rapid dilation and version, three of them dying from shock shortly afterward. Recently we have used Bossi's dilators with extraction of the child by forceps in four cases, with two deaths. In both of these fatal cases the patients were moribund when admitted, one dying less than an hour after admission and the other within six hours. The two women who recovered were easily and quickly delivered, without showing any evidence of shock. The time required to secure a full dilation of the cervix to 11 cm., there being no dilation of the canal at all when the operation was begun, was about 8

minutes. The whole delivery occupies only some 10 or 12 minutes, and is very easily accomplished. If we now possess in these dilators a method of delivering a woman easily and quickly, without severe shock, the procedure is certainly reasonable, and the patient is undoubtedly better off when her uterus is emptied. Care must be taken not to dilate the cervix too rapidly, as the instrument is very powerful and may injure the cervix severely. This method of delivery seems by far the best, if the cervix is undilated, and merits a more extended trial.

Four women were delivered by forceps, the os being dilated and the head well down when they were admitted. All recovered. Labor was induced in eight cases after treatment to secure elimination had been carried out for periods varying from 24 hours to 4 days. One of these women died. One patient was delivered by craniotomy on account of a contracted pelvis. She recovered.

After delivery the convulsions cease in over half the cases. The treatment outlined above should be carried out energetically until the woman is passing large quantities of urine, which she usually begins to do within 48 hours. The severity of the treatment is then gradually relaxed until it is discontinued entirely. Eleven of the patients developed convulsions for the first time after labor, the first convulsion occurring from one-half hour to four days after delivery. Seven of these women, or 63.6%, died. These statistics, agreeing with others lately published, show that postpartum eclampsia is more dangerous than the older statistics would lead us to suppose.

In the majority of cases the women are discharged from the hospital three to four weeks after delivery, with their urine entirely free from albumin, or at the most showing merely a trace. When the albumin persists in measurable quantities, the condition is probably due to actual nephritis, which, as a rule, antedates pregnancy. Casts and a persistent low specific gravity may also be found.

## SYPHILITIC TOXEMIC HEMIPLEGIA.<sup>1</sup>

BY

CHARLES W. BURR, M.D.,  
of Philadelphia.

Professor of Mental Diseases, University of Pennsylvania; Neurologist to the Philadelphia Hospital.

The patient whom I shall study with you is now in good health, but her case, one of transient hemiplegia, is unusual, and presents points of interest that will well bear investigation. We will examine it solely from the point of view of differential diagnosis:

The history is as follows: She is a married woman of 25, and has been an excessive drinker, but denies venereal infection. For several weeks before her admission to the hospital, on February 25, 1903, she had been drinking heavily, but stopped five or six days before her admission. Some time during the debauch a man struck her violently upon the head. The day before her admission she complained of severe headache, and the negro at whose house she was, noticed that this was something other than mere drunkenness, and tried to induce her to take some medicine. The negro could give us no clear account of her symptoms, saying only "she was out of her head and queer." On the day of her admission she suddenly became unconscious and convulsed. When brought to the hospital she was in profound coma, and there were constant clonic twitchings of the arms and legs. Palsy could not be discovered. Examination of the urine showed a distinct line of albumin, but no casts. Her head was shaved and the scalp examined, but no evidence of a fracture was found. There was no discharge from the ears. The skin was free from any syphilitic scars. I saw her for the first time the next day. She was still completely unconscious. Respiration was stertorous and the lips were covered with bloody foam, but there were no convulsive movements. The left pupil was widely dilated and did not respond to light, but the right was normal in size and shape and reacted well.

<sup>1</sup> From a clinical lecture delivered at the Philadelphia Hospital, March 14, 1903.

There was no palsy of the face or extremities. The bladder was incontinent. This I am sure was due to her mental condition, not to palsy. The knee-jerks were present, equal, but not active. Examination of the heart and lungs was negative. Two days after the onset of unconsciousness but not earlier the left arm and leg were distinctly more relaxed, fell more heavily when lifted, than the right. The face was unparalyzed. The left knee-jerk now appeared to be greater than the right but the apparent difference was so slight that I am not sure about it. The plantar jerk on the left side was capricious. Often on stroking the sole there followed a slow extension of the great toe or of several toes but sometimes there was flexion. There was never any reflex movement of the foot or leg. The plantar jerk on the right side was normal. Neither albumin nor casts were present in the urine. On the following day Dr. Charles A. Oliver kindly examined her eyes and reported: "Right pupil 2½ mm. in diameter, left 4. The irides fail to respond to light stimuli, though sluggishly to accommodation and convergence. Eye ground normal. High hypermetropia, more marked in left eye." She was now partially conscious. There was no change in the palsy. She was put upon mercurial inunctions. On the next day consciousness had so far returned that she understood and obeyed simple commands such as to put out the tongue, lift the right hand, and turn the head. She could flex and extend the fingers of the left hand slightly, but had no other movement of the left arm. She could also move the toes of the left foot a little and weakly, and slightly flex and extend the knee. The left lower face was slightly palsied. She could talk, but only in a whisper and only a few words at a time. The speech trouble was not aphasic nor paralytic, but due to weakness and hebetude. There was distinct ptosis of the left eyelid, which had come on within 24 hours. The knee-jerk was distinctly more marked upon the left side. Ankle-clonus was absent and the Achilles jerk was equal on the two sides. Stroking the left sole always caused extension of the great toe with or without similar movement of the other toes. The right plantar jerk continued normal. The left arm and leg were a trifle rigid. The bladder remained incontinent. Sensibility to touch was normal on the palsied side and of course upon the other also. By March 4 she was very much better. She could use the left arm well and move the leg quite strongly, but she could not yet walk. There was still some but only slight ptosis. At rest the pupils were equal and the left responded sluggishly to light, the right promptly. Mentally, she was much clearer, but was still somewhat confused. She could not remember for more than a few minutes that she was in a hospital, could answer a short but not a long question, could give only a disjointed account of the mode of onset of her illness, but on the other hand she knew her nurse, recognized the doctor, and would ask for food and water. She still wet the bed. On March 6 ptosis had disappeared, the knee-jerks were normal, muscular rigidity had passed away, there was no longer a Babinski reflex, and no palsy of the face, arm, or leg. She was still somewhat confused. On March 11 she walked, talked, and thought well. There was neither palsy, ataxia, nor anesthesia of the extremities, and the reflexes were all normal. Pupillary symptoms alone remained. The left pupil, under conditions of equal illumination of both eyes and with accommodation guarded against, was sometimes a little larger than, sometimes equal in size to, the right. Both responded to light and with accommodation. On covering the right pupil the left dilated, but on covering the left the right remained immobile. On looking to the extreme right there was a slight, irregular, lateral oscillation of the eyeballs—an inability to fix the eyes firmly on an object far to the right. This was not a true nystagmus. There was a moderate contraction of the fields of vision without reversal. (She was kept in the hospital until March 24, and during that time there was no recurrence of any symptom.)

We may sum up the case briefly thus: A young woman while recovering from a debauch is seized with headache, becomes queer and dazed, and on the next day falls unconscious and convulsed, the convulsive movements lasting many hours, the unconsciousness several days. While unconscious a slowly oncoming hemiplegia, preceded by dilation of the left pupil, develops; later there are changes in the reflexes, and left-sided ptosis, and consciousness slowly returns; still later the hemiplegia rapidly and completely passes away, the ptosis disappears, and finally, two weeks after the onset, she is, barring slight pupillary disturbances, well.

The interesting question is, What caused the symptoms? The thing first thought of after her admission was fracture of the skull. This was easily excluded and dismissed. The disease that you probably most thought of as I read the history was hysteria. We all think of it first when we see a young woman who without very patent cause presents any nervous symptoms. We often diagnose it on insufficient grounds and through carelessness or mental laziness, and though the word is frequent on the tongues of men the thing is rare, much

rarer than the organic diseases mistaken for it. In this case its exclusion is not difficult. The unconsciousness was not hysteric but was identical in character with that seen only as the result of organic brain disease or some cerebral toxemia. The intensity of the coma, the character of the respiration, the slowness with which consciousness returned, the epileptoid nature of the convulsive movements, entirely unlike that seen in an hysteric fit, all point strongly against hysteria. The kind of hemiplegia present and its mode of onset also indicate some other cause. Remember, it began during coma, not with the onset of unconsciousness, and that it came on slowly, requiring a couple of days before it reached its acme, and then after consciousness had been established slowly passed off. Hysteric hemiplegia does not come on during the fit, but after it, and it is usually accompanied by anesthesia. The pupillary symptoms and the unilateral ptosis do not support the diagnosis of hysteria. The presence of the Babinski jerk is interesting. I do not believe it ever occurs in hysteria, but I am also quite sure that its presence does not prove organic disease of the lateral tract, nor even gross, that is macroscopically visible disease of the brain. I am sure it occurs as a consequence of cerebral cellular poisoning. It has been noticed in the so-called uremic hemiplegia. For these reasons we may dismiss hysteria. Did our patient have some gross organic brain disease? I think not for the following reasons. We may exclude hemorrhage at once because of the age of the patient, the softness of the palpable arteries, and the rapidity and completeness of recovery. Surely there was not a tumor of the brain, for one does not recover so quickly from that even if the growth be a recent, soft, and easily absorbable gumma. Syphilitic endarteritis would explain the symptoms perfectly but not their extremely rapid disappearance. Finally have we to do really with a toxemia? I mean were the symptoms caused by the local and direct action of some poison upon the brain cells producing perversion and abolition of function and causing lesions either invisible or visible only on microscopic examination. There are such intoxications. The one best known is that which occurs in uremia. In it, as is well known, there may be mimicry of cerebral hemorrhage, thrombosis, or even tumor, and at necropsy nothing be found save microscopic changes in the structure of the cerebral nerve cells. Indeed even these are not always present in definite shape. There may be local or general epileptiform convulsions, hemiplegia, aphasia, even an optic neuritis indistinguishable from that seen in tumor. There may be the general symptoms of tumor, headache, vertigo, vomiting. Death may follow or the symptoms may quickly pass off. Frequently, and this is of diagnostic value in distinguishing the condition from hemorrhage, the palsy varies from hour to hour, is now worse, now better. In our case Bright's disease is out of the question. She had, it is true, a transitory albuminuria during the coma, but this is frequent in states of unconsciousness due to cerebral disease from any cause and she presented neither signs nor symptoms of any form of nephritis. Some authorities hold that there is an alcoholic toxemic hemiplegia. I am not willing to deny this dogmatically, but confess I am very skeptical about it. Chronic alcoholism is so very frequently associated with arterial sclerosis and nephritis that I am inclined to believe that the palsies and convulsions are due to them and not to alcoholic toxemia. I know of no case reported presenting the symptoms and the march of symptoms shown by our case, hemiplegia coming on during coma and associated with pupillary symptoms and ptosis, caused by alcohol. Hemorrhage is of course frequent in old alcoholics.

Lead poisoning may cause cerebral symptoms, including hemiplegia, either by the direct action of the lead on the cerebral nerve cells, or of some poison arising in the body because of the metabolic disturbances produced by the lead. Only recently a man, a worker in white lead, was brought to the hospital with the symptoms of an

apoplectic stroke. A few days later he died, and the autopsy showed no gross lesion. In his case there was probably no direct poisoning of the cerebral cells by lead itself, because Dr. Edsal was not able to detect even a trace by chemical examination. Lead poisoning had no part in the illness of the woman before us. We come finally to what I believe to have been the real cause, namely, syphilitic intoxication: the direct action of the virus upon the nerve cells without the production of any lesion sufficiently gross to be visible to the naked eye. It has been known for many years that transient palsies are characteristic of syphilis. It also is of course well known that the characteristic gross lesion of syphilis is endarteritis and inflammation of the neuroglia. It hence was assumed by some that syphilis has no direct influence upon the nerve elements proper, and that disturbance of their functions is caused by mechanical pressure only. The transitory symptoms were explained by the assumption of local vascular spasm. The possibility of local vascular spasm can not be disproved, but its occurrence in a diseased cerebral artery is doubtful. In late years quite a number of cases have come to necropsy which have shown no gross lesion at all, and nothing microscopically except cellular changes more or less definite. We are therefore justified in saying that in syphilis, as in uremia, there may be a true cerebral intoxication. In our case, diagnosis can only be made by exclusion. I am quite sure there was no organic disease in the common meaning of the word—a lesion visible to the naked eye. Recovery was too rapid. On the other hand, the only direct evidence we have of the patient being syphilitic is that she has borne daily inunctions of mercury well, and has grown fat under them, and that the symptoms themselves were characteristic of syphilis.

### AN INTERESTING COMPLICATION IN THE DIAGNOSIS OF GALLSTONE.

BY

GUY L. HUNNER, M.D.,  
of Baltimore, Md.

Associate in Gynecology, Johns Hopkins University, Baltimore, Md.

Every diagnostician knows the difficulties sometimes encountered in differentiating gallstone colic. Gastralgia, pseudobiliary colic in nervous women, stone in the right kidney, movable kidney with kink of the ureter and consequent distention of the kidney pelvis, and appendicitis are the conditions most frequently confounded with gallstone symptoms. Together with these more common conditions one must bear in mind carcinoma in the epigastric region, diseases of the pancreas, and adhesions between the gallbladder and adjacent organs.

It has recently been my privilege to observe in two patients a condition which I have not before seen mentioned as a possible complication in the diagnosis of gallstones. These have been cases of omental adhesions to old operation wounds situated at some distance from the gallbladder. In one case the diagnosis of gallstones was only tentative, while in the other a positive diagnosis was made. Every surgeon is familiar with various local symptoms due to adhesions; *e. g.*, symptoms of gallstones due to adhesions following a previous cholecystitis or a gallstone operation, gastric symptoms due to adhesions of the stomach, and symptoms of chronic appendicitis following removal of the vermiform appendix. Secondary operations are performed in each of these regions, resulting only in the finding of adhesions and in the entire disappearance of the symptoms after breaking up the adhesions.

Dr. Keen,<sup>1</sup> in his Cartwright lectures, devotes a section to the subject of gastrololysis, or the operation of

loosening the stomach from adhesions, and speaks of the excellent results in relieving symptoms by this operation.

I have seen three cases with well-marked local symptoms due to adhesions of the sigmoid. In each of these cases there were reflex gastric symptoms as well as marked local pain and discomfort. Gastric symptoms are not uncommon in cases of ventral hernia, and formerly the diagnosis was often made of the presence of the stomach in a hernia, when subsequent operation would show the fallacy of such conclusion. Small ventral hernias with omental contents are often accompanied by gastric symptoms, and one of the great difficulties in distinguishing such a hernia from preperitoneal lipoma is the fact that the latter is likewise a frequent cause of gastric symptoms. It is the preperitoneal lipomas which give us a clue to the actual source of the gastric pains. Developing as they do from the subperitoneal fatty tissue, their escape through the vessel openings of the linea alba is followed by a tugging on the peritoneum and resultant reflex gastric pains.

Our observations during abdominal operations under cocain anesthesia, and particularly the accurate results so faithfully recorded by Lennander,<sup>1</sup> all point to the same conclusion, that the pain associated with omental adhesions, like that caused by a preperitoneal lipoma, is a reflex due to disturbance of the parietal peritoneum.

The two following cases are of interest because of the striking manner in which the true diagnosis in the second case was suggested only during the operation, and this as a result of observations made while operating on the first patient. They are reported with the belief that the reader, by bearing them in mind, may some day be saved a disagreeable error in diagnosis, and that the patient may be spared an unnecessary incision or possibly a failure in having his malady discovered during an exploratory operation.

The presence of a scar showing a former abdominal operation should place the surgeon on his guard when making a diagnosis of any obscure abdominal condition, no matter how distant the scar from the site of the annoying symptoms.

CASE I.—Mrs. C., aged 36, entered the Johns Hopkins Hospital June 14, 1901, complaining of headaches, constant pain in the left lower abdomen and much nausea at times. She was married fifteen years ago, and is the mother of two healthy children, aged respectively 13 and 2 years. Both labors were difficult, the first one being a forceps delivery. The perineum was repaired a few years after the first childbirth and again one year after the second child was born.

Since eighteen years of age she has had some dysmenorrhea. She has been troubled with headaches since about the time of her marriage. She dates her present illness, however, from the time of her second pregnancy. About two months before the birth of her second child she was forced to go to bed because of severe pains in the lower left abdomen. On getting up about one month after labor these symptoms grew worse, and she began to suffer with headache, nausea and extreme nervousness, and has been on the verge of invalidism ever since. At the time of admission to the hospital the complaints were as follow: The pain in the left side is of a peculiar drawing character and is exaggerated by exercise. Stooping or sudden turning often causes increase of the pain and intense nausea. The abdomen is frequently distended with gas, and when in this condition the symptoms in the left inguinal region are increased with each deep inspiration. The appetite is usually good. Her digestion is good except for the bloating, which does not seem to be influenced by her meals.

Examination.—The patient is a large well-nourished woman with florid complexion and mucous membranes of good color. The heart and lung examination is negative. The abdomen is full and rounded, the walls being rather thick, but everywhere lax and easily palpated. The liver seems normal in size and the kidneys are in good position. The location of the left inguinal pain seems to be between the anterior spine and the umbilicus, somewhat nearer the spine. Intestinal gurgling is felt here, but no mass can be palpated. Deep pressure over the usual course of the sigmoid causes nausea.

During a period of five days the patient was carefully watched, and she gave the impression of being in a state of nervous exhaustion, but at the same time retaining a splendid

<sup>1</sup> The Philadelphia Med. Jour., 1898, Vol. i, p. 829.

<sup>1</sup> Beobachtungen über die Sensibilität in der Bauchhöhle; Mitteilungen aus dem Grenzgebieten der Medizin und Chirurgie, 1902, Vol. vii, p. 88.

forced control over her nervous apparatus, and exhibiting none of the phenomena usually classed under the disease neurasthenia.

Although the vaginal outlet had been repaired, it was greatly relaxed, high up in the area of the levator ani muscle, and the uterus was in descensus. Deep pressure in the left ovarian region elicited signs of considerable tenderness, but the pelvic organs seemed normal.

It was decided to repair the vaginal outlet, and then because of her positive complaints, to do an exploratory celiotomy.

*Operation, June 19, 1901.*—Repair of the relaxed vaginal outlet; freeing of omental adhesions from the left inguinal ring; freeing of sigmoid adhesions; suspension of the uterus.

On opening the abdomen a strip of omentum two inches in width was found stretched across the sigmoid and attached to the left round ligament and to the pelvic wall about the internal inguinal ring. On releasing the omentum, the sigmoid colon was found attached to the venter of the left ilium by a broad area of fairly dense adhesions. These adhesions were freed by cutting with scissors, as they were too firm to peel up by sponge pressure. There was but little hemorrhage. The uterus was suspended high above the symphysis by one silk suture.

July 19, one month after operation, the following note was made: "The patient has been up in a wheel chair daily for the past ten days. During the menstrual period just ended, she suffered considerably with headache, but her general discomfort has been less than usual. Deep massage over the sigmoid is being given 10 minutes daily, and she is having a daily high bowel irrigation with hot water."

She was discharged six weeks after operation in a much improved condition, and she was gaining steadily. For two months after reaching home her progress was satisfactory, but she was then subjected to severe overexertion with family duties, and soon reverted to a condition similar to that before operation. Her family physician wrote me in March, 1902, nine months after operation: "She is never entirely free from pain, and before, during, and for one week after her monthly menses she suffers intensely with severe pains, usually beginning in the right pectoral region, and extending around to the spine, and thence up to the base of the brain. The latter pain is so severe that her head feels drawn back."

The patient returned to me and was admitted to the Church Home in July, 1902. She impressed me at first as suffering with symptoms similar to those complained of at her previous admission to the Johns Hopkins Hospital, but after careful study of her condition for a month a suspicion of gallstones was aroused. She had a great deal of nausea, and her chief pain seemed to be in the region of the gallbladder and upward through the right shoulder. She had distinct and persistent tenderness over the gallbladder and at the lower angle of the right shoulder-blade. After the more severe attacks of pain and nausea the stools were sifted for gallstones, but with negative results.

I called Dr. W. S. Thayer in consultation and he inclined to the diagnosis of intercostal neuralgia. With his advice the patient was given large doses of strychnin carried to the physiologic limit, but this failed to affect her pain.

The patient was kept on general tonics, cold packs, and massage throughout the summer and her condition improved.

But at each menstrual period she was completely prostrated by the general abdominal pain, which was most severe in the region of the sigmoid and the gallbladder. For a week she could take but little nourishment; all active treatment had to be stopped; she was kept in a darkened room and given occasional doses of morphia and other anodynes and hypnotics.

As she was 38 years old I decided to remove the pelvic organs, hoping that by bringing about the menopause she would no longer have these monthly setbacks. The abdominal incision would give opportunity to release the sigmoid adhesions again, which I felt were one source of her pains, and to examine the gallbladder.

On November 5, 1902, I operated and found that the former abdominal wound had slightly separated and was plugged by a very adherent omentum. The omentum was adherent over the sigmoid region as at the former operation, but the sigmoid itself was not so densely bound down as before. The gallbladder was normal and free from stone.

The omentum was released and its ragged edges were resected. The sigmoid was released and after the panhysterectomy two iodoform gauze drains were laid between the sigmoid and the pelvic wall and carried out through the vaginal vault. The gauze was gradually withdrawn from the fourth to the seventh days. Hot vaginal douches were begun on the eighth day. After the twelfth day the foot of the bed was given a daily elevation of about 18 inches in order to cause an upward pull on the lower edge of the omentum. To facilitate further the loosening of the omental adhesions shot bags, one weighing ten and one five pounds, were placed across the pelvic portion of the abdomen while the patient was in the elevated position.

The patient was allowed to leave her bed on the twentieth day but spent from two to four hours in bed each day in the elevated pelvic position. Her first postoperative menstrual epoch occurred about November 20, and for a few days she was very uncomfortable but she rejoiced because of the lessened time and severity of her symptoms. Her December epoch was still less marked. But in spite of her determination to grow well and strong I could see that she was gradually being more

harassed by pain after being up and about the hospital, and on December 26, while taking her tub bath she felt a sensation "as of something snapping" in the lower abdomen, and she had to be helped back to her room. For the succeeding week she suffered from occasional nausea and vomiting and a return of the pain in the gallbladder region and up under the shoulder-blades.

It was evident that the omentum had again become adherent and I decided that her only hope for relief would be in its complete resection.

Our former unhappy experiences demonstrated that it would be necessary after removal of the omentum to keep its stump in the upper abdominal cavity away from the field of operation trauma. It would be desirable therefore to keep the patient in the elevated pelvic position from the time of operation. Another desideratum would be the avoidance of intestinal distention so common after general anesthesia. For these two reasons I attempted the operation under local anesthesia.

I operated on January 7, 1903, using Schleich's solution for the local anesthesia, but on reaching the abdominal cavity the omentum was found so generally and so densely adherent that the patient could not bear the pain incident to its release. After thorough anesthesia with chloroform the omentum was released from dense adhesions to the former wound and to the parietal peritoneum of both inguinal regions. It was resected close to the transverse colon. A knuckle of the sigmoid was freed from the stump of the right ovarian vessels and the main portion of the sigmoid was again freed from the left pelvic wall.

The abdomen was filled with normal salt solution and closed with silver wire mattress sutures. The patient was kept in the elevated pelvic position from the time of the operation. She recovered with very little nausea and no apparent distention.

The patient seemed to have an idiosyncrasy for the formation of adhesions and for a hypersensitiveness of the peritoneum. After 48 hours the bed had to be lowered because of extreme pain in each hypochondriac region, or, in other words, at about the points one would expect the omental stumps of each colonic flexure to lie when the bed was elevated at the foot. Lowering the bed each night seemed to relieve the pain. Turning to either side increased the pain in the opposite hypochondrium. The pain in these regions gradually lessened until the patient regained her feet, when for a few days it was increased if the erect posture was taken. One month after the last operation these pains are gradually growing milder, but a rather severe pain still persists in the region of the right ovarian vessels and down the anterior part of the right thigh. The discomfort of the sigmoid region is greatly decreased, the appetite is better, the patient sleeps without anodynes.

*CASE II.*—Dr. L., aged 27, entered Dr. Kelly's private sanatorium November 24, 1902, suffering, as he supposed, with gallstones.

On June 8, 1900, he had been operated upon in Philadelphia for catarrhal appendicitis. On about the sixth day his wound broke down, and after the insertion of gauze drainage it healed by granulation. He was catheterized after the appendix operation, and soon became the victim of cystitis and ascending pyelitis.

On July 5, 1900, Dr. Kelly performed left nephrotomy, draining a large abscess of the kidney. The drainage sinus healed kindly, and under treatment with benzoic acid and urotropin the urine became clear, and the patient again enjoyed good health.

The present illness began in May, six months before his second admission to the sanatorium. He was seized with attacks of pain in the hepatic region, and these attacks before the end of a month became very severe. They lasted 15 to 20 minutes, and were accompanied by a rise of temperature of from 2° to 4°, profuse sweating, nausea and at times severe vomiting. He often vomited bile, particularly during early morning attacks.

The pain was most commonly located in the gallbladder region, but it often radiated up under the scapula, and over the deltoid region. At one period he was taking salicylates for supposed rheumatism in the right shoulder. The attacks of pain were generally intermittent, a week elapsing at times between two attacks.

There was marked local tenderness in the hepatic region, the patient being unable during an attack to wear a stiff-bosomed shirt or a vest. Frequently icterus was noticeable and the stools were light-colored, although never of the typical clayey variety. The stools were never sifted for stones and the urine was not examined for the presence of bile.

In view of these symptoms it was not strange that the patient had made his own diagnosis of gallstones and that Dr. Kelly concurred.

*Operation, Dr. Kelly.*—Exploratory incision over the gallbladder. Loosening of omental adhesions from a ventral hernia in the region of the former appendix incision. Resection of a portion of the omentum. Radical cure of the ventral hernia.

On opening the abdomen a careful examination of the gallbladder and its ducts revealed a normal condition. Dr. Kelly then carefully palpated the right kidney for stone, and began different displacement tests to ascertain whether the kidney could have been interfering with the bile passages, or whether

there was mobility enough to cause kink of the ureter and renal symptoms.

During these manipulations, the presence of the old appendix scar reminded me of the conditions found in my patient a few weeks previously; and on examination, Dr. Kelly found the omentum densely adherent to the abdominal wall about the site of the former operation wound. On freeing the omentum it was found to be partially contained in a small postoperative hernia, the sac of which it completely filled. On withdrawal of the omental contents, the index finger could be inserted to its first joint in the small hernia. The radical operation was done for the hernia. About half the omentum was resected, and the abdominal wound was closed in layers with catgut sutures.

The patient had an uneventful recovery. There was considerable nausea and some distention until the bowels were moved on the fourth day. On the fifth day the foot of the bed was elevated about 12 inches, and this elevation was soon increased to about 18 inches, where it was kept daily throughout the convalescence.

There was some complaint of pain about the two operation wounds during the first week, particularly if the patient attempted to lie on his left side. The patient wrote one month after leaving the sanatorium that he was feeling perfectly well and doing a good deal of work, and wished to know whether he could take up gymnastic training.

#### PERITONITIS IN TYPHOID FEVER WITHOUT PERFORATION, WITH A REPORT OF ONE CASE CAUSED BY THE BACILLUS TYPHOSUS, AND ANOTHER SIMULATING ACUTE APPENDICITIS.\*

BY

J. L. YATES, M.D.,  
of Philadelphia.

Assistant Demonstrator of Pathology, University of Pennsylvania.

Peritonitis in typhoid fever has been so extensively discussed of late that the diagnosis and treatment of the conditions attendant upon perforation admit of but slight additions, and these will probably be more in the nature of the operative procedures. Depending upon the character of the infection, that is, the organisms present in the peritoneal exudate, there might well be attempted the establishment of an increased local, and possibly general resistance, or even the production of some degree of passive immunization by the local introduction of benign nonspecific solutions or of antitoxins.

Durham's<sup>1</sup> experiments along these lines are most suggestive. By the previous introduction of 1 cc. of a 1% sodium chlorid solution into the peritoneal cavity he was able to protect his animals against what had already been established as a minimal fatal dose of the typhoid bacillus, and with a typhoid antitoxin this protection was three times as efficient. Nor is the action of the antitoxin purely specific, as it increases the resistance to other varieties of bacteria as well, if to a less degree.

Peritonitis without perforation is a sufficiently frequent complication to warrant its consideration. In the records of 4,300 cases reported or quoted by Horton-Smith,<sup>2</sup> Hölischer,<sup>3</sup> and Liebermeister,<sup>4</sup> it was found 73 times (1.7%), which is approximately one-third as frequent as the perforative form.

The etiology is evident in most instances—namely, a direct extension from or rupture of an intra or extra-abdominal focus of infection which may be suppurative. It frequently happens that no explanation can be found for the origin of the peritonitis. Fitz<sup>5</sup> gives the following specific causes: Acute intestinal obstruction, rupture of a softened infarction of the spleen, or of the spleen itself, of a softened mesenteric gland, abscess in the wall of the urinary bladder, ovarian and tubal abscesses, abscess in the liver or in the sheath of the rectus muscle, perforation of the gallbladder or as the result of an endometritis due to a concomitant parturition. To these

may be added: By propagation from mucosa to serosa\* (Murchison<sup>6</sup>), infarction of the spleen (Liebermeister<sup>4</sup> and Fraenkel<sup>8</sup>), abscess of the spleen (Curschmann<sup>9</sup>), and thrombosis of the intestinal vessels (Thatcher<sup>10</sup>).

In the instances of indeterminate origin, as for example those referred to by Murchison<sup>6</sup> where the peritonitis developed "before ulceration had commenced and even during the first week of the fever," the bacteria must have reached the peritoneal cavity either by penetrating the intestinal wall or through the general circulation. As Curschmann has pointed out, peritonitis is seldom independent of the specific lesions in the solitary follicles of Peyer's patches. No record is to be found of a peritonitis occurring in those rare instances of typhoid without intestinal lesions. It is most improbable that bacteria ever penetrate a perfectly normal intestinal wall and reach the peritoneum. However, the variations from the normal that make the wall penetrable may be at times comparatively slight (Tavel and Lanz,<sup>11</sup> Arndt,<sup>12</sup> Bönneken<sup>13</sup>).

Nothnagel<sup>14</sup> is of the opinion that individual variation plays an important part in the conditions that do permit of this migration of bacteria through the intestinal wall. His conviction came from the great irregularity of the conditions in which it has been observed. Variations in the intestinal circulation, especially with an associated edema, seem particularly apt to predispose to this migration. That the mere presence of bacteria within the peritoneal cavity is commonly insufficient to produce a peritonitis, though a source at times of fatal infection, is too well known from the experiments of Grawitz,<sup>15</sup> Waterhouse,<sup>16</sup> Orth,<sup>17</sup> and Halsted<sup>18</sup> to need any reference. However, the positive results of Burginski<sup>19</sup> and Palowski<sup>20</sup> in obtaining a peritonitis by the simple inoculation of virulent bacteria might justify the assumption that such an origin is a clinical possibility however uncommon it may appear to be.

The careful experiments of Dmochowski and Janowski<sup>21</sup> upon the pyogenic property of the typhoid bacillus show that simple inoculation of the peritoneum does not cause inflammation unless there is produced a simultaneous irritation of the serosa. Even then it is inconstant; results that agree well with the classical experiments with the more common pyogenic microorganisms. From their experimental evidence these authors could not conclude, however, that in man the origin of a peritonitis by the escape of bacteria from the intestine *per contiguum* is impossible. Hölischer attributed the peritonitis without perforation in the Munich cases to a "deep-seated ulceration reaching to the serosa." In such instances there is probably a localized inflammation of the serosa at the base of the ulcers which would be sufficient in the presence of bacteria to give rise to a spreading peritonitis. When there is slight ulceration, or none at all, this etiological factor is hardly conceivable. Decreased power of peritoneal absorption, however, may be an important causative agency in such cases. There is abundant clinical and experimental evidence that this factor predisposes to peritonitis in other conditions than typhoid, and Dmochowski and Panowski have shown that virulent typhoid bacilli may thus give rise to a generalized inflammation of the peritoneum experimentally. They were unable to produce a peritonitis by irritating the peritoneum and then injecting the typhoid bacilli subcutaneously, somewhat after the plan of similar, but successful, experiments of Waterhouse and Orth with *Staphylococcus aureus*. But one positive observation of this nature is reported. Gilbert and Girode,<sup>22</sup> in one of many experiments to determine the pyogenic action of the typhoid bacillus, caused a fatal purulent peritonitis in a guineapig 24 hours after the inoculation of 1 cc. of a bouillon culture of the organism subcutaneously in the back. They recovered the bacillus

\* From the Pathological Laboratory of the University of Pennsylvania.

\* Deulafoy<sup>7</sup> objects to the expression peritonitis by propagation, as the histological evidence does not support the definition, and he favors the denomination "peritonitis by migration."

in pure culture from the peritoneal exudate. No local predisposing factor could be found. This observation, exceptional as it certainly is, may be taken as indicating that an hematogenous peritonitis is possible in typhoid fever, since from the work of Cole,<sup>23</sup> Auerbach and Unger,<sup>24</sup> and others it is certain that bacteremia is common. Moreover, the number of instances where the typhoid bacillus has been the cause of metastatic abscess formation, pleurisy, and even pneumonia, is already large, and additional observations are being constantly made. According to Nothnagel, however, hematogenous peritonitis in acute diseases is the greatest exception, if indeed it ever takes place, which is well confirmed by Flexner's<sup>25</sup> study of peritonitis. He found the primary variety only in a terminal infection in chronic diseases, and most frequently in those complicated with ascites. At any rate, in these cases of cryptogenic peritonitis the bacteria, and I think under such conditions the typhoid bacillus is frequently present, reach the peritoneum probably by migration through the intestinal wall or possibly through the lymphatic or general circulation.

A simultaneous if not preexisting localized inflammation of the serosa arising from the path of migration, from a periadenitis, or from a decrease in the normal peritoneal absorption may be taken as the likely secondary etiologic factors, regarding the bacteria as the primary.

The causative significance of simple infarction of the spleen may be disregarded. Fraenkel suggested the possibility, but it was not present in his case. Infarction is of rather frequent occurrence. Horton-Smith found it in 3%, Hoffman<sup>26</sup> in 3.6%, and Griessinger<sup>26</sup> in 7% of fatal cases, which is more frequent than nonperforative peritonitis, and no causal relationship has been remarked as there would have been had there been frequent association of these conditions. The coagulative necrosis, particularly in the anemic variety, would render the migration of bacteria difficult without some softening. In the experiments of Walthard,<sup>27</sup> in which the uterus was ligated, thus making it an infarct, it was found not to act as a predisposing factor to peritonitis in the presence of bacteria, and that after such an inflammation had been induced it played only a passive part. Tavel and Lanz conclude from this that mere injury to the serosa is insufficient to aid in the causation of a peritonitis unless there can and does develop from this injury an inflammatory reaction. Halsted tied off a tip of omentum with silk thread and then applied a bouillon culture of *Staphylococcus aureus*. Of the eight dogs so treated, two developed a general and two a localized peritonitis, whereas four recovered without any local reaction. The omentum is particularly prone to react to mechanical irritation, so that in these experiments the positive results could easily be accounted for by an inflammation due to the foreign body and arising on the proximal side of the ligature.

There is one condition that theoretically, at least, is a predisposing factor in the development of nonperforative peritonitis, and to which no allusion is to be found, namely, meteorism. The untoward effects of grave distention upon the clinical condition and prognosis are only too well recognized. The tenderness that may occur with advanced meteorism can mask almost completely the symptoms of peritonitis in certain cases. The origin of the distention is to be attributed to the defective tone in the walls with serous infiltration in severe cases (Osler<sup>28</sup>) resulting from the intensity of the general intoxication (Curschmann<sup>29</sup>). Nothnagel<sup>30</sup> supposes that a slight primary distention may lead to the formation of a vicious circle by the progressively increasing limitation of the intestinal absorption and thus to a consequently greater distention and advancing paresis of the intestinal muscles. This conception is based on clinical and experimental observations, and thus is explained those extreme cases of enormous distention simulating the conditions secondary to intestinal stenosis. Indeed,

they are entirely comparable to bowel obstruction excepting as to the causation.

Anyone who has seen the autopsies on such cases must have noticed the numerous sharp angular bends in the intestinal coils, practically a series of physiologic obstructions, with the tense thin-walled sausage-like bowel between them. The futility of attempting to relieve such conditions by any but the most radical methods is evident. Those who have seen multiple enterotomy done in such conditions can recall the great difficulty of even thus expelling the gaseous and fluid bowel contents.

Experimentally Grawitz has demonstrated that meteorism associated with an intact mucosa is not accompanied with a migration of bacteria into the peritoneal cavity, but when there is a concomitant ulceration or necrosis of the mucosa or diphtheric inflammation this transmigration is present and these organisms are then capable of causing a peritonitis. The inhibition of the vermicular movements of the intestine and the limitation of the action of the diaphragm must result in a decrease in the peritoneal absorption, a secondary cause of peritonitis even in the presence of the typhoid bacillus alone. As these conditions are exactly those present with the meteorism of typhoid fever and as distention is a well recognized predisposing factor to perforation it is perfectly reasonable to propose the performance of a low ileostomy in cases of progressing or intractable tympanites. Not only would this aid in overcoming a very serious complication that is otherwise practically irremediable, but would have a certain prophylactic value against peritonitis. Three years ago Cushing<sup>31</sup> advocated this procedure in treating peritonitis resulting from perforation when associated with distention and deep ulceration and employed it once in a secondary operation under these conditions. Escher<sup>32</sup> has recently reported the successful application of this method in three out of four cases. The operation may be done quickly and without in itself being detrimental to the patient's condition. The exact location for the establishment of the fistula would, of course, have to be determined by the conditions found in the bowel, such as the location and depth of the ulcers. From Escher's results it would appear that spontaneous closure was to be expected so that the dangers of a second operation might be somewhat disregarded.

The bacteriology of nonperforative peritonitis has been too little observed to give any clue as to the microorganisms most frequently present. It is possible, however, that the typhoid bacillus occurs more frequently, particularly in pure culture, than in the perforative cases. In the few instances where it has occurred there has usually followed a rapidly fatal inflammation that has fallen in well with the dictum that the extent of the local lesion varies inversely with the severity of the infection. This indicates, as Shattuck, Warren, and Cobb<sup>33</sup> have pointed out, a most unexpected virulence in the typhoid bacillus. The longer the inflammation exists, as exemplified by the localized forms and by Körte's case, the more pronounced is the degree of suppuration coinciding with the observations on the action of the pyogenic cocci.

Pathologically there is nothing characteristic about the peritonitis. It may be general or localized, serofibrinous or purulent. The assumption that the nonperforative inflammation is more apt to be localized because of a slower invasion of the peritoneum does not seem to be borne out. However, it must be remembered that such conditions would be the less apt to lead to operation or to autopsy.

The records of 12 cases of generalized peritonitis with fairly complete clinical notes have been found; they are reported by Gairdner,<sup>34</sup> Shattuck, Cobb and Warren, Körte,<sup>35</sup> and Moser.<sup>36</sup> To these are added two cases: One occurred in the service of Dr. Edsall at the Episcopal Hospital, and the other came to autopsy during Prof.

Flexner's service at the Philadelphia Hospital. A study of the clinical histories of these cases, adding where possible data from the incomplete records of seven others referred to by Murchison, Keen,<sup>37</sup> Loison,<sup>38</sup> and McCrae and Mitchell,<sup>39</sup> has developed the following facts: The average age is 21; the oldest 50; the youngest 6; 14 out of 18 below 30; 7 in the second and 6 in the third decades; 8 males; 6 females; the time of onset of the peritonitic symptoms was most frequently at (about the twenty-second day) the end of the third week; the earliest on the tenth, and the latest on the thirty-sixth day. Five of the 13 were suffering from a severe attack of the fever; in 4 it was not stated; 3 were but mildly affected; 1 moderately so, and 1 (Dr. Edsall's case) was a typical example of walking typhoid. It is interesting that of the three mild cases two had but little ulceration, and the third was caused by a rupture of the mesenteric glands. There were five cases associated with intestinal hemorrhages, in two of which a hemorrhage immediately preceded the appearance of the peritonitic symptoms. In one case that had had hemorrhage, the peritonitis followed the rupture of a mesenteric gland. Two had previous abdominal tenderness and one tympanites and diarrhea. Distention was noted at operation several times, but it was not stated to have preceded the symptoms of peritonitis. In 11 of the 14 cases the onset was acute, the one of these occurring in walking typhoid was diagnosed appendicitis. All the others were thought to be perforation or peritonitis following perforation. The three cases with a gradual onset were all suffering from a sharp attack, and in two at least there was some stupor. The abdominal pain is the most constant symptom noted. It may be diffuse and general, but is more often more particularly referred to the right side. It may be in the upper part of the abdomen. The condition of the abdomen was not noted in each instance, but rigidity appears to be commonly if not constantly present at some time during the development of the peritonitis. There may be a rise or fall in the temperature, or the fall may be preceded by a rise. The pulse-rate seems to follow the temperature curve somewhat. The leukocytes have been counted in but three cases. In the one suspected of being appendicitis they were 9,000 just before operation, in another they were 7,000 before and 12,000 after the onset of the peritonitic symptoms; in the third no count was made before the signs of supposed perforation were recognized; three subsequent counts varied between 7,000 and 8,000. The evident similarity to the conditions existing with perforation is striking.

The results of the peritonitis continue the analogy. Of the 11 cases operated on 4 recovered, and of 9 unoperated cases all died, or naturally they would not have been recognized as of nonperforative origin. It is manifestly impossible to come to any conclusion as to the proportion of spontaneous recoveries, but it cannot be far from that of the perforative type. In the Basle cases the nonperforative form was present 16 times with 13 deaths, but no clinical data were found relative to them. The following pathologic condition was found at the time of operation or postmortem: In 8 cases the ulceration was deep, in 4 reaching to the serosa; in 3 there was little ulceration, and in 2 there had been rupture of the mesenteric lymph glands. In 1 case the peritonitis was thought to have started from a suppurating but unruptured lymph gland. The bases of these ulcers may be found to be more or less necrotic or the corresponding serosa covered with a localized exudate of fibrin, or there may be no relationship between the condition of the serosa and the ulceration. Infarction of the spleen was present twice, once hemorrhagic and associated with considerable intestinal ulceration, and once anemic and associated with very slight ulceration. Ileocolotyphus was present once, and the ulceration was considerable. The peritonitis was variously described as serofibrinous, seropurulent and

fibrinopurulent. Cultures were taken at operation twice; no growth developed from either, but in one a cover slip preparation showed cocci and bacilli. In Körte's case an exploratory paracentesis was done and the typhoid bacillus was obtained in pure culture. The typhoid bacillus has been found three times in pure culture in the postmortem examination of the peritoneum, once with a ruptured lymph gland, once with a ruptured spleen, and once in the case reported here where there was no definite cause.

It is evident that so far as can be judged from so small a number of cases and from the findings of Hölischer that the majority of cases of nonperforative peritonitis are consequent upon deep-seated intestinal ulceration. However, from a comparison of the clinical histories and the anatomic conditions which were subsequently found, there appears to be no relationship whatever between the character and acuteness of the onset, the severity of the resulting peritonitis, and the nature of the intestinal lesion, *i. e.*, whether the ulceration is slight or deep and even with a necrotic base. The ruptured lymph glands in both cases lead to a sudden onset and a severe peritonitis. One was operated on, and both were rapidly fatal. The case supposed to be due to extension of the infection from a lymph gland lived 25 days after the onset of peritonitis and two days after operation, which apparently would never have been performed had not the development of a suppurative parotitis demanded surgical procedure. The pus from the parotid contained the typhoid bacillus and a staphylococcus.

The clinical diagnoses in these cases were made from symptoms arising from peritoneal inflammation, and it was impossible in a single instance to differentiate them from cases of perforation, for which they were all mistaken, except the one diagnosed appendicitis. This is exactly in accordance with an opinion expressed years ago by Fitz: "The so-called symptoms of perforation merely indicate the beginning of a peritonitis, and may be present as the result of other local causes of peritonitis in typhoid fever than a perforative enteritis." Shattuck, Cobb, and Warren have more recently given expression to the same conviction. The preperforative stage described by Cushing<sup>40</sup> is doubtless present in a certain number of cases, but the perforation may not take place or adhesions form, whereas the peritonitis is already established.

The study of the conditions causing or caused by the localized form of nonperforative peritonitis is less satisfactory. Fairly numerous records are to be found of instances of intraabdominal abscess formation. Some have healed spontaneously by discharging into the intestine or externally. Others have been successfully opened and drained. These that have been examined postmortem show that the origin may be traced to the same conditions that cause the general peritonitis with or without perforation. It is probable that there is also similarity to the clinical conditions under which the general form occurs; namely, the age, sex (all of the four recorded cases, however, are in males), time of onset, character of the attack, etc. The symptoms are somewhat varied—there may be an acute onset that is in no way to be distinguished from that seen in the spreading form, then a gradual decrease in the severe symptoms, and a formation of an abdominal tumor with or without symptoms directly referable to it. In other cases associated with little more than a rise in temperature and probably a leukocytosis, there is gradually formed an intraabdominal swelling, which may be without pain and tenderness. The rupture of the spleen or of an abscess, or a softened infarction in it, may give rise to a local or general peritonitis. This complication might be recognized, as Curschmann<sup>41</sup> has suggested, by the sudden appearance of pain in the left flank, just beneath the costal margin. Such a diagnosis could only be made by exclusion, and in view of the great rarity

of the complication and the variation in subjective symptoms it would be apt to escape detection. McCrae<sup>42</sup> thinks that certain of those cases of obscure abdominal pain in the course of the fever may be due rarely to a localized inflammation over the base of an intestinal ulcer. As evidence he reports a laparotomy done under local anesthesia for suspected perforation. An area of slight exudation was found over the base of an ulcer, which when touched caused pain like that experienced before the abdomen was opened. The surrounding intestine was devoid of painful sensation.

As examples illustrating the conditions as described above may be taken the following cases reported respectively by Fraenkel, Klein,<sup>43</sup> and Roux<sup>44</sup>:

1. Male, aged 20. Severe primary attack complicated by bronchopneumonia and facial erysipelas. On the sixth day of a relapse these developed signs of peritonitis which gradually disappeared. Four and a half months after the onset of the fever a tumor appeared in the left lower quadrant of the abdomen. This was aspirated and finally incised. Death took place later from ileus. No cause for the peritonitis could be found at the postmortem examination.

2. Male, aged 34. Suffered from a primary attack lasting 40 days, was then afebrile for 10 days, when his temperature rose to 103°. There was an increase in the area of dullness over the spleen, but no tenderness. This area of dullness and an underlying tumor gradually increased in size. Aspiration followed by incision, with evacuation of three liters of pus, and drainage resulted in recovery. Neither the spleen nor any other structures could be recognized at operation.

3. Male, aged 21. On the twenty-second day of a moderately severe attack complained of a severe pain beneath the left costal margin. Tenderness was present. Perforation was suspected. He grew weaker and died on the thirty-third day. *Phlegmasia alba dolens* developed in the last two days of life. At autopsy the intestinal ulcers were found to be healing and there was no perforation. The spleen was found adherent at its lower pole to the parietal peritoneum. Breaking up these adhesions disclosed an abscess the size of a walnut. In the splenic pulp were found other abscesses the size of "kidney beans."

From all of these cases, as well as one reported by Lehmann<sup>45</sup> and apparently due to suppuration in a mesenteric gland which seems not to have ruptured, the *Bacillus typhosus* was recovered in pure culture. No other reported cases of localized abscess formation were found in which it seemed fairly certain that no perforation had occurred. These findings give additional evidence in favor of the assumption that the nonperforative infections are usually caused by the typhoid bacillus. The prognosis in these cases of intraabdominal abscess formation is manifestly good so far as death from peritonitis is concerned if the proper procedures are promptly instituted.

Dr. Edsall kindly furnished me with the history of the case simulating appendicitis, an abstract of which follows. I also wish to thank him for the permission to publish it here:

G. G., aged 30, male. Barber. Admitted to the Episcopal Hospital November 2, 1902. Discharged December 27, 1902. There was no history of a previous typhoid attack. The illness began about a month before admission with transient chilly sensations occurring in the afternoon and evening which persisted for about ten days. There was some associated headache which continued somewhat longer. The bowels were constipated. A moderate diarrhea followed the use of a laxative and continued to the onset of the abdominal pain, which was sudden, severe, and general. Up to this time the patient had kept at work. Several hours later there was nausea and vomiting. This was succeeded by eructations.

On admission the tongue was dry and brown. The abdomen was distended and rigid, particularly on the right side. The tenderness was diffuse and general. The areas of liver and spleen dullness were normal and the spleen impalpable. Leukocytes, 9,000.

Operation by Dr. Hutchinson 47 hours after onset of pain. Incision through the right rectus. Yellow purulent fluid welled up when the peritoneum was opened. Fibrin flakes were present on the intestine and the purulent fluid was found free in the general cavity. The appendix was removed, but as it was not the cause of the peritonitis the ileum was examined. It appeared congested and suggested typhoid; 35 cm. to 40 cm. from the cecum a tip of the omentum was found adherent to the ileum at a point opposite the mesenteric attachment. Removal of the omentum disclosed the base of a well-marked ulcer, with a dark central spot but no macroscopic perforation was to be made out. This whole area was inverted by inter-

rupted sutures. Other ulcers were observed, but none deep enough to require inversion. The abdomen was washed out with hot saline solution and the wound partially closed; gauze and rubber tube drainage.

The patient made an uninterrupted recovery and was discharged well on the thirty-sixth day after operation.

For the following clinical notes on the other case I am indebted to Dr. R. H. Spangler, of the Philadelphia Hospital:

M. C., aged 24. Norwegian sailor. Admitted November 18, 1902; died November 25, 1902. He was brought in an ambulance to the Philadelphia Hospital complaining of general indisposition, slight cough, diarrhea, and some abdominal pain. There was a history of a gradual onset two weeks previously, while on shipboard, with loss of appetite, diarrhea, headache, chilly sensations, and general malaise. The progress of the disease up to the time of admission was uneventful.

On examination at the hospital he presented a quite characteristic typhoid condition. The pulse was rapid, weak, and distinctly dicrotic. On the abdomen were found typical rose spots. Palpation revealed an enlarged spleen and some rigidity of the abdominal muscles and a moderate degree of distention. No tenderness was noted.

The general condition appeared good and there was a satisfactory reaction to sponges manifested at once. His temperature on the morning of admission was 102.2° and reached 104.2° late in the afternoon. Through the day there was complaint of chilly feeling and abdominal pains. During the next three days his condition became progressively worse. Restlessness, delirium, and carphologia developed and later incontinence of urine and feces. The stools were fluid, yellowish and fairly frequent, two to five a day. The temperature varied from 101° to 104.5°. The pulse became more rapid and weaker.

On the fourth day after admission the patient complained of more abdominal pain. He was very restless during the day and delirious at night, trying repeatedly to get out of bed. During the 24 hours he had two shaking chills, the temperature reaching 103.8° after one at 10 a.m., and 103.6° after the second at 11 p.m. The leukocytes were 7,000. On the morning of the fifth day there was little change in the general condition, but the pulse became weaker and the distention was more evident. At 11 a.m. he vomited a large amount of greenish fluid. The delirium and incontinence continued. By 2 p.m. his temperature had dropped in 10 hours from 102.5° to 97°. He had become very restless, the abdomen was more tender and tympanitic. The patient was lying on his back with the thighs slightly flexed. The leukocytes were 7,200. Dr. Hughes, who saw him at this time, made a diagnosis of perforation. At 4 p.m. the abdominal distention and tenderness had increased. Dr. Salinger concurred in the diagnosis of peritonitis and the patient was at once transferred to the surgical department where the following note was made:

The temperature has fallen in the last 12 hours from 103.4° to subnormal. Abdominal distention and tenderness are very noticeable. The superficial abdominal veins are distended. The leukocyte count is 7,900.

At 6.45 p.m. an operation was performed by Dr. Hearn. The abdominal cavity was opened through a median incision and immediately the greatly distended loops of intestine forced themselves out through the wound. The intestines were deeply congested and in spots echymotic. The mesentery was also deeply congested and here and there contained dark red enlargements suggesting thrombi. In spite of a most careful search no sign of perforation was found nor was the contained abdominal fluid in the least suggestive of a perforation. During the operation the exposed intestines became more deeply congested and in places almost black. After a thorough irrigation the intestines were replaced and the wound closed with interrupted through-and-through sutures.

During the night the patient was continuously restless and delirious. The vomiting and incontinence continued. The distention persisted. At 6 o'clock in the morning the temperature had risen to 105.4°; it fell gradually to 98.6° at 2 p.m., rising to 105° at 11 p.m. Active delirium persisted during the day so that forcible restraint was at times necessary. The face and body became markedly cyanotic during the evening. The general condition grew weaker steadily and he died quietly at 11 p.m. on the night of about the twenty-first day of his illness.

At the necropsy, done 17½ hours after postmortem, the following conditions were found:

The body was that of a large, moderately well-nourished male; rigor mortis was present. There was a marked pallor of the lips and conjunctivas. The pupils were equal. Over the abdomen and thorax were scattered irregular patches of bluish-red discoloration of the skin. In the fold of the left elbow was a short closed incision (transfusion). Below the umbilicus and just to the right of the middle line was an incision 8 cm. in length closed by interrupted sutures. The abdomen was much distended, tense and extremely tympanitic, with only a slight relative dullness in the flanks. On opening the peritoneal cavity the intestines were found to be greatly distended and congested and largely covered with a dry granular, fibrinous exudate. Many moist yellowish flakes of fibrin were also present. There were a few slight fibrinous adhesions between the loops of bowel and the mesial side of the abdominal wound.

Contiguous serous surfaces were found glued together by similar material. In the dependent parts of the abdominal cavity and in the pelvis there was an excess of slightly turbid fluid. (Cultures were taken from this fluid; the needle was also rubbed gently over the fibrinous exudate.) The distention was found to be quite general except for a localized contraction in the sigmoid flexure, but nothing seen was indicative in the slightest of an obstruction. The distention was somewhat less in the upper jejunum and the distal portion of the ileum. The greatest injection seemed to be confined to the jejunum and upper ileum, showing here also occasional ecchymotic patches. In the greater part of the ileum there was almost no deep injection, but there appeared here and there deep red (and some black) thickened patches. These were inconstant in their position, not corresponding to the lymphoid structures of the intestine in many cases. They varied in size from that of a dime to that of a quarter, and were all apparently beneath the serous surface. At no place could the Peyer's patches be definitely recognized from the outside of the intestine; nor could the slightest evidence of a perforation be found, no gas escaping even under considerable pressure upon the intestinal contents. The appendix was free and hung into the pelvic cavity, its serous surface was but little affected in the general process. The mesenteric glands were enlarged but firm, and of a very curious brown color. It was thought that these glands had been seen during operation, and raised the question of thrombosis. There was no evidence of any more acute or long long standing process noticed about any of them than existed elsewhere in the peritoneal cavity. Aside from the slight fibrinous adhesions described above the peritoneal cavity was free.

**Thorax.**—Both pleural sacs contained old fibrous adhesions which almost obliterated the right cavity. The apex of the left lung was puckered and consolidated, but otherwise the lungs were crepitant throughout. On section, the right apex showed characteristic appearances of tuberculosis, caseous, and a few miliary tubercles with some gelatinous and caseous pneumonia. The rest of the lung was apparently normal, showing only slight hypostatic congestion.

The pericardial cavity was free from adhesions and contained a slight excess of clear fluid. The heart, which was not enlarged, was somewhat soft, and aside from well-marked fatty changes in the myocardium was entirely normal. Weight, 230 grams.

**Spleen** was enlarged, somewhat soft, and the surface smooth except for the slight fibrinous exudate. At both poles were irregular white areas a little raised above the surface and slightly firmer than the balance of the spleen. On section, the pulp was found to be pale, quite soft, and the malpighian bodies obscured. The white areas above described were seen to enter irregularly into the spleen tissue and to have a sharp margin about which was a very distinct, narrow, and slightly darker reddish rim. The cut surface was opaque, white, dry, and granular, and very slightly raised above the cut surface of the more normal spleen. No softened areas were encountered though the infarcted areas were cut into thin sections. Weight, 200 grams.

**Liver.**—The surface was found to be generally covered with the same granular fibrinous exudate which, as elsewhere, was easily removed. Otherwise there was no apparent abnormality. The cut section was firm and pale, and the lobular markings quite obscured. Here and there were to be seen a very few fine, opaque, white foci. No areas of softening were found. Weight, 14,500 grams.

The gallbladder and bile ducts were smooth and free. The contained bile unusually watery and of a very light green color.

**Kidneys** were normal in size and consistence. The capsule stripped away easily, leaving a slightly injected, smooth surface. On section the epithelium looked yellowish and opaque. The cortex was normal and the glomeruli were distinctly visible.

**Bladder** was moderately distended with cloudy urine, but the mucosa was quite normal. The genitalia was apparently normal.

**Pancreas** was normal in size, shape, consistence, and in the appearance of cut sections.

**Stomach** contained a slight amount of tenacious mucus; the mucosa was very slightly injected. Just beyond the pylorus the duodenum was slightly injected.

**Intestines.**—The jejunum in its upper portion showed a slight diffuse injection of the mucosa and in the lower jejunum and ileum occurred those dark, thickened areas above described. Over these the mucosa was apparently intact and unchanged. Sections of the intestinal wall through these patches showed lenticular accumulation of blood within the tissue of the intestinal wall. Their noncoincidence with the lymphoid tissue was again evidenced. These same hemorrhagic plaques were found irregularly throughout the small intestine, but were more numerous in the ileum. In the ileum there was a similar injection of the mucosa, nowhere particularly pronounced. The first Peyer's patches encountered were evidently not much changed. They, however, began to show some slight swelling as the cecum was approached, but the mucosa over them seemed to be intact. In the center of the most distal patch a small irregular excoriation was found, which extended very slightly into the subjacent tissue. The base of this ulcer was

rough, uneven, and necrotic, the slough evidently having been incompletely removed. The Peyer's patches all had a suggestion of a "shaven-beard appearance."

The appendix was normal. In the colon there was again a very slight injection of the mucosa and the solitary follicles practically all had a dark center. The rectum was similar in appearance.

The mesenteric lymph glands were enlarged to a moderate degree, firm, and gave no evidence of matting together. On section, rather brownish in color, firm, and not particularly moist. No foci of softening were observed. The retroperitoneal glands were also slightly enlarged, of somewhat the same color, but on section showed redness in streaks.

**Anatomic Diagnosis.**—Acute ulcerative enteritis with multiple intramural hemorrhages and meteorism, acute general serofibrinous peritonitis, parenchymatous degeneration of liver and kidneys, focal necroses of liver, anemic infarctions of spleen, fatty degeneration of myocardium, chronic tuberculosis of the apex of the right lung, recent abdominal incision.

**Microscopic Examination.**—Heart: No abnormality is apparent in any of the cardiac structures. A few small round cells are present about the smaller vessels.

**Liver:** In the capsule is found some round-celled infiltration. The surface exudate does not appear in the sections. Throughout the parenchyma the liver cells are more or less swollen and granular. Scattered here and there are foci of necrosis, usually small with but partial granular degeneration of the liver cells and little or no cellular accumulation. In the connective tissue of the portal spaces are some occasional round cell accumulations containing also a few polymorphonuclear leukocytes.

**Spleen:** The capsule is quite normal save for an acute fibrinous exudate, the cells of which are few and for the most part of mononuclear varieties. The pulp is swollen and the Malpighian bodies are small and relatively infrequent. In the pulp occur large numbers of typical red blood-corpucle carrying cells which rarely contain nucleated elements. A few scattered foci necroses are present but not the least evidence of abscess formation.

The white areas seen macroscopically are typical anemic infarctions surrounded by the two characteristic zones of infiltration and congestion. The inner zone of infiltration is made up almost entirely of round cells. In these karyorrhesis is marked. The outer zone of congestion is peculiar in that the red blood-corpucle, unlike similar cells in the immediately adjacent pulp, do not appear as "shadows," but take a deep eosin stain and have a distinctly hyaline appearance. Their relationship is such that their outlines often are undifferentiated and a fused condition is suggested. Throughout the infarcted area the architecture of the spleen is preserved and no softening is to be observed. The blood-corpucle are as a rule well differentiated. The coagulative necrosis is practically homogeneous and complete. Through it are clumps of hematoïdin crystals. No thrombosis is present in the vessels in the more normal pulp but appears in those which extend into the infarction. Aside from the fibrin filaments, red blood-corpucle and leukocytes there are irregular hyaline globular masses that stain deeply with the eosin. These also suggest fused red blood-corpucle. Weigert's fibrin stain leaves them unaffected and sharply differentiated from the stained fibrin filaments adjacent to them, giving support to the probability of their being agglutinated red corpucle.

**Kidneys:** There is no thickening of the capsule, nor is there any diffuse increase in the stroma, although a slight increase in the periglomerular tissue is present. An advanced granular swelling is present in the epithelium of the convoluted tubules. In the lumina of the tubules and within the spaces in Bowman's capsule is a considerable deposit of granular detritus staining with eosin. Hyaline tube-casts are present in fairly large numbers. No congestion is present.

**Pancreas:** No abnormality is apparent.

**Intestine:** Perhaps owing to the fact that these preparations had all been placed on blotting-paper before immersion in hardening fluid none showed any exudate. Moderate congestion of the vessels of all the intestinal coats is the only abnormality present in places. In others, where there had been some macroscopic swelling, there is a moderate endothelial hyperplasia in the lymphoid tissue. An inconsiderable degree of phagocytosis is noticeable. The mucosa is generally well preserved, though there is some postmortem change as well as some little characteristic sloughing. There had been so little loss of tissue, however, that the bases of Lieberkühn's crypts are rather constantly present. The section of the ragged ulcer found in the lowermost of Peyer's patches shows a perfectly definite, but also superficial loss of substance. Beneath this ulcer is a typical zone of necrosis. The submucosa is not involved, the necrosis not extending even to the base of the lymphoid tissue. Except for some edema in one section the muscular coats are normal. There is a slight infiltration with small round cells in places, but this is more particularly just beneath the serosa.

The most striking feature is the appearance of the hemorrhagic plaques that were so conspicuous macroscopically, both at the operation and postmortem. These accumulations of blood are found to be confined to the submucosa, the structures on either side not being at all affected. The bloodvessels in this area are as a rule quite free and normal. In some there

are present an abnormally large proportion of nucleated cells, most of which are of a large mononuclear variety. In some sections of a veinule there occurs a considerable increase in these nucleated cells, but here also the red corpuscles are in the peculiar condition described in the spleen, densely staining, highly refractive, and apparently agglutinated. This was traceable in serial sections.

**Mesenteric Lymph Gland:** A very pronounced endothelial hyperplasia is present, but with only a slight degree of phagocytosis. Some small nucleated cells as well as red blood-corpuscles are to be found in the large cells. A few very minute and perhaps questionable foci of necrosis are present. In the lymph sinuses a few red blood-corpuscles are occasionally to be found, particularly in the peripheral sinus. Very occasional small deposits of refractile yellow pigment are to be seen. There is a slight round-cell infiltration in the puriglandular fat, but no outspoken periaiditis.

**Retroperitoneal Lymph Gland:** The condition here is practically identical with that found in the mesenteric glands except that in places the sinuses are quite filled with red blood-corpuscles, a hemolymph gland.

**Bacteriologic Examination.**—The agar slant inoculated from the peritoneal exudate gave an abundant growth in 24 hours—apparently a pure culture had developed. A hanging drop preparation made from the water of condensation showed a small, rapidly motile bacillus. No other forms were seen here or in a stained smear. Agar plates were made from dilutions in bouillon of the original growth. After incubation two or three of these plates showed colonies that were typically those of *Bacillus subtilis*. These were excluded as a certain contamination. Eighteen or 20 agar tubes were inoculated from deep and surface colonies that were other than characteristically those of the *subtilis*. In all but two or three of these slants there developed a growth of bacilli, motile and apparently identical with those of the original culture. The remaining tubes had developed a growth of a staphylococcus.

By the usual methods it was determined that all of the bacillary cultures were of the same organism. Their growths upon the various culture media, the absence of gas formation in the presence of sugars, glucose, lactose, and saccharose, as well as their morphologic and staining characteristics, were identical with those of the typhoid bacillus. Through the kindness of Dr. W. T. Longcope, a Gruber-Widal test was made at the Ayer Laboratory of the Pennsylvania Hospital. A positive reaction occurred with the serum of a typhoid patient in a dilution of 1-500 after three hours, which satisfactorily completed the identification as the typhoid bacillus.

The staphylococcus was found to agree in size and staining peculiarities with the ordinary pyogenic staphylococci. The agar growth remained free from colored pigment but became gradually opaque; there was a definite whitish growth on potato. There was no coagulation of milk. Liquefaction of gelatin was slight and took place slowly. The gelatin was not particularly firm and other organisms caused rapid liquefaction. The characteristics were considered sufficient to identify *Staphylococcus epidermidis albus*. Ten or 12 days after the original subcultures were made, the bouillon tubes from which the plates had been seeded were reexamined. The cocci appeared to equal the bacilli in number, whereas the day after inoculation of these tubes the presence of the cocci had escaped detection.

The pyogenic properties of the typhoid bacillus have been established beyond contention, the exception of Baumgarten to prove the rule. That it may also cause peritonitis is proved by the experiments of Dmochowski and Janowski, and clinically by the observations reported by Fraenkel, Weichselbaum,<sup>46</sup> Roux, Körte, Lehmann, Klein, Shattuck, Cobb, and Warren. (Fraenkel, Roux, Klein, and Lehmann isolated the typhoid bacillus in pure culture from nonperforative localized peritonitis. Weichselbaum obtained it in pure culture from a general peritonitis following a rupture of the spleen, and Körte in a similar condition arising from a suppurating lymph gland. Shattuck, Cobb, and Warren report two other cases of general peritonitis where it alone was cultivated, one following perforation in which the culture was taken at time of operation, and one due to rupture of a suppurating mesenteric lymph gland.)

The presence of *Staphylococcus epidermidis albus* in the peritoneum in the case here reported in no way lessens the probability that the typhoid bacillus was the primary microorganism concerned in the production of the peritonitis. Welch<sup>47</sup> has shown that *Staphylococcus epidermidis albus* may give rise to a peritonitis if there is a ready communication between the peritoneum and the skin incision; as, for example, along a drain track. But in this case the peritonitis was established before there was any possibility for such an infection. Also the cultures show that the coccus was originally greatly

in the minority. It is most probable that the coccal infection took place at the time of operation.

There is but one other instance on record, and that one is unsatisfactory, of a general peritonitis due neither to rupture of the spleen or a lymph-gland nor to an intestinal perforation in which the typhoid bacillus has been found in pure culture. Keen<sup>48</sup> was unable to find a case in which it had been present under these conditions.

The histological examination has some very striking features. The hemorrhagic plaques in the intestinal walls, so evident at the operation and postmortem, are particularly noteworthy. Not only were they the possible result of thrombosis, and that of a peculiar type, but the consequent circulatory disturbance, particularly the edema as seen in one section, have aided materially in the transmigration of the bacilli into the peritoneal cavity. But of the greatest interest from a pathologic viewpoint is the appearance of agglutinated red blood-corpuscles in the thrombi, in the intestinal and splenic vessels, and in the zone of congestion about the area of infarction in the spleen. Flexner<sup>49</sup> has already pointed out the existence of the thrombosis due to agglutination of the red blood-corpuscles. He has observed it several times in the vessels of the intestine, omentum, and lung in typhoid fever; in those of the lung in a case of bronchiectasis and pneumonia, and in the vessels of the stomach in carbolic acid poisoning, and in the hemorrhagic necroses of the liver in eclampsia. Experimentally he reproduced similar conditions by the intravenous injection of rabbits with ricin, ether, and dog's blood-serum. Boxmeyer<sup>50</sup> in a study of the focal necroses seen in the livers of rabbits and mice after inoculation with the hog-cholera bacillus, came independently to the same explanation of a similar process in these lesions. He suggests that such thrombi may be found as the result of freezing, burning, and the action of certain mineral poisons.

It was attempted to make a comparative study of sections of masses of red blood-corpuscles agglutinated *in vitro* and those present in the tissue as described. Human and dog's blood was defibrinated and the corpuscles suspended in 19 times the amount of 0.85% sodium chloride solution, and then agglutinated by the action of ricin and snake venom, or the dog's blood also with normal horse serum. It was found impossible to harden these masses, which microscopically were characteristically agglutinated, without causing an immediate disassociation of the corpuscles and a more or less complete restitution of the normal form of the erythrocytes. The usual hardening fluids were used and modifications tried and fixation by heating employed, but this disassociation always occurred. Sections of relatively large clumps showed nothing but groups of distinct corpuscles. This process of disassociation could be watched under the microscope by allowing the hardening fluid to run under the cover glass.

This is similar to the action of potassium permanganate on corpuscles agglutinated by the action of snake venoms, first pointed out by Mitchell and Stewart<sup>51</sup> and studied more recently by Flexner and Noguchi.<sup>52</sup> The former also found that hydrogen peroxid had a similar influence. Eisenberg and Volk<sup>53</sup> have noticed the same effect upon agglutinated bacteria treated with various organic and inorganic acids, acid salts, alkalis, saturated sodium chloride, and urea solutions, formalin, and also by heating. The disassociated bacteria showed some change in appearance, varying in extent with the method employed. Reagglutination may take place.

Kraus and Ludwig<sup>54</sup> were able to demonstrate hemolysis and hemagglutination of dogs' corpuscles when acted upon by the living cultures of certain bacteria, but not by the action of the typhoid bacillus. Following their methods somewhat, using a culture of typhoid bacilli recently obtained from a fatal case of the fever, and a 5% suspension of defibrinated human blood in

0.85% salt solution, agglutination was observed. Groups of test-tubes containing 1 cc. of the blood suspension were inoculated with from one to five drops of a 24-hour bouillon culture. Five such groups were prepared, each one with a control containing only the blood suspension. Three of these groups were incubated at 37° C. for from 2 to 18 hours and then placed in a refrigerator. One was left at room temperature for 24 hours, incubated for 8 hours, and then put in a refrigerator, and one was kept constantly in the refrigerator. At 42 hours from the time of preparation slight macroscopic and microscopic agglutination was present in all but the group that had been constantly at low temperature. The reaction was slight but perfectly distinct. At 116 hours all showed some agglutination. This could be broken up macroscopically, but on standing 24 hours had reappeared.

For obtaining the toxin from the tubercle bacilli the method of Koch as applied by Neisser and Shiga<sup>55</sup> to the typhoid and dysentery bacilli in their study of free receptors was also used. A 24-hours' growth of the same typhoid culture upon agar-agar was suspended in 10 cc. saline solution, heated for an hour at 60° C., kept for two days at 37° C., and then passed through a Pasteur filter. Another series of tubes was prepared as before, and similar amounts of the filtrate added to them. The agglutination took place more quickly and in proportion to the amount of the filtrate added. There was also slight hemolysis. The clumps here were similar to those of the preceding experiment, and after being broken up by shaking reappeared after 24 hours.

Still another series was used. In this case a 56-hour bouillon culture was put through the Pasteur filter and the filtrate added as before. The agglutination took place very slowly, and was never as evident macroscopically as in the other two tests. The reformation of visible clumps took place here also after dissipation by shaking.

Agglutination of human blood may take place, therefore, *in vitro*, in the presence of a living culture, the filtrate from a living culture, or the filtrate from a salt solution extract of the bodies of the dead bacilli which owes its efficacy to autolysis as shown by Conradi.<sup>56</sup> This occurs more rapidly at the body temperature, and may be observed with or independent of hemolysis. The agglutination is less pronounced microscopically and macroscopically than that resulting from the action of sera or venoms.

In conclusion it may be said that the treatment of these cases is manifestly the same as of the perforative peritonitis with suitable variations in the details to meet the conditions found. In the first of the two cases here reported it is perhaps questionable whether the use of drainage resulted in any particular benefit. The prophylactic value, had the sutures failed in obliterating the source of infection, is indisputable. On the other hand, the presence of a foreign body in any tissue certainly does not favor the resistance against infection. Moreover, the immediate and remote complications arising from adhesions must be taken into consideration. Delbet,<sup>57</sup> from experiments, concludes that effective and prolonged drainage of the general peritoneal cavity is impossible, and that the serous discharge which flows out along the drain comes, in the majority of cases, from an exudation from the adhesions in the drain tract. In the second case it is doubtful whether the patient would have survived without any complication in view of the profound intoxication shown by his symptoms, but there was no improvement in the prognosis through the delay in resorting to surgical treatment. Nor did this treatment have any beneficial effect upon the condition, general or local, as shown by the subsequent history and the postmortem. This is largely due to the fact that the surgeon was practically asked to make an antemortem examination. It would be in just such cases as this, taken early, even before the onset of the peritonitis, that enterostomy might be of the greatest value.

## CONCLUSIONS.

1. Nonperforative peritonitis usually results from an extension of inflammation through the bases of deep intestinal ulcers, but may also arise from the migration of bacteria through an intestinal wall which is relatively but slightly abnormal.

2. Meteorism thus predisposes to infection of the peritoneal cavity and by decreasing the normal peritoneal absorption furnishes a secondary cause for peritonitis.

3. An hematogenous origin of peritonitis is possible in typhoid fever.

4. Nonperforative peritonitis is commonly caused by the typhoid bacillus and the resulting inflammation is usually diffuse and often severe.

5. The inception of such a peritonitis is clinically indistinguishable from the so-called signs of perforation, and the symptoms in both are due to peritoneal inflammation. The prognosis is probably equally grave in the two forms.

6. There should be appropriate surgical intervention immediately the peritonitis can be recognized. Enterostomy is indicated when there is meteorism with the peritonitis or when it affects the prognosis and is intractable to ordinary therapeutics.

7. Thrombi, and among them those composed of agglutinated red blood-corpuscles, may lead to hemorrhages into the wall of the intestine and the resulting changes favor the transmigration of bacteria into the peritoneal cavity.

8. Infarction of the spleen may have a similar thrombotic causation, but simple splenic infarction is probably not a cause of peritonitis.

9. The specific action upon human blood of an agglutinin generated by the typhoid bacillus can be demonstrated *in vitro*.

**Hygiene in Manila.**—The report of the Secretary of the Interior states that by direction of the Commission the board of health in Manila has taken upon itself the disposition of the night soil of the city, so far as this can be collected with existing facilities, and it has perfected plans for the introduction of the so-called "pail conservancy system." Adequate appropriation has been made by the Commission for initiating the installation of this system, which has begun and is progressing favorably. An immense amount of sanitary work has been done by the board and its employes. Many of the worst districts of the city have been thoroughly cleaned and a strict inspection of the buildings of the city has been maintained.

**The Insular Board of Health of the Philippine Islands** in conformity with the legal requirement that it do so has recommended to the Commission legislation on the following subjects: "An act regulating the practice of medicine and surgery in the Philippine Islands;" "an act regulating the practice of pharmacy in the Philippine Islands;" "an act regulating the practice of dentistry in the Philippine Islands;" "an act regulating the practice of veterinary medicine, surgery, and dentistry in the Philippine Islands;" "an act providing for the establishment of provincial boards of health, and fixing their powers and duties;" "an act providing for the establishment of municipal boards of health, and fixing their powers and duties;" "an act providing for the compulsory vaccination of the inhabitants of the Philippine Islands;" "an act providing for the control and suppression of leprosy in the Philippine Islands;" "an act regulating the manufacture, sale, and other disposition of alcoholic beverages in the Philippine Islands;" and "an act transferring the employes of the Board of Health of the city of Manila under the Provost Marshal-General to the Board of Health for the Philippine Islands."

## SPECIAL ARTICLES

## THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Proceedings Reported by the Secretary,  
WILLIAM J. GIES, M.S., Ph.D.,  
of New York.

**PRELIMINARY CONFERENCE.**—On January 19 last a number of biologists met by invitation at the home of Professor Graham Lusk to consider the desirability of perfecting an organization of active investigators in biology and medicine. This project was originally suggested by Dr. S. J. Meltzer and received the unanimous endorsement of all present. The temporary chairman of the meeting, Professor Frederick S. Lee, appointed Drs. Meltzer, Lusk, and Gies a committee on permanent organization.

**PERMANENT ORGANIZATION AND FIRST PROGRAM.**—The Society for Experimental Biology and Medicine was permanently organized in the Laboratory of Physiological Chemistry of Columbia University on the evening of February 25, where it met at the invitation of Dr. Gies.

**Constitution:** The objects and general character of the society are indicated by the following summary of provisions in its constitution and by-laws:

a. The main object of the society is the cultivation of the experimental method of investigation in the sciences of animal biology and medicine.

b. No one can be elected to membership who has not completed a meritorious independent experimental research in animal biology or medicine.

c. Every member shall be expected to conduct an experimental investigation and give public notice of it at least once in two years. Noncompliance with this requirement carries with it forfeiture of membership.

d. The program of each meeting shall consist of brief presentations of the essential points of experimental investigations in biology and medicine or allied natural sciences, preferably of *demonstrations* of actual experiments.

e. The meetings will be held in suitable laboratories.

f. Membership is not confined to residents of New York City.

**Officers:** The officers elected to serve for the present calendar year are: President, Dr. S. J. Meltzer; vice-president, Dr. Win. H. Park; secretary, Dr. William J. Gies; librarian, Dr. Graham Lusk; treasurer, Dr. Gary N. Calkins.

**FIRST PROGRAM.**—Although much of the time at the second meeting was taken up with the details of organization, the society emphasized its main purpose and function by carrying out, in addition, the following program of demonstrations of original work:

"An experiment to show the difference in effect between the simple cutting of the cervical sympathetic and the removal of the superior ganglion": S. J. MELTZER.

Dr. Meltzer presented a rabbit in which the cervical sympathetic had been cut on one side, and the superior ganglion had been removed on the other side. Both pupils were of the same size. About two hours before the demonstration one hind leg was tightly constricted and 1 cc. adrenalin injected into it (peripheral to the ligature). On removal of the ligature the pupil on the side from which the ganglion had been excised became greatly dilated, while the pupil on the other side remained unaffected.

"Differentiation of monkey blood from human blood by the precipitin serum test": JAMES EWING.

It has been known for some time that the serum of an animal immunized against a particular alien blood will precipitate proteids, not only in the particular blood used in the immunization, but also, to a lesser degree, in the blood-serum of closely related animals. Thus the serum of a rabbit immunized

The secretary has received an abstract of each report from the member making it, and in editing these abstracts has made only occasional verbal alterations in them, such as abbreviations and the like. The abstracts here given are in fact, therefore, the contributions of the several members themselves, and should be so credited.

against ox blood will precipitate proteids not only in ox blood but also in sheep and goat blood, etc. It is only when the anti-serum is diluted to a considerable degree that the precipitate forms only in the particular blood used in the immunization. This dilution, as a rule, must be as high as 1-50. In a series of tests with various humanized rabbit sera, it was found that monkey blood, which is very closely related to human blood, can be distinguished from human blood if the humanized rabbit serum is diluted in the proportion of 1-100 before it is added to the blood to be tested. In this dilution very active humanized rabbit sera fail to cause precipitates in the blood of lower monkeys (baboon, rhesus, and Java), while still causing flocculent precipitates within one to two hours in human blood.

The serum used by Dr. Ewing in this demonstration was obtained from a chicken which had received five injections each of 10 cc. of human placenta blood. This serum proved to be much more selective than the ordinary humanized rabbit serum. The chicken serum in various dilutions up to 1-100 was added to specimens of human and monkey serum in dilutions also of 1-100. It produced turbidities in all the specimens of human blood, but failed entirely to affect the monkey blood. Finally, the chicken serum was added in a dilution 1-5 to specimens of both human and monkey blood. In the human blood a milky ring formed instantly at the line of junction of the test serum with the human serum, and a flocculent precipitate formed in fifteen minutes, while in the monkey serum no change whatever could be observed.

"An improved cage for metabolism experiments": WILLIAM J. GIES.

A cage specially designed for experiments on dogs was shown. The parts are so adjusted as to favor the collection and separation of feces, urine and hair. The improvements consist mainly of mechanical devices suggested by experimental experiences of the past few years in metabolism work, all of which are designed to ensure quantitative accuracy as well as comparative convenience in the collection of excreta.

"Properties of 'Bence-Jones' body": WILLIAM J. GIES.

Through the kindness of Dr. Meltzer a patient's urine containing this substance had been placed at our disposal for chemical study. Some of the results of this investigation were presented and various properties of the body demonstrated. Special attention was drawn to a test of Boston's new method of detecting "Bence-Jones' body" in the urine.

FIRST REGULAR MEETING AND SECOND PROGRAM.—The third session of the society was held on the evening of April 15 in Professor Graham Lusk's laboratory at the University and Bellevue Hospital Medical College, New York City. Dr. S. J. Meltzer presided. In harmony with the aims of the society the evening was devoted mainly to reports of original work done by the members, with demonstrations of methods and results. The program was as follows:

#### I. REPORTS OF ORIGINAL WORK, WITH DEMONSTRATIONS.

"Changes in the blood-volume of the vein of the submaxillary gland on stimulation of the chorda tympani and sympathetic nerves": R. BURTON OPITZ.

Dr. Burton-Opitz explained the mechanism of a recording stromuhr by means of which he made quantitative determinations of the blood flow in the vein conveying the blood from the submaxillary gland. The blood-volume was measured previous to, as well as during the stimulation of the secretory nerves. The curves which were exhibited showed very striking changes in the blood flow, namely, an increase on stimulation of the chorda and a decrease when the current was applied to the sympathetic fibers. In the former case the volume of the blood flow (cc. per second) was from about two to nearly six times as great as normal, and in the latter case it was from about one-half to one-fifth the normal volume. By using a strong stimulus a complete cessation of flow can be produced.

"Does a backward flow ever occur in the veins?": R. BURTON-OPITZ.

The results of this investigation may be summarized as follows: A backward swaying of the column of blood in the central veins is a constant, normal phenomenon. It is pro-

duced by two factors: first, by the contraction of the right side of the heart; and second, by high intrathoracic pressure (forced expiration). If the distal conditions in the venous system are favorable, this backward movement can also be obtained in the peripheral veins (femoral veins). The same instrument was used in this investigation as in the former.

"A new method of studying metabolism": GARY N. CALKINS.

Dr. Calkins described experiments now in progress upon metabolism in unicellular animal organisms. These forms, reproducing by simple division, offer the same protoplasm for study generation after generation, and with each division the daughter organisms, by reason of the functions of regulation and regeneration, perfect themselves in the race-type, while digestion, assimilation, waste, repair and growth are handed down unchanged from cell to cell. The problem is to ascertain whether these various functions will continue their activities indefinitely or whether protoplasmic old age will supervene to put an end to the race. In nature such an end is prevented by sexual union, whereby the conjugating organisms are rejuvenated.

In the experiments by Dr. Calkins this function was prevented by isolation. The general metabolic functions were out four consecutive times at intervals of six months, and each time, except the last, the race was saved only by a change in diet or by chemical stimuli. The phenomena were analogous to those in the artificial fertilization experiments of Loeb and others, with this difference, that if comparable with artificial parthenogenesis, the process was repeated with the same protoplasm three consecutive times. In the fourth period of degeneration the stimuli previously tried were no longer effective and the race died out, 742 generations old. Structural changes were different in the different periods of depression. The degenerate animals, in the periods which were successfully overcome, had curiously altered nuclei and endoplasm. In the last period of depression which was not overcome, the nucleus and endoplasm were normal, while abnormal parts were found in the micronucleus and the cortical plasm.

The conclusions which this part of the work seems to justify are: 1. That "old age," so-called, of the cell may be due either to the wearing out of functions, or to the degeneration of structural parts. The former is capable of artificial rejuvenescence, the latter apparently not. 2. The ordinary functions of metabolism, such as digestion, assimilation, excretion, growth, etc., are dependent upon certain definite portions of the cell (macronucleus and endoplasm), while the dividing energy is a function of the micronucleus and of the cortical plasm. 3. After conjugation the organisms start with high potentials of metabolic energy which gradually wear out, but which can be restored artificially. So, too, the dividing energy starts with a high initial potential energy, but which cannot be restored after exhaustion.

In the light of these experiments it would be pertinent and instructive to ascertain whether artificial parthenogenesis, in sea-urchins for example, could be repeated more than once on the same continuous protoplasm. On a priori grounds a successful result would be extremely doubtful.

"On the origin of cholesterin in gallstones": C. A. HERTER.

Dr. Herter said that experiments made in his laboratory by Dr. Wakeman give strong support to the views that inflammatory conditions of the walls of the gallbladder may lead to an increase in the cholesterin of the bile. Dr. Wakeman injected strong solutions of bichlorid of mercury into the gallbladders of dogs previously starved for three days. After periods of from two to five days the animals were killed. As a rule the gallbladder walls were much thickened and the epithelium was proliferated and desquamated. The solids of the bile were diminished in percentage. The cholesterin content was much increased. The contents of the gallbladder in these experiments were sterile. These facts are of great interest in relation to the etiology of gallstones.

"On nucleic acid": P. A. LEVENE.

According to Osborne, nucleic acid derived from the plant cell differs from that of the animal cell with variations in the characters of the pyrimidin base present in its molecule. Dr.

Levene has devised a new method of separating the pyrimidin bases, in which he avoids the precipitation with silver. With this method he has obtained from the animal nuclei acid (derived from the spleen and pancreas), beside thymine and cytosine, also uracil. The radicle of the latter substance had been supposed to occur only in the plant nucleic acid. Kossel and Stendel have made this same observation in regard to the nucleic acids derived from the thymus gland and from fish sperm.

"*Respiration experiments in phlorhizin diabetes*": GRAHAM LUSK (with A. R. Mandel).

An experiment on a diabetic dog showed that, whether fasting or fed on meat alone, or on meat and fat, no more fat was burned than in the same dog when he was normal and fasting.

"*A modified Eck fistula, with a note on adrenalin glycaemia*": A. N. RICHARDS.

A method devised by Vosburgh and Richards for establishing communication between the portal vein and the inferior vena cava of the dog was described and demonstrated. In this method two cannulas are employed. They are constructed on the same principle as the one used by Vosburgh and Richards in collecting blood from the hepatic and portal veins without interfering with the normal circulation in those vessels.<sup>1</sup> After suitable incision through the abdominal wall a cannula of that type, 1 cm. long, was inserted into the portal vein about 2 cm. below the entrance of the pancreatico-duodenalis. A second cannula of similar design was introduced into the vena cava at a corresponding point. By connecting the cannulas with a rubber tube, communication was established between the two vessels. On ligating the hepatic arteries and the portal vein at the hilum of the liver, circulation through the liver ceased and the gland was extirpated.

By the successful use of this method Vosburgh and Richards have found that the application of adrenalin to the surface of the pancreas brings about a slight rise in the sugar content of the blood even after extirpation of the liver. Their experiments thus far have covered periods of from two to three hours, no systematic attempts having yet been made to get the animals to survive the operation.

## II. REVIEW.

"*Aims and achievements in recent experimental cytology*": GARY N. CALKINS.

A review of Loeb's, Wilson's, and Boveri's experimental researches.

**No Quarantine Against Cuba.**—Health Officer Dr. A. H. Doty says there will be no quarantine against passengers arriving from Cuban ports during the coming season, which generally begins on May 1, unless there was some evidence that yellow fever prevailed at Cuban ports. Cuba has been unusually free from yellow fever during the past two years, not a single case being reported at Havana or any of the other ports during that time. Last year's quarantine did not go into effect until July 1, two months later than the usual time.

**Suicide in Army.**—A French student has been investigating the subject of suicides in the armies of Europe, and has reached some curious results. Everywhere, except in Russia, the number of military suicides is decreasing; in that country, however, the average for some years past has been 133 in every 100,000. In France the proportion now is 18 in 100,000; in Italy, 24; in Germany, 36, and in Austria, 105 to every 100,000. In civil life in this country the Germans provide the largest proportion of suicides; it is curious to find them surpassed in Europe by the Austrian and Russian soldiers.

**To Stop Milk Inspection.**—What is regarded as a covert attempt on the part of local milk dealers to defeat the present salutary law which makes punishable adulterations and dilutions of milk has been found tucked away in an ambiguously worded bill. According to this measure prosecutors would be compelled to show "wilful intent" on the part of violators before they could be held amenable to the law. Those sections of the law which would be superseded by the new act involve the sale and inspection of milk within the boundaries of the city, and heretofore the officers of the Health Department have secured convictions in the cases which they have prosecuted on the analysis of the inspectors, and the fact that the laws regulating the milk traffic are too well known to permit of violations through ignorance. To be compelled to prove "wilful intent" practically would put an end to all prosecution unless a bureau of detectives is placed at the disposal of the Health Department to work in conjunction with the inspectors.

## 2.—Requirements for Admission to Medical Colleges.

—E. A. de Schweinitz believes that a student should have had training in biology before entering a medical college, though this is not absolutely essential. He is of opinion that the present tendency in medical colleges is toward too great specialization in the various branches. We should give each student a good, general, solid groundwork, and afford him an opportunity to determine in his own mind the particular line to which he is best adapted. Requirements in Latin could with good results be substituted for French and German, though requirements in these languages for entrance is unnecessary. Familiarity with French and German is not so essential in the present advanced state of medical journalism as formerly, since excellent abstracts of all foreign articles appear in the various journals. High school graduates usually make better students than the average college graduates. Advanced standing should be refused to graduates in veterinary medicine, dentistry, pharmacy, and from literary colleges. Certain medical studies should be allowed to count toward an A.B. degree, but the latter should not count toward a medical degree. No medical college should receive a student from a similar college unless he holds a special letter from the dean of the school from which he comes. Only in this way can fraud be prevented. [A.B.C.]

## 3.—Requirements for Admission to Medical Schools.

—J. R. Parsons, Jr., defends the present position and standard established by the New York board of regents, making it necessary for students before they enter a medical college to attain certain literary proficiency. At present only 4 medical schools in the United States exceed more in quantity than is represented by the New York medical student certificate. When medical schools conduct their own entrance examinations the tests are often mere matters of form, hence the benefit of a board of regents. The board of regents in New York takes as its basis for requirements for entrance into a medical college a 4 years' high school course based on an 8-year elementary course; 17 medical colleges in the United States require a standard equivalent to this. Seventy-nine out of 80 medical schools communicated with accept the New York medical student certificate at its face value. The author believes that authorities should not be too specific in prescribed entrance requirements—that is, that certain alternatives within reasonable bounds should be permitted. He also believes that as medical schools are strengthened and their faculties increased they can admit to the second year of medicine more freely those with baccalaureate degrees, embracing a general training in the languages, physics, chemistry, biology, and mathematics. In other words, that a 3-year professional course based on a 4-year college course is preferable to a 4-year medical course based on a high school course only. [A.B.C.]

**4.—Oblique Inguinal Hernia.**—A. E. Benjamin gives a more or less theoretic discussion on the treatment of this condition, and wisely asserts that the numerous methods in treatment simply illustrate the fact that no one method answers every specific purpose in all cases. He believes that too vigorous scrubbing of the parts before operation conduces to infection. Other contributing causes or factors toward failure to secure good results are careless preparation of the operator's hands; operation on patients suffering from some constitutional or local disease so-called; sutures that are absorbed too quickly; improperly

sterilized sutures; failure of proper approximation of tissues; too great tension on tied sutures; incomplete dissection and ligation of the union of absorbent sutures; and mauling of the tissues. The present tendency is toward operative rather than palliative treatment in cases suitable for operation. The truss for elderly and debilitated persons and operation for young and vigorous middle-aged persons is the general rule. The author describes an operation which follows in a general way Bagnini's method, except that in closing the wound the sutures are brought out through the skin and tied over a roll of gauze, and are thus capable of being removed when healing has been accomplished. [A.B.C.]

**5.—Treatment of Cancer of the Rectum.**—C. H. Mayo reviews the literature of the subject and mentions the various operations which have been advocated for treating this baleful condition. After the best operative methods of the present time only about 15% of patients secure anything like a controllable anus. The present tendency is toward the combined abdominal and sacral routes unless the growth be situated very low down where it may be attacked by the perirenal route only. If permanent colostomy becomes necessary the author advocates a median incision, double clamp and cut the sigmoid above the cancerous growth, inverting the mucous membrane of the proximal end, ligating the superior hemorrhoidal artery, and bringing the proximal portion out through the abdominal wall by a McBurney gridiron incision in the left iliac fossa. It is claimed that this gives better control of the bowel contents. The main objections of the past as summed up by the author are ineffectual removal and local recurrence; extensive mutilation by the Kraske method; frequent failure by all methods of union between the proximal and distal portions of the bowel; frequent formation of stricture following operation; straightening and tension on the sigmoid, destroying it as a fecal container. The advantages of the combined method are radical removal *en masse* of all glands, fat, and connective tissue, or colostomy for palliation; retention of the sigmoid as a fecal container; peculiar formation of the anus, giving a fair degree of control in an accessible situation. [A.B.C.]

**6.—Sclerema Neonatorum.**—E. R. Stillman reports the case. He has found but seven such cases reported in American literature, and a few in European literature. The patient was an infant which showed the typical symptoms of sclerema neonatorum. The skin on the back was hard, indurated, could not be pinched up in folds, was densely adherent, and seemed to be fused indefinitely with the underlying structures. The condition grew worse. The infiltrated areas were bluish-black. The legs were flexed at an angle of 45%, stiff, and could not be bent. Later, the sclerema extended to the chest. A blood examination showed 6,000,000 erythrocytes, the bowels moved sluggishly, the urine came in small amounts and at frequent intervals. Death occurred, and necropsy showed nothing to account for the peculiar condition. [A.B.C.]

**7.—Hypertrophy of the Synovial Fringes of the Knee-joint.**—E. G. Abbott gives an interesting discussion on this subject, dealing with the etiology, pathology, symptoms and treatment in these cases. He reports in some detail 12 cases, and his conclusions are that these cases should be considered individually and not included among the other diseases of the knee-joint. A microscopic examination of the tissue removed shows the pathologic process to be inflammatory and not due to microorganism. The etiology is obscure, but apparently due to the weight-bearing structures of the lower extremities. Pes planus in nearly all cases precedes the knee-joint trouble, and the use of a plate is of great service in treating the affection. Diagnosis is not difficult, although a torn cartilage may simulate this condition. Intact cartilages were found in all cases in which operation was performed. Paralysis of the quadriceps muscle was found in three instances previous to operation which could not be accounted for, and in several instances this occurred after operation, and was the last symptom to disappear. The question whether a case should be treated by operation or by mechanical means must be left to the judgment of the operator. [A.B.C.]

**8.—The Use of a Mydriatic After the Age of Forty-five.**—H. M. Starkey concludes his article on this subject reporting

many cases, and entering somewhat technically into the discussion. His final conclusions are that no age can be arbitrarily fixed beyond which cycloplegics must not be used and they are as necessary in certain cases after 45 as they are before. They are required in fewer cases as life advances, but since there is more danger of glaucoma in the elderly and as mydriatics tend to increase intraocular tension, these drugs should be used with caution after the age of 40 and in certain cases should not be used at all. [A.B.C.]

**9.—Carcinoma Epibulbare Pianum.**—B. Matys defines epibulbar tumors as those which are located on the margin of the cornea where it joins the sclera, from which they spread over the cornea and conjunctiva and sometimes into the sclera. They do not include secondary tumors occurring in the ciliary body, choroid or lids. He reports a case occurring in a man of 78 and exhibits a number of illustrations. He calls attention to the common error of neglecting an incipient tumor occurring at the limbus or its vicinity, and notes the differential diagnosis between phlyctenula and tumor in the cornea, also between these and carcinoma or sarcoma of this region. [A.B.C.]

**10.—Laboratory Inspection of Vaccine.**—Adolph Gehrmann reports on the vaccine examined by the Chicago Department of Health. He says that since July, 1894, an extended investigation of vaccine has been made, which showed that glycerinated lymph contained fewer bacteria and had a longer period of efficiency than the dry vaccine points. The former was therefore introduced, and has been exclusively used ever since. There have been distributed to the vaccinators approximately 1,000,000 individual vaccinations from the above date. Each lot is subject to a test before it is allowed to be used. Vaccine as now prepared consists essentially of ground up epithelium in a variable percentage of glycerin and water. If this mixture is not accurately adjusted it may be too thin, and separation takes place in time, injuring the quality of it. The virus must be as clean as possible, but it cannot be made initially sterile by using antiseptics. *Bacillus subtilis*, *Cladothrix dichotoma* and various molds and yeasts have been found in such quantities as to require rejection. Animal experiments are made on guinea pigs. He states that from such experiments the bacillus of tetanus and tuberculosis and other specific bacteria could be found. The statement is made that after several hundred inoculations the author had not seen a single animal die of tetanus, nor show tuberculosis at the point of injection. These bacteria occur with extreme rarity in vaccine, and probably in the few cases where they have been reported they could have been found in considerable numbers. [A.B.C.]

#### Boston Medical and Surgical Journal.

1. The Reaction Time of Corrosive Sublimate in Different Dilutions Against Various Species of Bacteria. CHARLES HARRINGTON and HAROLD WALKER.
2. The Cortical Cell Changes in Epilepsy: Their Significance and Clinical Interpretation. L. PIERCE CLARK and THOMAS P. PROUT.
3. Double Uterus and Vagina. C. H. HARE.
4. A Case of Uterus Bicornis Duplex, with Two Cervical Canals Above, One External Os and Stricture of Vagina. W. L. BURRAGE.
5. Pregnancy in a Uterus Bicornis Simulating Extrauterine Pregnancy. FRANK A. HIGGINS.

**1.—Corrosive Sublimate Solution and Bacteria.**—C. Harrington and H. Walker, after a rather exhaustive study, conclude as follows: 1. Different species of pathogenic bacteria and different cultures of the same species vary very greatly in their resistance to the action of corrosive sublimate. 2. With some species resistance is diminished in a remarkable degree by a condition of dryness, so that even the 1:10,000 solution can bring about sterility in a very short time. But some species are not materially affected in this respect by dryness. 3. Corrosive sublimate in as weak solution as 1:5,000 is ineffective against the common pathogenic bacteria, including the pus organisms, when they are moist, excepting after prolonged contact. Since fifteen minutes' contact is not sufficient for the destruction of *B. coli communis*, *B. pyocyaneus* and *Staphylococcus pyogenes albus* in the moist state, or of *Staphylococcus pyogenes aureus* whether moist or dry, the use of this and of weaker preparations in surgical work and for irrigation and similar purposes should be abandoned. 4. Corrosive sublimate

in the 1:1,000 solution is very slow in its action on some of the commonest of the skin bacteria, and since under the most favorable conditions more than ten minutes' contact may be necessary for it to kill *Staphylococcus pyogenes albus* it should not be relied upon to any great extent to ensure sterility of the hands or of instruments. [A.B.C.]

**2.—Cortical Cell Changes in Epilepsy.**—P. Clark and T. P. Prout, after a careful study, express their conclusions as follows: That the missing links of our knowledge of epilepsy consist in the fact that its pathogenic agents and the organic anomaly of the cortex, which constitute its predisposition, still hold the mystery of frequent relapses. By this study, however, we claim to have narrowed the gap between the terminal gliosis and the toxic and autotoxic agents in the disease pathogenesis, and we believe this is largely comprised in cell changes and those particularly of the nucleus. [A.B.C.]

**3.—Double Uterus and Vagina.**—C. H. Hare reports five cases of double uterus and vagina coming under his personal observation. The external genitals with little exception were normal, a septum dividing the vagina into two canals, both containing a cervix penetrable by sounds without touching. In two cases the fundus also was double, but in the others there was a single fundus. In one case both tubes and the right ovary were removed for double pyosalpinx; in another case a cyst the size of a lemon of the left ovary was removed; in the others the abdomen was not opened. [w.k.]

**4.—Uterus Bicornis.**—W. L. Burrage gives the history of a woman suffering from persistent dysmenorrhea. In 1895 the constricted vagina was dilated and the uterus curetted with only temporary relief. This treatment was repeated in 1898 with similar unsatisfactory results, and in 1903 she again entered the hospital under Burrage's care. The abdomen was opened when it was seen that the uterus was double and adherent. Supravaginal amputation was performed and two distinct cervical canals were found and two separate uterine cavities. Several fibroid nodules were imbedded in the uterine tissue and there was much soft tissue lining each uterine cavity. [w.k.]

**5.—Pregnancy in Uterus Bicornis.**—F. A. Higgins thinks that cases of uterus bicornis are not very rare. Since most cases reported are discovered by accident it is fair to suppose that the average case gives rise to no symptoms. He gives the history of a woman who had an operation for repair of cervix and a curetment. Six weeks later she began to suffer from almost daily hemorrhage, and the physician diagnosed extra-uterine pregnancy, advising operation. The abdomen was opened, and the inner third of the left tube was enlarged, the other tube and both ovaries being normal. This apparent tumor was dissected out at the uterine surface by a V-shaped incision and the uterus closed in. The patient recovered, and at the time of her discharge was 4½ months pregnant, conception having taken place about a week before the first operation. There was no further hemorrhage after the operation, and the writer assumes that it was the left cornu of the uterus which was curetted while the ovum was lodged in the right cornu. These two operations seem to demonstrate the remarkable tolerance of the pregnant uterus in many cases of operable procedure. [w.k.]

### Medical Record.

April 25, 1903. [Vol. 63, No. 17.]

1. Observations on Some Limitations of Diagnosis. EDWARD G. JANEWAY.
2. The Toxicity of Appendicitis, with a Report of Two Cases of "Appendicular Vomito Negro." GEORGE RYERSON FOWLER.
3. Cardioposis and Its Association with Floating Liver. MAX EINHORN.
4. The Pathogenesis of Diabetes. HENRY S. STARK.

**1.—Limitations of Diagnosis.**—Janeway gives numerous illustrations indicating the difficulty at times of differentiating variola and varicella. Great responsibility rests here upon the physician, because an incorrect diagnosis may be of enormously serious import. Textbooks are at variance with each other and inconsistent in themselves in describing the two diseases, especially in differentiating them. In his experience that severe form of variola called purpura variolosa has become epidemic as a result of being diagnosed black measles, spotted fever, or purpura. While mistakes in this connection are sel-

dom made now typhoid and typhus were formerly often mistaken the one for the other. The Widal test and the present infrequency of typhus cause fewer mistakes now. One child in a family dies of meningitis, apparently, when a second comes down with a well-marked case of scarlet fever. The strong probabilities are that both were the latter. All know how frequent have diphtheria and other throat affections been mistaken the one for the other. Limitations in diagnosis is evidenced by the urgent quest of surgeons for some means of making early diagnosis of malignant disease of the internal organs, particularly the stomach and intestines; by the frequent inability to differentiate internal tertiary lesions of syphilis from tuberculosis, malignant disease, etc.; by the frequent difficulty of arriving at a correct diagnosis when the patient complains of symptoms of dyspepsia and cardiac disturbance, particularly if of the nature of angina. Optic neuritis was once thought to point almost conclusively to tumor of the brain, and absence of hydrochloric acid to malignant disease of the stomach. Both are now considered collateral signs only. [A.B.C.]

**2.—Toxicity of Appendicitis: Black Vomit.**—G. R. Fowler reports two cases of "black vomit" occurring in appendicitis. In both cases the appendix was gangrenous, "black vomit" began some hours after operation, and in both instances the color was found by laboratory examination to be due to blood. Both patients died. Necropsy was secure in but one case and in the stomach was found from 200 to 300 small ulcers. He says in a most conservative summing up it may be said that the occurrence of hematemesis has added another to the long list of grave complications of appendicitis. From the pathologic standpoint it is interesting to note that the exclusion of embolism in the production of the ulceration of the gastric mucosa by Nitzsche is not borne out by Prof. Van Cott's findings in the author's own case, in which both emboli and staphylococci were found. The view that the microorganisms were transported to and produced thrombi and subsequent embolism in the vessels is sustained, first, by the fact that in one of the sections there is a focus of necrotic tissue in which the microorganisms appear, the vessels of the submucosa near this area containing recent thrombi, and second, in another section an embolus appears involving a vessel in the mucosa near its bifurcation. [A.B.C.]

**3.—Cardioposis Associated with Hepatoposis.**—M. Einhorn calls attention to this condition and reports several cases. Etiology is not well understood, but emaciation and neurasthenia are mentioned. It occurs much more frequently in men, the supporting action of the corset in women probably accounting in part for this. Symptoms are palpitation, vertigo, and occasional inability to lie on the left side. The heart, otherwise normal, is displaced downward, usually the width of a rib and intercostal space, and its range of mobility is somewhat increased. In nearly half the cases of cardioposis a general enteroposis is found, and in all cases some degree of hepatoposis. This point seems to have escaped the attention of most observers. It seems at first singular that in all cases of cardioposis a hepatoposis should be present. Descent of the heart, however, necessarily causes descent of the diaphragm, and the latter condition causes the hepatoposis. Not all cases of hepatoposis, however, are associated with cardioposis. Prognosis is good, life being in no special danger. The treatment is psychologic, hygienic, and symptomatic. [A.B.C.]

**4.—Pathogenesis of Diabetes.**—H. S. Stark deals rather exhaustively with several theoretic explanations of the etiology of diabetes and offers his conclusions as follow: 1. The exact truth of the pathology of diabetes is not known. 2. There are no acknowledged and constant anatomic appearances of liver or of pancreas associated with diabetes. 3. There are no characteristic lesions in any other organ. 4. An impairment of the physiologic functions of the ductless glands may be at the root of the disease. 5. Artificial glycosuria is not diabetes. The facility with which this phenomenon can be elicited implies its insignificance as a pathologic factor. 6. So far as can be ascertained from competent sources there is hope that the vacuum in our knowledge of the nature of diabetes will soon be filled. [A.B.C.]

## New York Medical Journal.

April 18, 1903. [VOL. LXXVII, No. 16.]

1. The Therapeutic Value of the Röntgen Ray in the Treatment of Pseudoleukemia. N. SENN.
2. A Plea for the Hospital or Office Treatment of Diseases of the Rectum and Anus. SAMUEL G. GANT.
3. The Practical Uses of Hypnotic Suggestion. WILLIAM LEE HOWARD.
4. The Work Performed by the Diagnosis Laboratory of the Department of Health in Connection with Ehrlich's Diazo Reaction During 1902. J. S. BILLINGS, JR.
5. The Treatment of Some of the Surgical Complications in Typhoid Fever. JOHN F. ERDMANN.
6. Is the Cognomen, "Chemical Physiology," Scientific? A Study of Vital Processes. JOSEPH CLEMENTS.

**1.—Röntgen Ray Treatment of Pseudoleukemia.**—N. Senn reports two cases of pseudoleukemia treated successfully by this method. The first is that of a man of 43. The glandular affection dated back one year, and involved extensively the glands of the cervical, axillary, and inguinal regions. He was given treatment daily for the first 10 days, 60 volts, 8 amperes, being used each day; distance of tube from surface, 12 inches, a medium vacuum tube being used. After 10 treatments the glands had undergone a noticeable reduction in size. There was considerable dermatitis, and it was necessary to reduce the voltage and ampérage to 42 and 6 respectively. After six treatments the voltage was again reduced. After 24 treatments had been given, it was found that the affected glands had almost disappeared. The burns were extensive and the treatment discontinued. Two weeks later the glands had entirely disappeared. Three months later the cervical and axillary glands were slightly enlarged. Ten daily treatments were given and the glands promptly disappeared. Several months have elapsed and there has been no return of the disease. The second case is that of a man of 53. The glandular involvement dated back 10 years, the glands of the neck, axilla, and groin being extensively involved. The Röntgen rays were applied to the neck, axillas, elbows, chest, abdomen, and groin of each side every alternate day. After four or five sittings there was unusual softening of the glands and a gradual diminution in their size. After 15 treatments, a slight dermatitis appeared and general symptoms of toxemia. Treatment was discontinued for three weeks, when the glands were found much diminished in size. The applications were again resumed. After 12 treatments the symptoms of toxemia were so pronounced that further treatment was discontinued. Only two small glands could be found and these soon disappeared. Several months have elapsed and the patient considers himself in perfect health. [C.A.O.]

**2.—Office Treatment of Rectal Diseases.**—S. G. Gant points out the many rectal diseases suitable for office treatment and discusses what he considers the simplest, safest and least painful procedures which accomplish the most certain results. The local anesthetic preferred is eucain B, 3%. He has recently radically cured in his office many cases of small bleeding and protruding hemorrhoids by eucanizing and ligating the tumors, the ligatures being applied in a shallow incision made around their bases. Such piles may be treated by the clamp and cautery, but the operation is not so well suited for the office treatment. Polypoid growths can be easily removed in the office, and abscess cavities can be opened, irrigated and drained. The methods which may be employed in the office treatment of anal fistula are complete division, ligation, and injection. Complete division is the best procedure. The ligation operation is occasionally justifiable in debilitated, phthisic subjects, because it avoids the loss of blood. Complete division of the sphincter is the most certain method of relieving fissure. Superficial ulcers may be speedily cured by securing soft evacuations, cleansing the parts, and applying a solution of ichthyol 10%, silver nitrate 3%, zinc sulfate 4%, or balsam of Peru 25%. Deeper ulcers should be cauterized. Coloproctitis and pruritus in most instances can be successfully treated in the office. The author believes that massage is one of the most essential features in the nonmedical treatment of chronic constipation. Electricity is a very valuable adjunct and faradism has given the best results. Enemas are sometimes necessary early in the treatment. The after-treatment following operations performed in the office consists mainly in keeping the wounds healthy by means of cleanliness, good drainage and topical applications, and in regulating the stools by prescribing two-ounce doses of carabana water, to be taken before break.

fast; and finally in the use of suppositories containing morphin, cocain, and belladonna, alone or in combination, when necessary to relieve pain. [C.A.O.]

**3.—Hypnotic suggestion** is discussed by W. L. Howard, and some of its practical uses presented. He finds its greatest value in making a diagnosis between functional and organic brain disturbances. The pains of locomotor ataxia, rheumatism, neuralgia, etc., may be relieved, but the relief is seldom enduring, and but few persons suffering from these diseases are good subjects. Hysteria is the best field for the practice of hypnotism. Pain is abolished and anesthesia produced, paralysis, spasm, and contracture corrected, affections of the digestive and genitourinary system, Raynaud's disease, polyuria, anuria, affections of the special senses, and all the expected or unexpected disturbances arising from an unstable nervous organization are cured or modified by hypnotic suggestion. [C.A.O.]

**4.—Diazo Reaction.**—J. S. Billings, Jr., gives a review of the work performed by the laboratory diagnosis of the health department of New York in connection with Ehrlich's diazo reaction during 1902. He has found that the reaction is more constant in typhoid fever than almost any other sign or symptom, not excepting the Widal reaction in the blood. It is most marked between the fourth and tenth days, being found in the great majority of cases by the fourth day, and in not a few on the third. The more intense the infection the earlier the appearance of the reaction. It begins to fade after the tenth day, and in many cases has disappeared by the beginning of the third week. [C.A.O.]

**5.—Surgical Typhoid Complications.**—J. F. Erdmann confines his paper to the subjects of abscess of the liver, subphrenic abscess, perforation of the gallbladder, cholecystitis and intestinal perforations. When the abscess of the liver is situated below or within the costal arch, the method of approach is that of an ordinary laparotomy. Should the patient be in a markedly low condition local anesthesia should be employed. When the abscess is behind the ribs a subpleural or transpleural and diaphragmatic operation may be required. This is often best done by the excision of sections of one or more ribs, and careful dissection of the pleura from the costal wall and then from the diaphragm, with puncture through the diaphragm, constituting the subpleural operation. This is only feasible in those hepatic and subphrenic abscesses occurring low in the costal region. Transpleural and transdiaphragmatic operations must be done in those cases in which the pus has collected high in the costal region. A case of perforation of the gallbladder in a woman of 46, occurring at the beginning of the sixth week of typhoid, is reported. An incision was made through the right rectus and a cholecystectomy done. Recovery and union was complete in three weeks. Operative interference in cholecystitis depends largely upon the symptoms presenting. If marked rigidity of the upper rectus segment continues for 36 to 48 hours without any diminution, if the temperature and pulse can be definitely ascribed to a septic condition other than that of the toxemia of typhoid, and if imminent rupture of the bladder is suspected, an operation should be done—cholecystotomy, if the patient's condition is bad or if cholangitis is present; cholecystectomy if cholangitis is not suspected or the patient's condition warrants this procedure. The author reviews the subject of intestinal perforation, and concludes that not more than three or four hours should be given for the shock to subside before operating. He believes that if a fairly clean toilet can be made, no drainage should be used. [C.A.O.]

## Medical News.

April 25, 1903. [Vol. 82, No. 17.]

1. The Treatment of Syphilis. W. D. TRENWITH.
2. The Treatment of Acute Gout. J. R. CLEMENS.
3. Chronic Parenchymatous Pulmonary Tuberculosis. WM. N. BEGGS.
4. Spinal Cord Injury, So-called Concussion of the Cord. FRANK PARSONS NORBURY.
5. Report of a Case of Monocular Inferior Hemianopsia. E. S. SAYLOR.
6. Hydragogin: Some Observations Upon Its Use in Diseases of the Heart and Kidneys. M. LORWENTHAL.
7. The Use of Normal Salt Solution. HARRY FRENCH THOMPSON.

**1.—Treatment of Syphilis.**—W. D. Trenwith says cleanliness is the main thing in treating the chancre. It should

be washed twice daily with warm water and soap, then with mercuric chlorid 1-2,000, then dressed with gauze wet with the same solution: No effort at excision of the chancre should be made. During the period between the appearance of the chancre and the eruption tonics containing iron should be given, the teeth should be put in the best possible condition, plenty of rest and sleep secured, the body should be well nourished, tobacco and alcoholic beverages should be limited, and everything done to prepare the patient for the oncoming attack. So soon as the eruption appears a serious talk should be had with the patient, and he warned of his necessity to cooperate with the physician. All tobacco, intemperance and coitus should be prohibited. The author now starts the administration of mercury, either by mouth or by inunction. If by mouth, this is not continued longer than the first two or three weeks, when it is replaced by inunctions. He used the official 50% ointment of mercury, and has it put up in wax papers of 30 to 40 grains each. Inunctions are made on successive parts of the body until all parts have received a treatment. After some two weeks this is replaced by a course of iodids for a like period, and then inunctions are again instituted for a like period, to again be replaced by iodids. This alternate treatment is continued for six or seven months, when a rest of three or four weeks is given, after which mixed treatment of the mercury biniodid and potassium iodid is continued to end of the first year. After this large doses of potassium iodid are given for about two months out of every four, with occasional administration of mixed treatment, to end of second year or longer, when all treatment is stopped and the patient watched carefully for a year or more. [A.B.C.]

**2.—Treatment of Acute Gout.**—J. R. Clemens institutes treatment by giving free doses of calomel, followed several hours later by black draught; this not only for purgation, but to relieve hepatic congestion. After this he keeps the bowels loose with salines and the tincture of colchicum. The latter should continue to be given in small doses so long as there is pain in the joints. The local treatment of the joints is important, and should always consist of some form of warmth. That recommended is a mixture consisting of sodium carbonate, tincture of opium, and belladonna mixed with hot water. Dressings wrung out of this are placed about the joint, covered with oiled paper, and this in turn by cotton wool and a bandage. The diet should be restricted during the acute stage and the patient kept in bed. Never apply cold to a gouty joint. Copious draughts of hot water should be drunk. [A.N.C.]

**3.—Chronic Parenchymatous Pulmonary Tuberculosis.**—W. N. Beggs calls attention to this form of tuberculosis and states that the great majority of textbooks gives a poor classification of tuberculosis of the lungs, many neglecting this form altogether. He quotes with approval Powell's description of this form of pulmonary tuberculosis, who designates it "chronic tuberculous phthisis." In a somewhat exhaustive paper the author reports 14 cases. He condemns the practice so common among physicians of sending these cases indiscriminately to Colorado when so many of them are doomed to early death. His conclusions are: It is a perfectly characteristic type of pulmonary tuberculosis, distinctly different from those generally recognized. It is constant in its progress and bad in its prognosis. It is scarcely less fatal than phthisis florida, though its duration is longer. It is very insidious, and this tends to cause error on the part of the physician and a mistaken sense of security to both patient and medical adviser. The preceding two reasons render its early recognition of great importance to both physician and patient. [A.B.C.]

4.—See *American Medicine*, Vol. IV, No. 17, p. 648.

**5.—Monocular Inferior Hemianopsia.**—E. S. Saylor reports the case. A woman of 27 in a fall struck her head against a heater, producing a severe wound. Two weeks later she experienced a flash of light followed by dimness of vision in the left eye. Later she noticed when looking at an object with this eye she only saw but the upper half of it. There was no pain and no inflammation. Examination of the eye showed vision much decreased; there was no detachment of the retina, tension was normal and the bloodvessels were nearly so. Embolism and cortical disease were ruled out. The author

concluded the affection must be retrobulbar neuritis of rheumatic origin. The administration of the salicylates was followed by almost complete relief. [A.B.C.]

**6.—Hydragogin in Cardiac and Renal Diseases.**—M. Loewenthal has used this drug in a number of cases, and his conclusions are that in hydragogin the profession has a valuable addition to the cardiac stimulants. For functional derangements, like palpitation, he knows of nothing superior to it; and it has a particular effect to increase the power of the heart's contraction in a more regular and uniform, though not in so powerful a manner as digitalis alone. For increasing the specific gravity of the urine in chronic Bright's disease it surpasses digitalis or any other drug known to the author. In severe cases of acute diseases, such as pneumonia, sudden prostrations in fevers, in peritonitis, cardiac exhaustion, and in many other like conditions, we meet with the most signal illustrations of the advantage of the combined action of cardiac remedies as presented in hydragogin. The author begins with 10-drop doses every two or three hours, but if nausea, weakness, copious dejections from the bowels, or intoxication occur, he suspends the remedy for 24 hours, then begins again. [A.B.C.]

**7.—Injection of Normal Salt Solution.**—H. F. Thompson gives his experience in the use of salt solution. A man of 40 ate plentifully of fish and cheese. Some hours later he was taken with retching, vomiting, and purging. Collapse supervened. His condition on the third day was critical. Ten ounces of normal salt solution injected into the axillary region caused immediate cessation of vomiting, and recovery followed. Another case was that of a woman of 31 with pulmonary tuberculosis not far advanced. She was taken with vomiting and for a week every drug known to the author which is recommended for persistent vomiting was tried without avail. At this time normal salt solution given subcutaneously in the axillary region controlled the vomiting and the patient made a complete rally from her depressed condition. Another was a case of pneumonia in a child of 4½ years. The whole right lung was involved. There was persistent high temperature which failed to respond to bathing. Subcutaneous injection of 6 ounces of normal salt solution had a profound influence on the temperature, reducing it almost immediately, though the child died a week later of heart failure. The author believes that the alarming condition in each of these cases was due to toxins circulating in the blood, hence the indication for the treatment given. For replacing the blood he refers to Anderson's reported case, in which salt solution was administered after each of five hemorrhages in a typhoid case. In each instance there was marked abatement of the symptoms and the patient finally recovered. [A.N.C.]

1. Problems in Sanitation: Presidential Address Before the American Public Health Association, New Orleans, December, 1902. HENRY D. HOLTON.
2. The Association of Tabes and Multiple Sclerosis: Report of a Classical Case of Tabes with Intention Tremor and Nystagmus. CHARLES J. ALDRICH.
3. The Curative Powers of the X-rays Upon Lupus and Malignant Growths, with Report of Cases. THOMAS J. BUCHANAN.
4. Splenic Anemia: Notes of a Case. A. L. BENEDICT.
5. Report of a Case of Cranial Fistula Cured by Operation. J. A. KEOWN and E. B. SCHILLENBACH.

1.—See *American Medicine*, Vol. IV, No. 25, p. 960.

**2.—The Association of Tabes and Multiple Sclerosis.**—Charles J. Aldrich details a case of tabes, combined with the following unusual complications: Laryngeal crises, complete abductor and partial adductor paralysis, complete arytenoid paralysis and partial paralyzes of the cricoarytenoidei laterales, hyperthermalgesia and hypercryalgia, truncal hyperesthesia and hyperalgesia, a localized fixed painful area on the wrist, a marked and classic intention tremor, and nystagmus. The patient is a street-car conductor of 53 years, who contracted syphilis 13 years ago, at which time he had three months' irregular treatment by an irregular practitioner. In the case here recorded there is a perfect type of intention tremor with nystagmus in a classic tabetic, yet, in view of the man's age and the fact that nystagmus may occur in locomotor ataxia as well as motor irritations such as tremor, impulsive movements, athe-

toid gestures, the author sees no necessity of complicating our pathology by assuming the simultaneous existence of the two diseases. This latter observation is especially worthy of attention since we have no definite knowledge of either the character or exact location of a lesion which uniformly and invariably produces intention tremor. [F.C.H.]

**3.—The Treatment of Lupus and Malignant Growths with the Röntgen Rays.**—T. J. Buchanan details five cases illustrative of the curative powers of the Röntgen rays upon lupus and malignant growths. The technic of Röntgen ray therapy and the manner in which Röntgen rays cure carcinoma are given. He concludes as follow: Superficial epitheliomas, lupus, rodent ulcers, eczema, and many kindred skin affections can positively in many cases be cured with the Röntgen rays; the growth of deep-seated carcinomas can sometimes be retarded and the pain very much lessened by means of the Röntgen rays, but that such patients can be permanently cured is as yet not demonstrated; a tube of medium high vacuum is better suited for Röntgen ray therapy than a tube of low power, particularly for deep-seated carcinomas; the part exposed should never be nearer the tube than 12 inches; an exposure should never last longer than 5 or 10 minutes at one sitting; an interval of 3 or 4 days should intervene between each sitting; in order to produce a cure it is neither necessary to produce a burn nor cause any reaction whatever; all cases of inoperable carcinomas, sarcomas, etc., should be treated with the Röntgen rays before they are abandoned as hopeless; the operator must be one well skilled in the use of the apparatus, and after the suspension of treatment carcinomas show a strong disposition to quickly return. [F.C.H.]

**4.—Splenic Anemia.**—A. L. Benedict details the case of a man of 40. He considers it is going too far to say that splenic anemia is simply the anemia of hepatic sclerosis plus the splenic enlargement and due to portal obstruction, but it may very well be that the hepatic sclerosis is the underlying cause, or that it begins coincidentally with the toxic influence upon the spleen and blood, but usually manifests itself late, simply because of various difficulties of diagnosis. [F.C.H.]

**5.—Cranial Fistula Cured by Operation.**—J. A. Keown and E. B. Schallenbach detail the case of a female of 25. The sinus was situated in the left frontal bone about four inches above the eyebrow, filled with pus, and extending down to the dura. Two operations were required with several months' intermission to effect a cure. The diagnosis was a probable tuberculous process in the cranial bones. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

### REVIEW OF LITERATURE

**Unusual Causes of Lead Poisoning, with Report of a Case.**—J. Zimmer<sup>1</sup> reports the case of a male 29 years of age, by occupation a lens polisher, at which he had been employed for seven years. From his symptoms plumbism was suspected in spite of the fact that the patient was not aware of handling lead. Lead was repeatedly found in the urine. Later an analysis of the rouge used in polishing the lenses showed unmistakable evidence of lead, although not in large quantities. The base of the preparation is the red oxid of iron, so that the lead is probably an impurity. In view of the obscure nature of this case it suggests that even where there is no direct history of working with lead, an examination of the gums, urine, and the like, might well be made a routine practice among workers in factories, when subjective symptoms are of an atypic character. [F.C.H.]

**A Fatal Case of Schonlein's Disease, with Autopsy.**—W. T. Watson<sup>2</sup> reports this case, which occurred in a female child of 10. She had been well up to the beginning of the attack, with the exception of slight and transient abdominal pain for two or three months, and frequent headaches for two weeks prior to the onset. The acute attack began January 28, and death occurred March 13. On February 3 the urine was

highly albuminous, and from February 9 the history was that of an acute nephritis. At autopsy the pathologic diagnosis was acute hemorrhagic glomerulo-nephritis, anasarca and bronchopneumonia. No cutaneous hemorrhages were visible. All the abdominal viscera were extremely edematous. The spleen was enlarged. [A.G.E.]

**Pathology and Treatment of Scleroderma in Childhood.**—W. Ebstein<sup>1</sup> reports two cases of scleroderma in children. The first patient, a boy of 8, had the disease in its incipency; it had begun with a "rheumatic" onset three weeks before. The skin was thick, did not glide over the underlying tissue, was cold and slightly edematous. There was vasomotor irritability; the tongue could not be put out, the lips and cheeks were stiff, etc.; the skin reflexes were increased. After a three months' course with baths containing from  $\frac{1}{4}\%$  to  $\frac{1}{2}\%$  of clay, massage with a borated salicylic ointment, and the internal administration of sodium salicylate, 3 grams (45 grains) daily, the boy was improved beyond expectation. The second patient, a boy of 5, reached the clinic one year after the onset of the disease. The sclerosis was very extensive, and contractures of some of the joints had formed. A number of pale scars were seen at different parts of the arms. In this case treatment availed but little. Of all therapeutic measures in this disease, Ebstein thinks better of massage than of any other, but if results are to be obtained, treatment must be early and energetic. [E.L.]

**The Symptom-complex of Basedow's Disease.**—L. von Schrötter<sup>2</sup> reports a case of exophthalmic goiter presenting the typical symptoms of that disease, and in addition a peculiar pigmentation of the skin and a swelling of the lower part of the body. The pigmentation was light and dark brown, irregularly distributed, and either sharply circumscribed or fading into the normal skin. The swelling included the lower part of the abdomen and the lower extremities, and gave an appearance similar to that of myxedema. Examination of small, excised pieces of skin and subcutaneous tissue showed a condition of lipomatosis. The case was therefore considered to be one of exophthalmic goiter with changes in the skin, due to altered internal secretion of the thyroid gland. The author is of the opinion that there are three forms of disease due to anomalies in the thyroid gland. (1) Basedow's disease, due to a condition of hyperthyroidism; (2) myxedema, due to a condition of athyroidism; and (3) a rarer class, due to abnormal secretion, or dysthyroidism. [B.K.]

**Notes on Urinary Chemistry.**—W. G. Smith<sup>3</sup> contributes notes on two cases. One patient was a female of 23, whose chief complaints were hypogastric pain and frequent micturition. The first specimen of urine obtained deposited a white sediment one-third inch in depth which, on examination, proved to be leucin. Smith, after an elaborate discussion of the subject, says that leucin is very rarely found in urinary sediments. He does not know of any previously recorded case in which it has appeared as a macroscopic sediment in bulk and unassociated with tyrosin. The second case is made the basis of a description of a reaction between urea and formaldehyd and its clinical significance. Smith concludes that to the clinical physician the relationship of formaldehyd to urine presents three points of practical interest: (1) It yields with urea a white precipitate (probably methylene-urea) which might easily be mistaken for leucin; (2) if present in urine formaldehyd will reduce the copper test, and so introduces a fallacy in testing for sugar; (3) formaldehyd interferes with the detection of small amounts of albumen by means of heat and acetic acid. [A.G.E.]

**The Origin of Pulmonary Tuberculosis.**—It has been the generally accepted theory that the infection in pulmonary tuberculosis comes by way of the air passages. E. Aufrecht<sup>4</sup> showed this view to be untenable and evolves a new theory. The tubercle bacilli usually gain entrance to the human body through the tonsils, whence they pass to the cervical and mediastinal lymph glands, which become swollen and often caseous. The adherent bloodvessels are penetrated by the bacilli, which thus gain access to the circulation. From the

<sup>2</sup> Maryland Medical Journal, April, 1903.

cervical glands they pass through the right heart and into the smallest branches of the pulmonary arteries. From the mediastinal glands they may pass directly into the lungs by way of the pulmonary arteries or into the general circulation by way of the pulmonary veins, in the latter case setting up a general miliary tuberculosis. The apices of the lungs are the seats of predilection for various reasons. When the bacilli reach the terminal arterioles they give rise to an increase in the cellular elements of the blood vessel walls, these cellular accumulations forming the so-called gray tubercles. The latter occur in the liver, where no terminal arteries exist. But in organs possessing end arteries, notably the lungs, spleen, and kidneys, a thrombosis occurs, which leads to necrosis and the formation of the so-called cheesy tubercles. Cavities are produced through the setting up of pneumonic processes in the alveoli, the exudates thus formed offering a foundation for the penetration of bacilli from the tubercles. [B.K.]

**Syphilitic Heart Disease.**—Syphilis of the heart and blood-vessels, at one time considered so rare as to deserve but little attention from clinicians, is today known to be a comparatively frequent sequela of a primary lesion. According to J. W. Runeburg,<sup>1</sup> the varieties deserving attention are gummatous bloodvessels and muscle affections, aortic, with dilation, aneurysmal dilation of the aorta; coronary disease with myomalacia, and sclerosis of the cardiac muscle (this is probably the commonest affection), and diffuse gummatous myocarditis. Cardiac syphilis is characterized by occasional or paroxysmal anginoid pain; cardiac asthma, irregular cardiac contraction with muffled heart sounds and indistinct pulse beats, occasionally murmurs; rarely the disease will lead to cardiac insufficiency with hypertrophy and dilation. If occurring in young or middle-aged persons, without diffuse sclerosis of the superficial vessels, and without other known causal factors, especially if a history of syphilitic infection can be obtained, the case is very likely one of cardiac syphilis. The statistics of aortic aneurysm show syphilitic antecedents, anywhere from 56% to 85%. He emphasizes the importance of an early diagnosis, as much good can be done by an early and thorough course of specific treatment, especially in cases of arteritis, aortitis, and arterial dilation, and even extensive processes are much improved by antisiphilitic treatment. The mortality from circulatory syphilis he places as at high a figure as from syphilis of the central nervous system. [E.L.]

**The Micrococcus of Acute Rheumatism.**—E. W. A. Walker<sup>2</sup> gives the results of investigations by himself and Beaton regarding the bacteriology of acute rheumatism. They agree entirely with Poynton that a particular microorganism, and no other, is constantly associated with acute rheumatic lesions and is their causal agent. They have obtained this micrococcus from 15 rheumatic patients and have obtained positive results from four specimens inoculated into rabbits. A minute description of the organism with its cultural characteristics is given. Walker is convinced that by observations of cultures and microscopic sections it is impossible to distinguish this organism from any ordinary streptococcus. He thinks that its recognition has been hindered by the term "diplococcus" usually applied and would replace it by some more general name, as for example, micrococcus rheumaticus. Upon the question of this organism being an ordinary streptococcus or specific hangs the whole argument for the specificity of rheumatism. Walker is strongly of the opinion that it is specific, but as yet can furnish no definite proof. Investigation along the line suggested by Marmorok promises much. The questions demanding investigation are: (1) The specificity of the organism in question; (2) the toxic specificity of rheumatism; (3) the pathways of infection; (4) a specific therapeutic agent. [A.G.E.]

**The Influence of Tuberculosis on the Duration of Life and the Earning Capacity.**—E. Stadler<sup>3</sup> has made investigations in 670 cases of pulmonary tuberculosis in working people, and finds the average length of life of these patients to be from 6 to 7 years. It is longer in persons between 14 and 39 years of age than in those beyond 40. Their occupation has no influ-

ence on the progress of the disease. The ability to work varies with the duration of the illness. After five years half of all patients are still capable of performing some work. Treatment in sanatoriums is of too recent origin to enable the drawing of any final conclusions, but statistics so far show that in one-fifth to one-fourth of cases in the first or second stages of the disease life is lengthened about three years. [B.K.]

**Communicability of Bovine Tuberculosis to Man.**—In discussing the communicability of tuberculosis from cattle to man, Koch<sup>1</sup> remarks about the unreliability of the statistics bearing upon primary intestinal tuberculosis. Some authors place it as low as 1.4%, others as high as 37.8%. As a matter of fact, Koch has not had a single case reported to him from all the hospitals and laboratories of Germany in 15 months, in spite of repeated requests. He therefore believes that none have been observed, and thinks that the individual judgment of the various observers must be at fault. He reviews the different cases of cutaneous infections reported as having occurred among veterinary surgeons and butchers, and since all but one remained localized, considers them of little value in bearing testimony, especially as many of them heal spontaneously. In the only case in which the skin was claimed to have led to a general infection, the infections were found upon close scrutiny to have been independent of each other. He briefly mentions the negative results of Baumgarten's experiments, who injected bovine tubercle bacilli to combat carcinoma, and in no instance produced tuberculosis. All such testimony, however, is but indirect proof against the communicability. The direct proof against it consists in the fact that when meat or milk containing bacilli are partaken of, groups of infection are observed. Example: Typhoid epidemics. No one has ever reported such epidemics of tuberculosis following the use of tuberculous meat, although it is constantly used in many sections of the country, and all human beings eat living tubercle bacilli at some time during their lives. Not even an isolated case has been reported which could be traced directly to tuberculous meat. The Prussian Government, after making extensive observations concerning such meat, permits its sale, as its infectivity has not been proved. Concerning epidemics and isolated cases occurring as the result of milk and butter from tuberculous cattle, he mentions a number, but as none of them was well studied, he thinks they do not deserve being seriously considered. To place the onus of tuberculous infection upon suspected milk, the clinical symptoms of the disease must be clear, and postmortems must confirm them. All other sources of infection must be excluded with absoluteness. Other individuals partaking of the same milk must be studied concerning their health, and the milk must come from cows with tuberculous udders. He concludes by saying that he cannot vary one point from the standpoint he took at the Tuberculosis Congress in London, where he stated that he does not believe either meat or milk coming from tuberculous cows dangerous to man. [E.L.]

**The Pathogenesis of Crises of Hepatic Colic.**—The conclusions of M. Dufourt<sup>2</sup> are that three different conditions, or combinations of conditions, may be instrumental in causing the syndrome known as hepatic colic. In the first series is placed peritonitis, more or less localized, having its origin in the gall-bladder; second, a latent peritoneal inflammation that is disclosed only by distention of the biliary passages, the latter having been caused by either a calculus or external pressure; third, pure biliary lithiasis, where the pain is caused by the passage of calculus and is explained by the classic theory usually given. [A.G.E.]

**Bovine and Human Tuberculosis.**—F. Schanz<sup>3</sup> suggests the possibility of identity of the human and bovine tubercle bacillus, but that through some unknown factor the latter is unable to produce in man the same disease as the human bacillus. The bovine bacillus is capable of producing a local skin affection in man (tuberculosis verrucosa cutis), but it cannot produce lupus, although apparently there is no difference in the two organisms. Some other factor, as yet unknown, seems to be necessary for the disease besides the tubercle bacillus. [E.L.]

## GENERAL SURGERY

A. B. CRAIG      MARTIN B. TINKER      C. A. ORR

## EDITORIAL COMMENT

**Surgery of the Gallbladder and Bile Ducts.**—The past few years have witnessed a marked advance in the surgical treatment of the excretory appendages of the liver. Various American and foreign surgeons have contributed important literature to the subject, reciting in some instances large series of cases. It is mainly from the conclusions which may be drawn from the composite picture of many cases, as viewed by different authorities, that we recognize the advance. Kehr,<sup>1</sup> of Halberstadt, has reported the largest series of cases by any one operator. From May, 1890, to August, 1902, he did 720 laparotomies for gallstones on 655 patients; of these 536 were women and 119 were men. The conclusions and suggestions of a surgeon with this enormous experience in the space of 12 years cannot but be of interest to the profession. In his report, Kehr takes to task the quacks, clothed or unclothed in ethical robes, who lead patients to believe they can be cured of gallstones by medical treatment; though in certain forms of cholelithiasis he quite agrees that internal treatment, especially a course at Carlsbad or a similar resort, may allay temporarily the symptoms. According to this surgeon, jaundice is absent in 80% to 90% of cases of cholelithiasis, and even in those cases in which the stone is in the hepatic or common duct, jaundice is absent in 33% of cases. He agrees with the dictum first announced by Courvoisier, and later confirmed by Mayo Robson, Cabot,<sup>2</sup> and others, that chronic cholelithiasis is most apt to present a thickened and contracted gallbladder. In 30 instances fistula was found between the biliary apparatus and the intestinal tract, and in several instances this had led to ascending cholangitis. Kehr believes that each case must be a law into itself so far as indications for operation are concerned. Corpulent men, as a rule, do not bear the operation well, while women, especially those who have borne children, lend themselves well to this surgical procedure. The indications for operation are different as applied to the rich and the poor. The latter can not afford the expense of temporizing with courses of treatment at the wellknown health resorts. Talleyrand said "statistics is the lie reduced to figures," but the recording by Kehr of a very considerable number of failures and of a mortality rate heightened by including every death from any cause whatever which occurred within 100 days after the operation gives confidence in the statements made. The following figures will indicate the relative frequency of the various operations on the biliary apparatus as performed by this surgeon; the most conspicuous features being the increased number of instances in which he now drains the hepatic duct and the vastly proportionate increase in the number of his cholecystectomies. During the first half of his activity in gallbladder surgery including 360 cases there were 54% cystotomies, 20% cystectomies, 13% choledochotomies, and 1% drainage of the hepatic duct. In the last 360 cases there were 20% cystotomies, 54% cystectomies, 6% choledochotomies, and 41% drainage of the hepatic duct. Thus it appears that cholecystectomy as first performed by Langenbuch in 1882 is becoming very popular with this operator, and according to him it is but 1% more dangerous than cholecystotomy. Mayo,<sup>3</sup> with experience in 454 operations for gallstones, places malignant disease as a complicating factor at 5% of operative cases. Kehr estimates it at 10% of those coming to operation, but this author believes since not more than about 5% of gallstone cases come to

operation, the part which stones play in the causation of cancer of the gallbladder must be very small indeed. Kehr found the pancreas normal, so far as palpation could ascertain, in but 66% of the reported gallstone cases. This agrees with the statement of Mayo Robson,<sup>1</sup> who says in cases of gallstone, 'especially where there are small floating stones, it is not uncommon to find the head of the pancreas enlarged and hard, the result of chronic pancreatitis, strongly simulating cancerous disease of that organ. Kehr has performed but one nephropexy in his last 360 gallstone operations. He claims to have had such good results in retaining a wandering kidney in position through the application of a bandage that he now almost universally resorts to this measure. This statement will cause surprise to many surgeons, since many textbooks consider this a troublesome, insecure and unreliable method of holding the kidney in position. Mayo in 454 gallstone operations<sup>2</sup> reports a mortality of less than 1%. Kehr places his mortality, including all cases of malignant disease, suppuration, etc., wherein the patient died within 100 days after operation, at 15.5%. In uncomplicated laparotomies for gallstone his mortality is 3.5%. In his last 200 uncomplicated laparotomies, in which there was neither diffuse cholangitis nor carcinoma, his mortality was but 1.5%. He asserts that a surgeon should perform at least 100 laparotomies before allowing himself an opinion on his mortality rate. He prefers to operate early, but this is often impractical. In about 10% of cases there are apparent recurrences, but doubtless in many of these is really no stone, the symptoms being due to adhesions, etc. From the above it will appear that this surgeon has contributed materially to the surgery of the biliary apparatus and it is believed that his technic within the abdomen, preceded by the abdominal incision as advocated by Mayo Robson,<sup>2</sup> marks a distinct advance in the surgical treatment of the gallbladder and bile ducts. Robson's incision is through and parallel with the right rectus muscle at the level of the gallbladder and prolonged upward or downward, as occasion may require. This freely exposes the gallbladder and when the edge of the liver is rolled upward brings the hepatic and common ducts into view, thus permitting proper treatment for any pathologic condition which may be found.

## REVIEW OF LITERATURE

**Trocar and Cannula for Treatment of Liver Abscess.**—Alexander Turnbull<sup>3</sup> reports three cases treated by this method. One was a marine officer who was convalescent from fever. He became jaundiced, was put to bed, where he slept well and had a good appetite. Temperature was usually normal in the morning, but rose to 102° in the evening, attended by sweating. Some days later he had a rigor and suffered from hepatic and right shoulder pain. This continued for a month. The liver was enlarged with slight tenderness. The appetite remained good, the tongue clean. It could be noticed that liver dulness was slowly ascending and there was increased hepatic tenderness. Almost three months after the beginning of the symptoms he was aspirated in the sixth intercostal space of the right side, below the nipple, and an abscess found 1½ inches below the surface. A few days later the abscess was evacuated by means of Manson's trocar and cannula. Two pints of pus were evacuated. Drainage was continued for some days and patient made a complete recovery. Two other similar cases given similar treatment likewise recovered. [A. B. C.]

**Postoperative Pneumonia.**—The statement is often made that pneumonia after operations is due to the deleterious influence of anesthetics, particularly ether, on the lungs. This fallacy is strikingly exploded by observations made on postoperative pneumonia occurring after laparotomies and other interventions under local anesthesia. In some instances the complication is indeed due to ether or chloroform vapor, but

<sup>1</sup> Münchener medicinische Wochenschrift Nos. 41, 42 and 43, 1902.  
<sup>2</sup> Medical News, November 30, 1901.  
<sup>3</sup> Medical Record, February 21, 1903.

<sup>1</sup> British Medical Journal, January 24, 1903.

<sup>2</sup> Loc. cit.

<sup>3</sup> British Medical Journal, February 21, 1903.

more frequently other etiologic factors are at work. Such causative agents are: Cardiac weakness, rigidly enforced; prolonged lying on the back; pulmonary embolism brought about by vomiting and swallowing food particles as well as embolism by way of the blood-current, and exposure of the patient's body to the cooling air during operation. Some of these factors have been shown experimentally to exert a pernicious action. Thus rabbits are unable to vomit, and artificially produced incarcerated hernia in them did not lead to pneumonia; on the other hand, dogs can vomit, and in them the same experiment resulted in pneumonia. Whether vagus paresis and infection through the mask are occasional causes of postoperative lung involvement is an open question. Laparotomy is more frequently followed by pneumonia than any other operation, the percentage being as high as 8%, with a mortality of 3% to 4%. Operations on the stomach are very apt to precipitate this complication, while it is seldom seen after operations on the liver. Herniotomy upon incarcerated hernia is frequently followed by pneumonia, which is very rare after herniotomy on nonincarcerated hernia. These facts have been elicited by numerous authors from statistical studies. S. F. Derujinsky<sup>1</sup> has in turn mobilized an exceptionally rich new array of original statistical data, embracing 4,946 operations, with 43 cases of pneumonia, or 0.8%, the mortality from the latter being 0.4%. The complication occurred 9 times after laparotomy, 7 times after radical operations for hernia, 4 times after amputation of cancerous mammas, and 8 times it followed operations on the lips, thyroid gland, esophagus and throat. Uterine operations were complicated by pneumonia 6 times. In 19 cases the causative relation between operation and pneumonia was definitely established; 13 times infection with streptococci was present, 3 times aspiration of food particles took place, and 3 patients suffered from emphysema and bronchitis before operation. The author proposes the following classification of postoperative pneumonia: (1) Cases appearing soon after operation and due to the anesthetic, narcosis pneumonia; (2) cases due to infection, occurring most frequently after obstinate vomiting, infectious pneumonia; and (3) hypostatic pneumonia. [L.J.]

**Recovery After Late Laparotomy for Gunshot Wounds of the Intestine.**—The case detailed by J. H. Mitchell<sup>2</sup> was that of a boy of 12, who shot himself with a 22-caliber revolver, the bullet entering the abdomen in the median line nearly two inches below the umbilicus. Operation was performed 16 hours after the injury. Beginning peritonitis was present and 11 perforations of the intestine were found. These were closed with Lembert sutures and the abdominal cavity flushed with large quantities of salt solution. The patient made a steady recovery, though a fecal fistula persisted for nearly two months. The patient was discharged as cured on the sixty-ninth day. [A.G.E.]
