**The Nature of Beri-beri.**—Arthur Stanley<sup>1</sup> presents an etiologic study of this disease among Chinese prisoners in Shanghai, from which he draws the following conclusions: 1. Incidence of beri-beri in Shanghai on Chinese prisoners under municipal police supervision is markedly greater than on the general public. 2. The incidence in four widely separated prisons completely isolated in every respect was of approximately the same degree. In none of these places were the European and Indian staff affected, though they resided in the same compound with the prisoners. The cause of the disease, therefore, does not arise either from the soil or its immediate surroundings. 3. The simultaneous instance at the gaol and police stations would point rather to a general cause than to place infection, but would also be explained by diffuse infection among the native community generally; a case admitted to aggregations of susceptible units as in gaol and police cells spreading by contagion (intimate contact). 4. The figures show a progressive development of infectivity of beri-beri on all the four places where municipal prisoners are aggregated. 5. The fact that beri-beri mainly occurs among natives aggregated for periods of over one month favors the idea of its propagation by contagion. Given the presence of the infective agent, whether conveyed in food or by parasites or by contagion, its operation would be favored by aggregation of potentially infective units. 6. Inasmuch as apart from rice the food-supply of three out of four prisons was from different sources, and a change of rice for all the prisons to one of recognized good quality produced no well-marked effect on the prevalence of the disease in two months, food infection would not appear to be a factor in the cause. 7. Beri-beri being a peripheral neuritis, which is a pathologic condition usually associated with toxemia, food would, in the absence of a primary lesion (as in diphtheria) seem especially indicated as a cause. For the same reason the cause would be met with in specifically contaminated food rather than in either qualitative or quantitative changes in diet. 8. The marked and apparently primary degenerative action of beri-beri on heart-muscle like that produced by diphtheria<sup>2</sup> and to a less degree by influenza and alcohol and arsenic poisoning, all of which may also cause peripheral neuritis, and the remarkable clinical resemblance of beri-beri to diphtheria in the frequency of death from sudden heart failure, would indicate a form of chronic poisoning.<sup>3</sup> 9. The identity of the pathologic changes in beri-beri, diphtheria and arsenic and alcohol poisoning, and the grouping of alcoholic poisoning with ergotism, pellagra, and lathyrism, which are caused by poisons produced by parasites in vegetable foods, suggest the possibility of the cause of beri-beri being a toxin derived from an extraneous parasite of some article of food. 10. In an outbreak in Richmond Asylum, Ireland, which is held to disprove the rice origin of the disease, it is impossible to eliminate from the diet such articles as rice, tapioca, sago, etc., which may have been derived from countries in which beri-beri is prevalent. Beri-beri seems to be markedly prevalent only in countries where rice is the staple food. 11. The oft-repeated statement that a beri-beri patient recovers quickly when removed to a fresh locality may not indicate that this disease is

<sup>3</sup> Jour. Trop. Med., September 1, 1901.

a place infection, but rather that the source of the toxin may be removed by change of residence. 12. Beri-beri does not seem to be associated with any particular trade or occupation. 13. Something more is required for the prevention of beri-beri than attention to general rules of sanitation, such as ventilation, cleanliness and diet. Moreover, isolation of cases as they arise, followed by disinfection, does not suffice to limit the disease. 14. The maximum incidence of beri-beri in Shanghai being at the end of the tropical summer (the remainder of the year being quite temperate) the liability to recurrence at this season in the same patient would be compatible with the elaboration of a toxin favored in its origin by the period of maximum atmospheric heat and moisture. 15. The blood in beri-beri is sterile. 16. The bacteria found by Pekelharing and Winkler<sup>1</sup> associated with beri-beri bear no causal relation to the disease. [C.S.D.]

**Trypanosoma Occurring in the Blood of Man.**—Laveran<sup>2</sup> read before the Academy a paper written by Duthen, of Liverpool, in which he reports finding trypanosoma in the blood of a European working along the Gambia river, and suffering from irregularly remittent fever. The organisms were especially plentiful during the stage of pyrexia. The symptoms included extraordinary weakness, edema of eyelids, injection of conjunctiva, enlarged and tender spleen, rapid pulse and respirations, without any organic basis. Malarial organisms were never found. Recovery took place under arsenic. The same organism was found by him in the blood of a native child. He describes this variety of trypanosoma very fully, considering it an entirely new species. It is smaller than any of the known members of the family; its method of propagation is unknown. He calls it *Trypanosoma gambiense*, and states that *Glossina palpalis*, a fly abundant along the marshes of the river Gambia, is the carrier of the infection. [E.L.]

**Human Botryomycosis.**—The observations of E. Bodin<sup>3</sup> of two cases of this affection in human beings leads him to question the specificity attributed to the characters of this affection by Poncet and Dor<sup>4</sup> and to regard it as entirely due to *Staphylococcus aureus*.

**Primary Sarcoma of the Pericardium.**—Pechere and Stordeur<sup>5</sup> report a primary sarcoma of the pericardium, the patient in whom it occurred being a man of 38. Before death he exhibited marked edema of the neck, trunk and upper extremities. Physical signs showed that there was invasion of the anterior mediastinum by tissue that extended beyond the sternum and surrounded the heart. There was left pleural effusion. Autopsy revealed a tumor 22 cm. (9 inches) in length by 9 cm. to 14 cm. (3.7 to 5.4) in width occupying the anterior mediastinum. Microscopic examination showed the growth to be a spindle-cell sarcoma. The point of origin is believed to have been the pericardium covering the anterior part of the ventricles. [A.G.E.]

**Examinations Concerning the Origin and Solubility of the Oxalic Acid Excreted in the Urine.**—Klemperer and Fritschler<sup>6</sup> have made extensive examinations into the derivation and solution of oxalic acid, and have formulated the following conclusions: It is derived chiefly from the vegetable constituents of the food. The oxalates are partly dissolved by water, partly by the hydrochloric acid of the gastric juice; from  $\frac{1}{10}$  to  $\frac{1}{5}$  of them are absorbed to be excreted by the urine as calcium oxalate. The remainder reaches the intestinal canal, to be destroyed by bacteria. A portion of the oxalic acid of the urine is derived from protoids; glycochol and its derivative, creatin, takes part in its formation. Urine is therefore never free of oxalic acid, even during starvation. A part of it may come from absorbed bile, inasmuch as glycochol is liberated in the intestine from glycocholic acid. That oxalic acid is not precipitated from urinary solutions depends upon its absolute and relative quantities. It is easiest kept in solution if 1 to 1½ mgr. of it is present for every 100 ccm. of water; high acid reaction,

large amount of magnesium salts and small amounts of calcium salts favor its being kept in solution. All these various conditions are best attained by using a diet composed of a mixture of meat, farinaceous food, leguminous vegetables and considerable water, with abstinence from milk, eggs and vegetables. Spinach, cocoa and tea are to be forbidden in cases of extreme oxaluria. If bitter salts are continued in small doses over a prolonged period of time, the magnesium salts of the urine will be increased and with them the solubility of the oxalates. [E.L.]

**Bacterial Intoxication and the Fatty Degeneration of Organs.**—O. Torri<sup>1</sup> presents the results of an extended anatomic-pathologic investigation of the organs of individuals whose death was the result of infectious diseases. The condition of the liver, kidney, and heart is stated as found in a series of autopsies, a series of similar observations made on experimentally inoculated animals. He concludes that poisoning by fungi gives rise to classic fatty degeneration of the liver, kidney, and heart, the degeneration being due to the direct action of the bacterial poisons on the cellular elements. [C.S.D.]

**The Romanowski Method of Staining Cancer Cells.**—Feinberg<sup>2</sup> gives the technic and describes the Romanowski methylene-blue-eosin staining method in differentiating the single-celled organisms of cancer. These cells have no nucleoli and stain entirely blue. The cancer cells have a nucleolus which stains red, while the body of the cell is colored blue. [W.E.R.]

**The Gelo-diagnostic Method.**—Chantemesse<sup>3</sup> reports the results of the researches made by Decobert upon the bacteriologic examination of the stools of typhoid fever by the "Gelo-diagnostic" method. In 18 cases, 16 had passed the stage of invasion and presented almost all of the clinical symptoms of typhoid fever, and two presented the symptoms of the sixth and seventh day of infection, respectively. In the first 16 cases the Widal reaction was positive on the day of admission, and an examination of the stools showed the presence of the typhoid bacillus. In the other two cases the Widal reaction was not present until the third or fourth day after admission, but the "Gelo-diagnostic" showed the presence of the typhoid bacillus in the stools on admission. They come to the following conclusions: The bacillus is constantly found during the febrile period. In 8 out of 10 cases during convalescence in which there had been no fever for five or six days the bacillus of Eberth was almost always present in the stools. In one the examination was negative for three days, then finally became positive on the fourth and following days. In the two remaining cases one free from fever for 15 days showed the presence of a number of colonies, and 18 days later again the bacillus of Eberth in the stools. In the second case apyretic for 11 days the stools appeared entirely free from the bacillus. Thus it is proved that the typhoid bacillus may exist in the stools a month after the patient has recovered from the disease. [J.H.W.R.]

**The Methods of the Conveyance of Yellow Fever.**—H. R. Carter<sup>4</sup> enumerates the arguments for the mosquito as a host and conveyer (if not perhaps the only one) of yellow fever, and sums up the evidence as follows: 1. The analogy of other diseases conveyed by insect hosts. 2. That all facts observed about the propagation of yellow fever agree with the necessary deductions of this theory. 3. No other theory explains all of the facts observed of its propagation. [C.S.D.]

**Lymphangitis Saccharomycotica Equorum.**—A. Dedyulin<sup>5</sup> describes in detail the symptoms and pathologic changes produced by this disease, which is found under a number of names, including African glanders, trembling lymphangitis, epizootic lymphangitis and curable farcy. In some cases all forms of treatment were unsatisfactory, but in other cases colloidal silver preparations given in intravenous injections proved beneficial, while for the external application upon ulcerated areas caustic potash, iodine with glycerin, corrosive sublimate, naphthalene and iodoform gave fairly good results. **Tissue Proliferation and Tumor Formation.**—Marchand<sup>1</sup> concludes that if a parasitic origin be excluded as the cause of the malignancy of epithelial tumors, it can only be explained by the acceptance of the theory of the formation of toxic substances in the cells during their life. The formation and accumulation of these substances is traceable to a degeneration of the cells through the abolition of the normal regulation of cell activity. This degeneration may vary both as regards degree and quality. An increase in proliferation may, especially in embryonal tissue, be independent of any degeneration, but even here the destruction of normal tissue by these proliferating elements presupposes the presence of toxic substances. [E.L.]

**The Pathogenic Agents of Metadiphtheric Septicemias.**—Deguy and Legros<sup>2</sup> having observed that in a certain number of deaths from diphtheria there were anatomic and clinical signs of septicemia, sought in the blood taken directly from the vein of a living infant and in the blood of the heart punctured immediately after death, for the microorganisms which caused death. They have isolated two closely allied species, *Diplococcus hemophilus pertucidus* and *Diplococcus hemophilus albus*, both mobile and very virulent. These are the agents in the production of metadiphtheric cardiac thrombosis. They possess very active hemolytic properties and may be examined directly from the blood in cover-glass preparations after the Gram method. [C.S.D.]

THE PUBLIC SERVICE

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 31, 1903:

SMALLPOX—UNITED STATES.

		Cases	Deaths	
California:	Los Angeles.....Jan. 4-17.....	6

**Changes in the Medical Corps of the U. S. Army for the week ended January 31, 1903:**

WOODS, O. W., contract surgeon, is assigned to the Base Hospital, Iloilo, Panay, for duty.

BYARS, CASPAR R., contract surgeon, will proceed to his home, Columbus, Tex., for annulment of contract.

LORD, LESTER W., contract surgeon, will proceed to his home, West Ossipee, N. H., for annulment of contract.

BRANCH, FRIDERICK D., contract surgeon, now at East Springfield, N. Y., will proceed to Columbia Arsenal, Tenn., for duty.

WALL, FRANCIS M., contract surgeon, leave granted December 29 is extended one month.

BUFORD, OLIVER H., contract surgeon, leave for seven days granted January 21 is extended seven days.

KEEFER, Major FRANK R., surgeon, is granted leave for one month and fifteen days, from about February 10.

FARR, First Lieutenant CHARLES W., assistant surgeon, is granted leave for three months, to take effect on or about March 1.

FLETCHER, RICHARD M., JR., contract surgeon, is relieved from duty at Fort Niobrara and will proceed to his home, Huntsville, Ala., for annulment of contract.

SCHUYLER, WILFRED H., hospital steward, now at Fort McDowell, will be sent to Benicia Barracks for temporary duty. When relieved by another hospital steward he will be sent to Manila, P. I., for assignment to duty.

LOWELL, CHARLES H., contract surgeon, is granted leave for one month, from about February 3.

TWEEDIE, HEDLEY V., contract surgeon, is relieved from duty in the department of California and will proceed to his home, Jackman, Me., for annulment of contract.

So much of orders of January 2 as relate to Hospital Steward William Lyon are revoked. Steward Lyon will be sent to the Army General Hospital, Washington Barracks, when able to travel, for observation and treatment.

NEIL, MATTHEW, hospital steward, Columbia Arsenal, Tenn., upon expiration of furlough authorized January 26, will report to the commanding officer, Company of Instruction No. 2, Hospital Corps, Fort McDowell, who will send him to Manila, P. I.

WAHLQUIST, CHARLES J., hospital steward, Fort Wingate, will be discharged from the Army by the commanding officer of his station, under the provisions of paragraphs 157 and 158 of the regulations.

**Changes in the Medical Corps of the U. S. Navy for the week ended January 31, 1903:**

ROSENBLEUTH, J. C., passed assistant surgeon, resignation accepted to take effect January 23, 1903—January 23.

WINSLOW, G. F., medical director, retired from active service after 40 years' service, upon his own application—January 24.

HAWKE, J. A., medical director, retired from active service, having reached the age of 62 years—January 24.

Drs. H. L. BROWN, T. C. BLACKBURN, P. L. COCKE, C. F. DUNCAN, V. DABNEY, J. B. MEARS, P. S. ROSSITER, and P. F. MCMURDO, appointed acting assistant surgeons from January 23, 1903—January 26.

STONE, M. V., assistant surgeon, detached from the Naval Training Station, Newport, R. I., ordered home and granted sick leave for two months—January 27.

HIGH, W. E. G., assistant surgeon, ordered to the Naval Training Station, Newport, R. I.

TAYLOR, J. S., assistant surgeon, ordered to report to the Surgeon-General of the Navy, Bureau of Medicine and Surgery, for duty—January 27.

KAINES, A. W., acting assistant surgeon, ordered to the Gloucester—January 28.

**Changes in the Public Health and Marine-Hospital Service for the week ended January 29, 1903:**

GEDDINGS, H. D., assistant surgeon-general, detailed to represent the service at meeting of Ohio Health Officers at Columbus, Ohio, January 29-30, 1903.

SPRAGUE, E. K., passed assistant surgeon, granted leave of absence for six days from January 15, 1903, under provisions of paragraph 151 of the regulations.

FOSTER, M. H., assistant surgeon, to report to chairman of board of examiners at San Francisco, Cal., February 16, 1903, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—January 27, 1903.

LUMSDEN, L. L., assistant surgeon, to report to chairman of board of examiners at San Francisco, Cal., February 16, 1903, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—January 27, 1903.

WARREN, B. S., assistant surgeon, granted leave of absence, on account of sickness, for one month from February 1—January 29, 1903.

HALL, L. P., pharmacist, granted leave of absence for seven days from January 9, 1903, under the provisions of paragraph 201 of the regulations.

**The Marshall Bill attack on the Tenement House Reform in New York**, according to all competent testimony, is a peculiarly vicious attempt to reintroduce the insanitary barbarism of olden times in the cities of the State. The bill has been called "a Bill for the Propagation of Tuberculosis," but it could be as aptly described as "for the encouragement of vice and prostitution," and "for the exploitation of the poor by builders and capitalists." A correspondent writes that 27 recorded deaths from tuberculosis have occurred in one old east side tenement house that should long ago have been torn down. The New York Academy of Medicine says that the Marshall bill would undo the great advances in reform and sanitation effected by the recent Tenement House law, and that lack of light and air is one of the chief causes of the 8,000 annual tuberculous deaths and 20,000 cases in the city. Resolutions were passed by the Academy requesting the legislature not to allow any lessening of the air and light in tenement houses. This protest of the academy should be followed by similar action of all the medical societies of the State. According to Commissioner de Forest 26,000 tenements built under the old law contain dark rooms, while of the 500 built under the present law there is not one dark room. The medical profession is solidly against a return to the old conditions.

**Legislators Should Consult Their State Boards of Health.**—One of the ridiculous, but at the same time, tragical illogicalities of our lawmakers is that they have, under not a little pressure, and also poorly, made laws to prevent quacks from practising medicine, while at the same time they allow the patent-medicine quack freely to sell his nostrums and carry on his frauds. Worse than this, by the copyright law they really protect the nostrum seller in his nefarious calling. In other words, the lay public is not capable of choosing medical advisers, but it is entirely capable of choosing medicines, especially on the say-so of a newspaper advertisement. We are glad to see that legislators are awakening to this scandalous condition of the law and are introducing bills to regulate the so-called patent, but really secret, medicine business. These bills spring from a sincere desire to lessen or eradicate the evil, but, as sincerity and desire alone do not equip one for any sort of reform, the faults of these bills are often so great that no practical progress

would or could result. They would not work when real administration should be attempted. In all such attempts at legislation on sanitary and medical matters the framers of bills should consult the experts. There is hardly any State in which the State Board of Health should not at least be asked for its advice.

**The Treatment of Epilepsy by Labor and Exercise.**—Dr. Spratling, of Craig Colony, New York, says that about 50% of patients admitted to the colony are able to do work of a remunerative kind; about 25% will be able to do light housework only, and the remaining 25% can do nothing at all. According to the chief physician of the Bielefeld Colony, of 1,771 epileptics under his care, 33% have diseased minds, 62% weak minds, and only 5% sound minds. The problem, therefore, of supplying these patients with work is a difficult one; but it may be added, a most necessary one, for labor is the greatest therapeutic agent in curing epilepsy. Idleness is a great handicap. Dr. Spratling, in a private letter, says that this fact is made evident by the record of seizures. On rainy days, holidays, and Sundays, when patients do no work, the fits are doubled and even trebled in number. Dr. Weeks, medical superintendent of the New Jersey State Village for Epileptics, says that when winter comes on, and out-of-door work ceases, there is a rapid increase in the number of convulsions and in the irritability and discontent of the patients. The obvious suggestion arises that thoroughgoing systems of gymnastics should be instituted under trained instructors, to replace and even to supplement other forms of labor. The epileptic fit is a tonic and clonic spasm of all of the muscles of the body. If the gymnastics could therefore simulate this extensive synchronous innervation of many muscles, the extensors and flexors simultaneously, as in "resistance exercises," would not this physiologic draining off of the innervation flood, all the more effectively, prevent the morbid overflow illustrated in the seizures?

**Laboratory of Criminology.**—The medical profession of this country have almost unanimously endorsed the plans incorporated in a bill now before Congress for establishing a national laboratory for the study of the criminal and other abnormal classes. This endorsement comes from six national medical societies and 22 State

medical societies. In addition to this, many scientific, legal, and religious associations have officially sanctioned the measure, among them the "International Congress of Criminology," the highest authority in Europe. The bill has been unanimously reported by the House Judiciary Committee and the Committee on Judiciary of the Senate. One would naturally suppose that a bill thus endorsed, fundamentally humanitarian in its character, and absolutely nonpolitical, would quickly be passed. But it seems that there are a few men who are aggressively opposed to it. As most bills that pass this session must be by unanimous consent, the opposition, even of a single man, may obstruct the most meritorious measures.

Crime alone costs this country several hundred million dollars a year. In this bill \$8,000 is to be appropriated for the study of the causes of crime. Thus our country pays out millions to catch, try, and care for criminals, and nothing to lessen this outlay by investigation of its sources. And yet it is reported that this bill is opposed on grounds of economy.

Many State institutions for the abnormal classes gather statistics annually, but little use is made of them; one State does not know what the other State is doing. These data should be summarized and made useful to all the States, thus also encouraging uniformity of method. Such work will not be done by one State, but naturally falls to the Federal Government.

It has been said that the government should not do laboratory work, and that it belongs to the university. But to gather statistics of sociologic, medical, and anthropologic nature would require a clerical force, etc., not undertaken by universities. The university prepares a man for his life work, but does not carry on this work.

Some think that the scientific study of the abnormal classes should be done under private munificence. There is no doubt that private endowment could do much. But to gather data from our State institutions of a more or less confidential nature would be much easier for the Federal Government than for any private institution, for the States have great confidence in our Central Government.

Another objection urged to the study of the relation of criminal propensities to physical signs is that if school children should become known "as possessing the bodily signs of degeneracy" it would discourage them in forming good habits and work injustice to them. A pupil with scarlet fever or diphtheria is required to leave school so long as it is liable to contaminate others, but if there is a morally diseased or degenerate pupil who is teaching the others bad habits and contaminating them with moral disease, which may be worse than any physical disease, this pupil should be allowed to remain in school unknown to the others, because it is thought this would be an injustice to one. As such degenerates are fortunately few what shall we say of the injustice done to the great mass of pupils by allowing them to be exposed to this moral contamination?

It is considered wise to study the causes and signs of physical disease in order to lessen its danger to others. It seems to us strange that any one should object to the

study of the causes and signs of moral disease or degeneracy, which are most pernicious and lasting in their effects upon the young.

When we consider that our government spends thousands for the erection of monuments and millions for the investigation of plants and animals and millions more for the study of their diseases it seems strange to hear objections to the spending of a few thousand dollars to study the greatest enemy of all government, crime.

**The Misuse of Eponyms by Medical Writers.**—Many lovers of medical lore find it pleasant to have the history of their favorite science recalled to mind by terms embodying the names of the masters of medicine, and they find it as convenient and safe to prescribe Fowler's solution or Hoffmann's anodyne as it would be to specify these preparations by their Latin official names. The designation of operative methods, special appliances, or peculiar affections by such names as Porro's operation, the Lorenz method, the Trendelenburg posture, Nelaton's probe, or Pott's disease cannot be improved upon by the substitution of any arbitrary combination of Greek or Latin derivatives in place of the name of the discoverer. In bacteriology the terms Petri-dish or Gram's method cause no confusion in the mind of the student. There is, however, among writers on bacteriologic subjects a custom that is reprehensible in the extreme, and for which there is no valid excuse, namely, the designation of specific bacteria by the name of some person connected with its isolation or description.

The following list gathered by a cursory survey of current literature will suffice to show the extent to which this custom prevails and the confusion to which it gives rise. The real names as determined by the rules of scientific nomenclature are added to show how little clue the eponymic term gives to the systematic relationships of the organisms referred to:

- Achard and Bensaude's bacillus: *B. paracolon* Gilbert.  
 Bonome's streptococcus: *Str. weichselbaumii*.  
 Bruce's micrococcus: *M. melitensis* Bruce.  
 Cushing's bacillus: *B. paracolon* Gilbert.  
 Danysz's bacillus: *B. murium* Löffler.  
 Davaine's bacillus: *Bacterium anthracis* (Cohn) Migula.  
 Demme's bacillus: *Bacterium erythematiss* (Kruse).  
 Deneke's spirillum: *Microspira tyrogena* (Deneke) Migula.  
 Doderlein's "Scheidenbacillus": *Bacterium vaginae* (Kruse).  
 Ducrey's bacillus: *Bacterium canerosi* Kruse.  
 Dungern's capsule bacillus: *Bacterium pneumoniae* Zopf.  
 Eberth's bacillus: *B. typhosus* Zopf.  
 Emmerich's bacillus: *B. coli* Escherich.  
 Fehleisen's streptococcus: *Str. erysipelatos* Fehleisen.  
 Ferchmin's bacillus of red pus: *Bacterium pyocinnabareum* (Kruse).  
 Finkler-Prior bacillus: *Microspira protea* (Buchner).  
 Flexner's bacillus: *B. Shigae* (Chester).  
 Fraenkel's pneumococcus: *Streptococcus pneumoniae* (Weichselbaum) Gamaleia.  
 Friedlander's pneumococcus: *Bacterium pneumoniae* Zopf.  
 Freire's micrococcus: *M. xanthogenicus* (Freire) Sternberg.  
 Frisch's bacillus: *Bacterium rhinoscleromatis* (Trevisan) Migula.  
 Gwyn's bacillus: *B. paracolon* Gilbert.  
 Hansen's bacillus: *Mycobacterium leprae* (Hansen) Lehmann-Neumann.  
 Hoffmann's bacillus: *Mycobacterium pseudodiphtherium* (Kruse).  
 Kitasato's bacillus: *B. pestis* Lehmann-Neumann.

Klebs-Löffler bacillus: *Bacterium diphtheriæ* (Flügge) Chester.  
 Koch's bacillus: *Mycobacterium tuberculosis* (Koch) Chester.  
 Koch-Weeks bacillus: *Bacterium ægypticum* (Trevisan) Chester.

Kochel's capsule bacillus: *Bacterium pneumoniae* Zopf.

Kruse's bacillus: *Bacterium subtiliforme* Schröter.

Kurth's bacillus: *B. paracolon* Gilbert.

Kutscher's spirillum: *Sp. tenerrimum* Lehmann-Neumann.

Löffler's bacillus: *Mycobacterium mallei* (Löffler) Migula.

Lumnitzer's bacillus: *Bacterium Lumnitzerii* (Sternberg) Chester.

Lustgarten's bacillus: *Mycobacteria syphilidis* (Schröter) Chester.

Malherbe and Mounier's bacillus: *B. paracolon* Gilbert.

Mallory-Wright's capsule bacillus: *Bacterium Wrightii* Chester.

Mandry's capsule bacillus: *Bacterium pneumoniae* Zopf.

Mannaberg's streptococcus: *Str. erysipelatos* Fehleisen.

Miller's spirillum: *Sp. sputigenum* Kruse.

Moore's bacillus: *Bacterium avium* Chester.

Neisser's gonococcus: *Micrococcus gonorrhoeæ* (Buum) Flügge.

Nicolaier's bacillus: *B. tetani* Flügge.

Nicolaier's capsule bacillus: *Bacterium Wrightii* Chester.

Obermeier's spirillum: *Spirochaeta Obermeieri* Cohn.

Ogata's bacillus: *B. dysenteriae* Kruse.

Pfeiffer's bacillus: *Mycobacterium influenzae* (Pfeiffer) Chester.

Pfeiffer's capsule bacillus: *Bacterium capsulatum* (Sternberg) Chester.

Sanarelli's bacillus: *B. icteroides* Sanarelli.

Schottmueller's bacillus: *B. paracolon* Gilbert.

Shiga's bacillus: *B. Shigæ* Chester.

Tils' bacillus: *B. carneus* Kruse.

Vignal's bacillus: *B. buccalis* Sternberg.

Widal and Nobecourt's bacillus: *B. paracolon* Gilbert.

Yersin's bacillus: *B. pestis* Lehmann-Neumann.

**Poisonous Spiders.**—The common people have generally believed that spiders are venomous, and the arachnologists have said the belief was false and the effects of the bites were the products of hypnotic suggestion. Notwithstanding the sweeping conclusions based upon the negative results obtained by experiments, a perusal of the work of Linstow<sup>1</sup> and that of Kobert<sup>2</sup> will afford abundant and authoritative evidence as to the secretion of venoms by many species of spiders, and that these venoms are, in the majority of cases, capable of producing serious disturbances, and at times even death in various species of animals as well as in man. The evidence usually adduced by writers on spiders, for the purpose, undoubtedly, of allaying the popular dread of these useful and interesting creatures, is entirely inadequate in view of the rapid increase which is taking place in our knowledge of toxalbumins; while recent discoveries concerning heterolysins and isolysins point to possible explanations of the apparently contradictory facts that many reputedly venomous spiders are immune to the bites of individuals of the same species or tribe, while other animals are affected more or less seriously by their venom. While Kobert was able to obtain poisonous extracts from the mouth parts of a large number of spiders, many of which are ordinarily regarded as harmless, as well as from species well known to be poisonous, and to cause the illness and death of animals intravenously injected with these extracts, his work leaves the field still open for further and more exact investigation, particularly of those species concerning which the consensus of popular

opinion as to their poisonous character is supported by the testimony of competent and reliable observers, not that of the "credulous doctors" to which the Rev. Henry McCook refers in his work on American spiders. The isolation of specific toxalbumins would definitely settle the exact cause and degree of toxicity of certain widely distributed species, and the southern and southwestern United States afford several which would serve as excellent material for an investigation in some of our new laboratories of experimental physiology and pathology.

**Newspaper doctors** are of two kinds, the sinners, and those sinned against. The sinners we all know. Those sinned against are they who despite their honest efforts to avoid yellow journal notoriety are quoted and reported by the conscienceless editors and reporters. Of course there are some newspapers which really try to respect the wishes of physicians, and who will not quote them except when permission is given. There are others, commonly called yellow, which say, "we will publish a poor, and perhaps false report if you do not give us the facts and allow us to use your name." All professionally minded physicians know that accounts of operations, cures, etc., by the yellow journals are harmful alike to the true physician, to the patient, and to the public. In spite of the most thoroughgoing precautions to prevent the reporter from getting any knowledge of a Lorenz operation recently performed in a large hospital of an Eastern city, what purported to be a full account with scare headlines, was sprawled in the columns of a paper the next morning. In excuse for the wrong the city editor cynically said, "How do we know that in your heart you do not wish us to advertise you in this way? You quote the great and famous Professor Blank as a hater of newspaper reports about himself. Bosh! I can prove to you that, while he is talking against these reports when made by others, and abuses us publicly when we tell of his opinions, lectures, operations, etc., we can at any time get his photographs and full accounts from the underlings of his 'literary bureau,' whom he supplies with all such information, well knowing, also, where it goes." It is strange, we may add, that the advertising professors are so stupid as to think their colleagues do not know of their "advertising departments" and "literary bureaus." After all it is a poor way to get practice and a mean advantage to take of honest rivals. It would be of the utmost benefit to the profession if the "liberty of the press" could be legally "muzzled" so that physicians should not be reported except when they wish, and only with signed permit in each case.

**The morbid and stupid fear of hospitals** on the part of some lay people when these institutions are to be located in their neighborhood is a strange bit of atavism long persistent in a civilized age. Twice recently this incongruous prejudice has appeared in Philadelphia, the last being as to the location of the Phipps Hospital, against which as many as 600 remonstrances were signed by citizens of the ward. Two of these remarkable persons are reported by the newspapers to have had the

<sup>1</sup> Otto von Linstow, Gifttiere und ihre Wirkung auf den Menschen. ein Handbuch für Mediziner, Berlin, 1894.

<sup>2</sup> R. Kobert, Beiträge zur Kenntniss der Giftspinnen, Stuttgart, 1901.

title "Dr." in front of their names, and to have spoken as follows:

Dr. Simon Dubin averred that the establishment of the Phipps Institute in a congested quarter of the city was against all precedent in this country or abroad. Dr. Samuel Stalberg commented on the slim attendance, and said: "If the residents of the ward are prepared to have it made the dumping ground for every squalid and dirty consumptive in the city, they will deserve it."

If these people were as wise as they are silly they would get up mass meetings and contributions to secure the location in their midst of these health-scattering and disease-killing institutions. The neighborhood of a modern hospital is the most *healthful* place in a large city.

The gap in the "Index Medicus" series cannot be filled. The publication was discontinued with the issue of April 30, 1899, so that the missing numbers will be those of nearly four years. The gathering of the data required could not be done except in the library of the Surgeon-General at Washington, as no where else in the world are the periodicals gathered. Even if workers could be secured to undertake the immense labor of collecting again the slips of four years, it would be very expensive, and at last the editorial supervision of Dr. Fletcher could not be obtained, and without that the work would likely be valueless. The profession is under great obligations to Dr. Fletcher for consenting to undertake the supervision of the new series. We have been at a great deal of pains to learn if a way could not be found to overcome the difficulties. The money could have been secured, we are convinced, but even Americans must learn that there are many things that money alone cannot do. Fortunately the missing literature of the four years may be found in the Index Catalog of the Surgeon-General, and bibliographers and researchers will have to govern themselves accordingly.

**Shirtmaker and Optician.**—As a consequence of the renunciation by the oculist of much of his true professional work for the benefit of the refracting optician, the latter gentleman naturally feels himself justified in taking on airs, and in fact, of seizing upon all the duties of the oculist, except perhaps a few surgical ones. Hence the riot of optical and ophthalmic quackery in every State and town of the land. The *Posted Graduate* even contends that there are no pathologic results of malfunction of the eyes, that errors of refraction can be diagnosed by machinery, and, if we understand our contemptuary correctly, advocates nickel-in-the-slot machines for furnishing spectacles. A similar condition of mind exists in a shirt-making company in one of our large cities, which writes to a physician as follows:

Dear Doctor:

We have added an optical department to our jewelry in charge of Dr. —. —, the wellknown optician, whose work we are in a position to guarantee. We especially desire to get patients from you, and by sending them to us we will reciprocate by mailing you a check for 15% of their purchases. We guarantee our prices to be as low as any representative optical house in the city.

Thanking you in advance and trusting to hear from you, we remain,

Very respectfully yours,

THE PALACE SHIRT CO.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**Army and Navy General Hospital, Fort Bayard.**—A proposition is under consideration to enlarge this institution so as to provide accommodations for tuberculous patients from the Navy. The contemplated enlargement will provide for 100 patients, and it is estimated an expenditure of \$100,000 will be required.

**Manila Free from Cholera.**—It is reported that the United States quarantine officials have declared Manila free from cholera, thus ending the quarantine which has lasted nearly a year. The disease, however, is still epidemic in parts of the islands. Since the outbreak there have been 130,363 cases, with 82,955 deaths.

**Inspection of Health Records.**—Senator Gallinger has introduced a bill in the United States Senate providing for the inspection of records of the health office. According to its provisions the records of births and deaths in the health office shall be open to inspection by any person who in his own right or in the right of some other person in whose interest he may act, has a substantial interest in some matter contained or reasonably believed to be contained in such records.

**Hospital Benefactions.**—NEWPORT, R. I.: It is estimated that at least \$250,000 will be expended by Mrs. Vanderbilt on the ward which she is erecting at Newport Hospital in memory of her husband, instead of the \$27,000 which was originally planned. NORRISTOWN, PA.: Mrs. Alan Wood, Jr., of Philadelphia, has given \$5,000 to the Charity Hospital for a free memorial bed in memory of her husband, who died recently. BALTIMORE, MD.: Alexander Shaw, of this city, has bequeathed the sum of \$5,000 each to the Union Protestant Infirmary and the Home for the Aged of the Methodist Episcopal Church.

**Plan for the McKinley Memorial Hospital Abandoned.**—At a meeting of the managers of the McKinley Memorial Hospital for Contagious Diseases recently, it was decided to convert all property which has come into the hands of the committee into cash and abandon the project of a hospital for contagious diseases which was to receive pay patients only. The committee began its work several years ago, and has not met the financial success which it had hoped to achieve, and sufficient funds have not been forthcoming to carry out the plans of those who conceived the project. It is said that the property in the hands of the committee amounts to something over \$12,000, which when converted into cash will be deposited in a bank to be turned over to any committee which shall in the future have a similar project in view.

**Diphtheria Among the Apaches.**—Secretary Hitchcock has received a message from Governor Otero asking that troops be sent to enforce the quarantine laws of the Territory. Recently diphtheria became epidemic among the Apaches on the San Carlos Reservation. The health officers attempted to quarantine the Indians to prevent a general spread of the disease. They were unable to enforce the quarantine measures, and the Indians refused to remain on the reservation or otherwise respect the regulations prescribed in the quarantine; hence, the Governor's request for troops. The Secretary has ordered an inspector to be sent to the Reservation and make an immediate investigation, and report by wire. This is the second time diphtheria has become epidemic among the Indians in New Mexico within 14 months, and such outbreak invariably brings trouble.

**Concealment of Plague.**—Information has reached the State Health Officer of Texas that the bubonic plague reached Mazatlan, Mexico, from San Francisco, and not, as at first reported, from China. Much as one would wish to deny the accuracy of this charge, so terribly humiliating to us as scientists and sanitarians, there is something more than a possibility that it is quite true. For many months now the plague has been claiming its victims in the slums of San Francisco, and the municipal authorities, instead of frankly admitting the existence of the disease there and taking the vigorous but not difficult measures necessary for its extirpation, have preferred to follow the bad old policy of concealment and to do what they could without creating a "scare" or interfering with business. This course has been denounced by various medical associations and by the Marine-Hospital Service, but without avail, and its results have been just what were to be expected. The infection has been like a fire smothered, not extinguished. The deaths have been few, but they have been constant, and the city has been a danger center of exactly the kind that Havana used to be and that Vera Cruz is now. It may well be that Mazatlan owes its epidemic to the criminal folly of San Francisco, and the fact that this may be so very considerably weakens our right to be severe in teaching responsibility in such matters to our southern neighbors.—[*New York Times*.]

## EASTERN STATES.

**Scarlet Fever Closes Mount St. Vincent School.**—The Academy of Mount St. Vincent at Riverdale-on-Hudson, one of the most popular Catholic institutions in this country for the education of girls, is now closed on account of an outbreak of scarlet fever. All but 40 of the girls attending the school were sent home. The Academy has about 200 pupils and nearly 40 teachers.

## NEW YORK.

**Mortality in New York.**—The annual bulletin of the New York State Department of Health, which has just been issued, states that 124,160 persons died in the State during the year, making a death rate of 17 per 1,000. This is about the average of the five preceding years, but is about 5,000 less than the mortality of 1901. Smallpox existed in the early months throughout the Adirondack region. During the year this disease has appeared in 135 municipalities throughout the State. It caused the same mortality as in 1901. There were 8,000 deaths from pneumonia, 5,500 from Bright's disease, and 4,000 from influenza.

**Physician Vaccinators Dismissed.**—Four physicians have been dismissed from their positions of city vaccinators by the commissioner of the Health Department of New York City for making false reports of their work. These vaccinators are required to make weekly statements to the Department of Health, giving the names and addresses of persons whom they have vaccinated. In order to check the reports of these vaccinators, inspectors are occasionally sent over the same territory to verify them, and by this means the commissioner has been able to detect those sending in false reports.

**Shall the Whipping-post be Revived?**—From an exchange we quote the following: "The merits of the whipping-post for wife beaters are once more under discussion, and the interesting statement is made that President Roosevelt, while in the Legislature several years ago, made a strenuous effort to provide this method of dealing with cruel husbands. After he had collected authenticated records showing the astonishing prevalence of this cowardly practice, he proposed a bill providing for the revival of the whipping-post 'for wife beaters only.' Nevertheless, the measure was defeated, the argument being that the revival of such punishment would be a return to barbarous methods. Present advocates of a whipping-post here claim that the results from that institution in Delaware have been excellent and wholesome."

**Typhoid Epidemic in Ithaca.**—The typhoid epidemic is said to be spreading with marked rapidity in the city of Ithaca. Forty new cases have been reported by the Health Board physicians in one day. The total number of cases now in the city is said to be 350. The City Hospital and Cornell Infirmary are filled with patients, and even churches are being utilized for hospitals to accommodate the increased number of patients. Dr. Curtis, of the State Board of Health, agrees with the City Board of Health that the source of the fever is in the water-supply, which is taken from a nearby creek. This source of contagion has only been recognized within the last few days, and now the health authorities advise all persons using the water to boil the same, and pure water is being brought from wells and springs of the surrounding country.

**Bill to Abolish Coroners.**—A special dispatch to the *New York Times* states that a bill has been introduced into the Legislature abolishing the office of coroner in the counties in New York City, the bill to take effect in September, 1903. It is proposed to substitute for the coroners, medical examiners, of which Manhattan will have 6, Brooklyn 4, Queens 2, the Bronx 2, and Richmond 1. These officers would be appointed by the Board of Health for a term of five years at a salary of \$3,500 a year. It is provided that all matters now subject to investigation by the coroners shall be first submitted to the Board of Health. The police powers now invested in the coroners would be vested in the district attorney, who would act in conjunction with the medical examiners in the investigation of all suspicious cases of death. The measure, which is said to be similar in all of its provisions to the present law of Massachusetts, is favored by the various New York medical associations.

**The Craig Colony Prize Awarded.**—The prize of \$200, annually given by Dr. Frederick Peterson for the best original essay on the etiology, pathology, and treatment of epilepsy, was awarded this year to Dr. Julius Donath, of Budapest, Hungary, for his paper on "The Presence of Cholin in Epilepsy and Its Significance in the Production of the Convulsive Attack." The award was made by a committee of the New York Neurological Society, consisting of Dr. Pearce Bailey, Dr. C. A. Herter, and Dr. George W. Jacoby, and the essay will be published as soon as possible. Dr. Peterson again offers a prize of like amount for the same purpose and under the same conditions, viz.: First, that the paper must show original research work. Second, that the subject matter of the essay shall not have been before published. Third, that all manuscripts submitted shall be in English and shall be sent Dr. Peterson, at 4 West Fiftieth street, New York City, before September 30, 1903, the successful manuscript becoming the exclusive property of the Craig Colony.

Fourth, each essay submitted must be accompanied by a sealed envelope containing the name and address of the author and bearing on the outside a motto or device, which is also to be inscribed upon the essay.

## PHILADELPHIA, PENNSYLVANIA, ETC.

**Smallpox in Pennsylvania.**—During January there were reported 940 cases of the disease with 55 deaths, as against 506 cases with 36 deaths in December. A large proportion of the cases occurred west of the Alleghenies. Philadelphia, however, had 129 cases and 9 deaths.

**Typhoid Fever in Philadelphia.**—During the current week there were reported to the Health Department 329 new cases of typhoid fever with 23 deaths, making the total 1,632 cases and 84 deaths since January 1. The Board of Health has again issued a proclamation ordering all water boiled before it is used.

**The Henry Phipps Institute Dispensary** for the treatment of tuberculous was opened February 10 and 29 persons applied for treatment. The Institute will be open every morning, except Sunday, from 11 to 12 o'clock. Clinics will be held on Monday and Thursday by Dr. Irwin; Tuesday and Friday, by Dr. Walsh; and Wednesday and Saturday, by Dr. Hatfield. About 150 applications for treatment have been received, 50 of these being for beds in the Institute.

**Free Medical Course Offered to Railroad Men.**—The Jefferson Medical College and Hospital, of Philadelphia, through the president, Mr. Wm. Potter, has offered to the various steam railroads running into Philadelphia a free course of lectures on "first aid to the injured." All the employees of such railroads as desire may attend these lectures. The presidents and managers of the various railroads have replied, heartily thanking Mr. Potter for his liberal offer in behalf of the College and Hospital.

**To Prohibit the Free Sale of Opium.**—The City Council of Wilmington, Del., has passed an ordinance requiring that cocaine and opium shall be sold within the city's limits only on a doctor's prescription, except the sale be from wholesalers to retailers. The object is to break up if possible the practice of using these drugs by young men and boys in that city. It is claimed that this practice is steadily increasing and that one small drug store in an out-of-the-way place is selling 16 times as much as one of the large stores on a prominent street.

**License to Practise.**—A bill has been introduced into the Pennsylvania Legislature which it is asserted is designed to check osteopathy and eddyte teaching. The bill does not apply to nurses practising their profession, and it would so amend the law for 1893 for licensing and examining practitioners of medicine and surgery as to punish a person for "entering or continuing in the profession or occupation of treating disease or injury by the use of medicine or any other means or agency," either for or without pay or valuable consideration, unless licensed under the specified act. The penalty is any sum between \$200 and \$500, and imprisonment for from 30 days to 6 months.

**"Sure Cures" and Tuberculosis.**—The Committee for the Prevention of Tuberculosis of the Charity Organization Society recognizing the wrong which is done to patients suffering from tuberculosis by those advertising sure cures and nostrums galore, has made a public statement which says: "There is no specific medicine for this disease known, and the so-called cures and specifics and special methods of treatment widely advertised in the daily papers are, in the opinion of the committee, without special value, and do not at all justify the extravagant claims made for them. It is the unanimous opinion of the members of this committee that there exists no specific medicine for the treatment of pulmonary tuberculosis, and that no cure can be expected from any kind of medicine or method, except the regularly accepted treatment which relies mainly upon pure air and nourishing food."

**Crusade Against Tuberculosis.**—Two bills which will be introduced into the Pennsylvania Legislature are of interest as bearing on the fight against tuberculosis which it is hoped will be inaugurated in Pennsylvania with the assistance of the State government. The first bill asks for \$300,000, to increase the capacity of the Free Hospital for Consumptives, at White Haven, by 200 beds, to establish 100 beds for advanced cases at a location between Philadelphia and White Haven and five dispensaries for outdoor treatment of tuberculous patients in Philadelphia and other large cities in the State. The second bill, which will be introduced later by the Pennsylvania Society for the Prevention of Tuberculosis, petitions the Legislature for \$500,000 for building sanatoriums in various sections of the State, beginning with two institutions in the State forestry preserves, one in the Pocono region, in Lackawanna, and the other in Franklin county, near Palo Alto region. Each structure will have a capacity for from 200 to 500 persons. The sites are to be selected by a commission of three, appointed by the Governor.

## SOUTHERN STATES.

**Cigaret Prohibition.**—The House of Representatives of Alabama has passed a bill by a vote of 61 to 35 to prohibit the sale or the giving away of cigarettes and cigaret papers in the State of Alabama. It leaves the smoker the alternative of having them shipped from abroad or doing without them, and even when he gets them he is prohibited from giving them away. Strong effort will be made to have the Senate likewise pass the bill.

**To Suppress Plague.**—A bill has been introduced in the House of Representatives by Congressman Slayden, of Texas, asking for an appropriation of \$50,000 to be used in suppressing bubonic plague in Mexico, and to prevent its dissemination into the United States. The bill authorizes and asks the President to send a commission of three medical officers of the U. S. Army and Navy to investigate and report conditions there found with reference to the plague.

**The Virginia Conference of Charities and Corrections** held its third annual meeting in Richmond, Va., February 10, 11, 12. An interesting program was rendered. The purposes of the conference are to educate the public mind to a proper conception of the needs of the indigent, defective and delinquent classes, to encourage a humane and philanthropic spirit; to create and foster a deeper and more general interest in charity and reformatory work; to procure data regarding the condition of the unfortunate classes, and to impress upon the people the advantages of organization in charitable and correctional efforts.

**Sanitary Regulations.**—At a recent meeting of the Washington Board of Trade a resolution was adopted authorizing its committees on public health to cooperate with the Board of Education of the District of Columbia in the matter of improving the sanitary conditions of the schools and the spreading of information concerning the various contagious diseases. The board recommends, that Congress provide for the medical inspection of schools in the District of Columbia and appropriate \$5,500 for such purpose. It recommends the establishment in the District of Columbia of proper hospital accommodations for persons suffering from tuberculosis. It asks the Board of Health to use its best efforts to obtain the enactment of a law prohibiting the spitting upon the sidewalks in the District of Columbia. It asks the committee on appropriations in the Senate to include in the amount necessary for expense in the District of Columbia \$35,000 for the collection and disposal of ashes and other refuse from hospitals, apartment houses, restaurants, etc., and also \$20,000 to provide for collecting a like refuse twice a week during the winter months from private residences instead of once a week as heretofore.

## WESTERN STATES.

**"Northwest Medicine."**—The first number of this journal, which is edited by Clarence A. Smith, A.M., M.D., of Seattle, Wash., was published January, 1903. The publication, which is designed to assist in the improvement and strengthening of the profession in the Northwest, will be published monthly by the Washington Library Association. The subscription price is \$2.50 yearly; single copies, 25 cents.

**Deaths From Pneumonia.**—The Chicago Bulletin of the Health Department for the week ended January 24 states that for 12 successive weeks the deaths from pneumonia have largely outnumbered those from tuberculosis. During this period there were 630 cases of tuberculosis and 1,089 cases of pneumonia. These two causes account for more than one-quarter (26.12%) of all deaths during the three months, and of these there were 42% more from pneumonia than from tuberculosis.

**Chicago School Board Bars Tuberculous Teachers.**—A public school teacher of Chicago has been barred from her school room by the board of education on the recommendation of the city superintendent because it is believed that she has advanced pulmonary tuberculosis. The teacher is a Christian Scientist and asserts that she has no disease, though she is being treated by a Christian Science healer. Medical members of the board of trustees have been appointed a committee to draw up appropriate resolutions to be adopted by the board requiring all teachers suspected to be suffering from tuberculosis or other infectious diseases to submit to medical examinations by the board's physicians before continuing their school work.

**The Blind Ask Aid From State.**—Blind persons in the State of Illinois will ask that a bill be introduced into the Legislature which will grant to each afflicted person who is not a charge of a charitable institution and who has resided in the State for five years the sum of \$150 annually. A circular has been sent out to all senators and representatives of those interested asking that the bill become a law. The plea is made that while Illinois maintains an institution for the blind, no provision is made for them after they leave the school, that they are thrown upon their own resources without a chance to profit by what they have learned. Those unable to seek employment are forced to rely upon the almshouse, their friends, or public charity. It is hoped the bill will pass.

## FOREIGN NEWS AND NOTES

## GENERAL.

**Plague** is reported to be increasing in Tokio, Japan. It is stated that the germs were imported in cotton from Bombay. Dr. Yokota, the quarantine officer is among those who have succumbed to the disease.

**Sanitation as Practised by the Japanese.**—By the treaty of Shimonoseki in 1895 the eastern extremity of the great Malayo-Chinese continent, together with 3,000,000 of population, was acquired by Japan. The islands and people were in a deplorable condition. The *Medical Press and Circular* gives the following account of the work accomplished by the Japanese in placing this territory in a sanitary condition: "Malaria and dengue were endemic, dysentery was common and in many of the cities continued fevers were ever present. Under Japanese rule the use of opium was prohibited, except as a medicinal agent prescribed by a physician. The city slums were pulled down, the narrow streets widened, every house was after a given date to be unoccupied until its sanitary arrangements were approved of by the sanitary authorities. A very excellent drainage system was made compulsory in every city, artesian wells were sunk for drinking water, and the roadways kept in good repair. In the seven years of Japanese rule mosquitoes have become almost unknown, dysentery of the acute form has disappeared from the latest list of diseases; continued fever is the exception in the cities of the island. But this is not all—railways are being constructed, so as to form a network over the country; telegraphic communication connects the island with China on the one hand and Honshin on the other; and, lastly, free schools are established all over the country, and compulsory education is strictly enforced. In the schools every child is taught the rudiments of sanitary science. The whole rising population are indoctrinated with the belief that disease is largely due to want of cleanliness in the homes and persons of those attacked. The nearest approach to this thoroughness in enforcing sanitary laws occurred under the able administration of General Woods, United States Army, when he was placed in charge of Cuba after the Spanish war of 1898. In both cases disease was driven out by application of sanitary laws.

## GREAT BRITAIN.

**For Cancer Research.**—Mr. T. Sutton Timmis, of Liverpool, has given a donation of about \$50,000 for the purpose of instituting systematic investigations into the origin and cure of cancer. The investigations will be carried on at the Liverpool Royal Infirmary and the new laboratories of experimental medicine in the University College in Liverpool.

## CONTINENTAL EUROPE.

**'Gift to Hospitals.**—The directors of the Savings Bank of Milan at a recent meeting decided that as their profits for the past year were larger than usual the sum of \$1,000,000 should be distributed to the hospitals of Lombardy. The money is to be used to introduce the latest discoveries of science and to provide for the comfort and wellbeing of patients.

**To Provide for Free Physicians.**—It is reported that a movement is on foot in Zurich, Switzerland, advocating the imposition of a tax on every inhabitant who is over 16 years of age, of 80 cents a year, the State to add 20 cents. With the \$118,000 thus obtained annually it is proposed to pay 40 physicians to take care of the entire population of the city.

## OBITUARIES.

**Herman Mynter**, the eminent surgeon, died at Buffalo, N. Y., February 9. Dr. Mynter was born in Denmark, and was graduated from the University of Copenhagen in 1871. He made the United States the country of his choice, and since locating in Buffalo, a number of years ago, has been a frequent contributor to medical literature, and has achieved an enviable reputation as one of the foremost surgeons of the country. His name has recently been brought prominently before the people of this country as being one of the physicians who attended President McKinley after his assassination at the Buffalo Exposition.

**Professor Max Saenger**, the eminent gynecologist, at Prague, January 12, aged 50. He began his professional career in 1878, when he was appointed assistant to Credé. He was the author of a monograph on Cesarean Section in the Treatment of Uterine Fibromata, and of about 150 publications on tumors, plastic operations, tubal pregnancy, laparotomy, retroversion and retroflexions of the uterus, etc. He was a pioneer of vaginal hysterectomy in Germany—an operation which he performed for the first time at Leipzig in 1881—and he was a strong advocate of antiseptic and aseptic methods in gynecologic surgery. In 1899 he accepted an invitation to succeed Roasthorn in the chair of gynecology in the University of Prague.

**J. Frank Valentine**, in Richmond Hill, Queens Borough, N. Y., February 5, aged 46. For many years he was visiting surgeon at St. Catharine's Hospital, Brooklyn. He also served as surgeon of the old Thirty-second Regiment, and for several years was coroner's physician in Brooklyn. He became chief surgeon of the Long Island Railroad in 1890, and also acted as visiting surgeon at St. John's Hospital, Long Island City, and as consulting surgeon to the Nassau Hospital, at Mineola, L. I. He was a member of the Queens-Nassau Medical Society, and an ex-president of the New York State Association of Railway Surgeons.

**Eugene Foster**, of Augusta, Ga., January 23, aged 53. He was graduated from the Medical College of Augusta, Ga., in 1872, and was professor of practice of medicine and sanitary science and dean of the faculty of the medical department of the University of Georgia. He was affiliated with many local medical organizations, and was a member of the American Medical Association, American Public Health Association, and the American Surgical Association. He was an acknowledged authority on municipal sanitation, and his contributions to medical literature are numerous and valuable.

**John Hornans**, of Boston, Mass., February 6, aged 67. He was graduated from the Harvard Medical School in 1862. He served as surgeon during the Civil war. He was also surgeon at the Boston Dispensary, the Children's Hospital and the Carney Hospital, and was also a visiting surgeon of the Massachusetts General Hospital, with which he has been especially identified, and was a lecturer in Harvard University. For many years his name had been especially associated with abdominal surgery. He was a contributor of much valuable material to medical journals.

**Harrison A. Lemen**, a retired physician, of Denver, Col., January 21, aged 62. He was graduated from the St. Louis Medical College in 1861. He was at one time president of the Denver Medical Society and of the Colorado State Medical Society, and was also emeritus professor of the principles and practice of medicine in the medical department of the University of Denver.

**Thomas N. DeBowes**, of Brooklyn, N. Y., February 6 aged 69. He was graduated from the New York University in 1858. He was also a graduate of Trinity College, Dublin, Ireland, and of Yale University. He was one of the founders of the St. Mary's Hospital in Brooklyn. During the Civil war he was surgeon in a Connecticut regiment.

**Henry Tomboeken**, in Terre Haute, Ind., February 7, aged 65. He was graduated from the Rush Medical College in 1866, and was one of the two members of the first graduating class of the Chicago College of Pharmacy. He practised his profession in Chicago for over 30 years, and retired about five years ago.

**Eugene Davis**, in Indianapolis, Ind., January 19, aged 30. He was graduated from the Medical College of Indiana, Indianapolis, in 1893. He was professor of ophthalmology at the Medical College of Indiana, and a member of the American Medical Association.

**Patrick H. Conley**, of Chicago, Ill., February 3, aged 43. He was graduated from the Rush Medical College, Chicago, in 1887. He was surgeon to the West Side Hospital, and professor of obstetrics and diseases of children at the Chicago Clinical School.

**Caleb Hornor**, of Philadelphia, February 7, aged 74. He was graduated from the Jefferson Medical College in 1849. He organized many hospitals and dispensaries throughout the Southern States and the District of Columbia during the Civil war.

**Cyrus Allen**, of Avon, N. Y., January 11, aged 65. He was graduated from the New York Homeopathic College and Hospital in 1864, and from the Berkshire Medical College, Pittsfield, Mass., in 1865.

**Charles B. Leavitt**, of Trenton, N. J., February 9. He was graduated from the medical department of the University of Pennsylvania in 1882. For two terms he held the office of county physician.

**Adam T. Van Vranken**, of Watervliet, N. Y., January 19, aged 55. He was graduated from the Albany Medical College in 1873, and was a member of the New York State Medical Association.

**R. Otway Owen**, of Kansas City, Mo., at San Bernardino, Cal., January 19, aged 38. He was graduated from the Medical College of Virginia, Richmond in 1889.

**Samuel Gray**, of Laurel, Md., January 30, aged 72. He was graduated from the University of Maryland School of Medicine, Baltimore, in 1858.

**E. M. Chapin**, of Washington, D. C., February 9, aged 82. He was a graduate of the medical department of the Columbian University.

**C. E. Watson**, of Conneaut, Ohio, January 18, aged 27. He was graduated from the Cleveland Homeopathic Medical College in 1898.

**Earle E. Woolworth**, of Brooklyn, N. Y., February 5, aged 30. He was graduated from the New York University in 1897.

**Charles W. Virmont**, of Chicago, Ill., February 1, aged 37. He was graduated from the University of Louisville in 1889.

**John J. Manlon**, in Charlotte, Ia., January 24. He was graduated from the Rush Medical College, Chicago, in 1895.

**Samuel D. Sanders**, at Georgetown, Tex., January 22, aged 80.

**J. S. Crom**, of Philadelphia, February 5, aged 75.

**George Harris**, of Bridgeton, N. J., February 10.

## SOCIETY REPORTS

### MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-seventh Annual Meeting, Held in Albany,  
January 27, 28 and 29, 1903.

[Specially Reported for *American Medicine*.]

#### FIRST DAY.

**Officers Elected.**—President, Dr. A. T. Bristow, Brooklyn; vice-president, Dr. Edward B. Angell, Rochester; secretary, Dr. F. C. Curtis, Albany; treasurer, Dr. O. D. Bzll, Albany. It was voted to hold a semiannual meeting in New York City next October.

**President's Inaugural Address.**—HENRY B. HOPKINS (Buffalo, N. Y.) speaking of the past history of the society, declared that its action in repealing the Code of Ethics was one of the most important steps that had been taken in many years, for it had brought the society into closer touch with the State government and had been indirectly the means of giving to the State its beneficent laws regulating the practice of medicine. This same action had been the means of securing the enactment of a law, by which the society was enabled to regulate its membership and increase the number of its delegates five fold. Commenting upon the movement just inaugurated, by which it was hoped that the registration of trained nurses under rules prescribed by the Board of Regents would be secured, Dr. Hopkins said that this action seemed to him wise and timely, and he hoped it would receive the support of this society. The hope was expressed that this country would imitate Great Britain in the matter of giving special instruction in sanitary science to those who assayed to be health officers, and that the new degree, D.P.H., of Doctor of Public Health, would be conferred on such as were properly qualified. With regard to the question of the hour in this State—that of securing unity of the medical profession here—the speaker expressed the hope that this would be attained before the society should reach its approaching centennial anniversary, but added that, although the rights of all should be given due consideration, the State society could never agree to sacrifice those principles for which it had so long contended.

**Report of Committee on Hygiene.**—JOHN L. HEFFRON (Syracuse), on behalf of this committee, stated that there had not been so many victims of typhoid in the past year as in previous ones, and that attention had been directed to other sources of typhoid infection than water. Smallpox had gradually increased during the past 10 years, and in the past year had been more prevalent than ever. If the people had not yet learned the value of vaccination it was certain that they could not be convinced on this point by any amount of argument. As scarlet fever had assumed a severe type, more than usual precautions should be taken by the health authorities to secure efficient and prolonged quarantine of these cases. With regard to tuberculosis, the report stated that this disease still continued to be the most prevalent of the preventable communicable diseases. That it was possible to effectually control it by appropriate measures was shown by the fact, that in recent years the deathrate from tuberculosis had fallen 45% in Great Britain, and in New York City there had been a reduction of nearly 40%. Moreover Dr. Bowditch had pointed out that at the sanatorium at Rutland, Mass., the disease had been arrested in 79% of those received in the first stage. Popular literature bearing on these points should be disseminated among the masses, and in this work it was probable that much help could be derived from enlisting the aid of the industrial insurance companies. The society should endeavor to maintain intact the present tenement-house laws, and should cooperate with the health authorities in securing the registration of every case of tuberculosis. This report was reinforced, in the matter of the tenement-house laws, by a resolution, introduced by Dr. George B. Fowler, of New York, and adopted by the society, which urged the Legislature not to permit any changes to be made in the present tenement-house laws which would lead to a decrease in the light and air available in such houses, or which would be a step backward in regard to their sanitary condition.

**Report of Committee on Legislation.**—ARTHUR G. ROOT (Albany) read this report, which stated that of the 78 medical bills presented to the last Legislature, 19 had become laws and 44 had died in committee. The others had either failed to receive the Governor's signature or had been vetoed by mayors of cities. A peculiarly vicious bill was that designed to relieve hospitals of responsibility for the acts of their officers and employes.

**Report of State Board of Medical Examiners.**—WILLIAM WARREN POTTER (Buffalo) presented a review stating that of the 7,034 candidates appearing since the establishment of the board, 5,528 or 78.5% were successful. Last year 685 applied for a license to practise medicine, and to 558 a license was issued. The yearly average for this board was 586; that for the homeopathic and eclectic boards, 46 and 16 respectively.

**Report of Committee on Unification of the Profession.**—HENRY L. ELSNER (Syracuse), the chairman of the

joint committee of conference, presented this report. The correspondence that had taken place between the two State committees was submitted, together with a detailed account of the labors of the committee. As might have been expected, the rock upon which they split was the Code of Ethics of the American Medical Association, but another by no means unimportant obstacle had been the method by which reorganization was to be effected. It was freely conceded that both committees were sincere in their desire for unity and that both State organizations were now powerful bodies, and the inference was plain that both were jealous of the rights already obtained. This was particularly so with the State society, for there was interwoven a very natural sentiment in favor of an unbroken existence for their society which had now nearly completed its first century. Although the State society's committee had agreed at one time to the proposition of the State Association that the latter should give up its name and charter and that both should take the title of the State society and apply jointly to the Legislature for a new charter, embodying the present organization of the State Association, the committee changed its opinion after learning from legal counsel that by applying for a new charter the old State society would end, and that moreover, such a step was not necessary. According to this legal opinion the State society possessed the power to amend its by-laws without applying to the Legislature so that members of the New York State Medical Association could be admitted to its membership. Various plans had been proposed for effecting the reorganization. The one which would probably come up for consideration at the meeting of the American Medical Association in New Orleans next June was, that by which members of county societies paid a single fee to the State treasurer and thereby became members of both the State and national bodies. With regard to the Code of Ethics, the committee reported that it had been informed by Dr. Billings, the president of the national organization, that this code was still in existence, and hence the committee was averse to recommending any action by the Medical Society of the State of New York until the American Medical Association should make it possible for that society to subscribe to its constitution and by-laws consistently and without sacrifice of principle. The committee was continued, with instructions to continue its labors.

**Arguments for the Existence of a Separate Cortical Center for Writing.**—HERMAN C. GORDINIER (Troy) reviewed the few cases already reported, including one case of his own, of glioma at the base of the second left frontal convolution. He insisted that there was now available sufficient pathologic and clinical data to prove that destruction of Broca's center did not necessarily cause agraphia.

**Medical School Inspection in the City of New York.**—HENRIETTA P. JOHNSON (New York) presented not only a brief review of the comparatively new work of medical inspection of the schools of the city, but described in an interesting manner many of the peculiar racial and sociologic problems that were encountered in the prosecution of this work in a cosmopolitan city like New York. The system of medical inspection of the schools inaugurated by the Board of Health originally comprised a division of the city into 35 districts and the appointment of 150 inspectors. The examinations made the first year amounted to 108,638, resulting in the exclusion of 6,829 children from the schools. Last fall a new system went into operation. This called for daily morning observations as before, but in addition a weekly examination of every pupil.

**The Care of the Insane.**—CHARLES G. WAGNER (Binghamton) contrasted the old, prison-like asylums, with their crude and often cruel modes of so-called treatment, with the modern hospital for the insane, where the keynote was the greatest personal liberty consistent with safety and the necessity for cheerful surroundings and suitable occupation. During the acute stage of mental disease, quiet was secured and proper nutrition maintained largely through the employment of skillful nurses.

**Differential Diagnosis of the Familiar Forms of Spinal Disease.**—FLOYD S. CREGO (Buffalo) said that, generally speaking, hemiplegias were due to brain disease. A very common diagnostic error was the confounding of functional and organic disease. This often resulted from the fact that the functional or hysteric element was so prominent as to obscure the organic basis. In the common form of acute myelitis, transverse softening in the mid-dorsal region of the cord, there was complete anesthesia below the level of the lesion, with gradual muscular wasting and exaggeration of the reflexes. In lumbar myelitis there was loss of the reflexes instead of exaggeration. In that form of acute ascending paralysis, known as Landry's disease, there was gradual loss of power, whereas in myelitis this loss of power was rapid, and was associated with a loss of sensation. Autopsies on such cases had yielded uniformly negative results.

**Erythrophium: A Clinical Study.**—REYNOLD W. WILCOX (New York) described some of the properties of this drug. Its action is similar to that of digitalis, but is more rapid. It was indicated in cases characterized by a rapid, but not extremely weak, heart action, associated with low tension.

**Observations on American Climates and Localities in the Treatment of Pulmonary Tuberculosis.**—JAMES K. CROOK (New York) expressed the belief that the climatic treatment of this disease had been hampered by the habit of physicians, of restricting themselves to the selection of two or

three regions, apparently ignoring the important fact that within the confines of the United States could be found typical examples of all the best forms of climate possessed by the Old World. Dr. Crook then briefly outlined some of the available climatic areas, calling attention to the fact that many of them, though hardly utilized in the past, were just as good as the more widely known of the old health resorts, and moreover, that some of them were quite accessible from New York. As an instance, special mention was made of the remarkably favorable climatic conditions now known to exist on Long Island, and of certain localities in Westchester county, only a few miles beyond the limits of New York City. The author said he was a firm believer in the very great importance of appropriate climatic treatment, but it should be a first, instead of, as was too often the case, a last resort. If resorted to early and with due discrimination, the results were most salutary; if employed late in the disease, it might be confidently expected that the disease would continue to progress in 99% of the cases. While thus earnestly advocating the climatic treatment, he was far from being unmindful of the benefit to be derived from good food and proper hygiene, and it was only when these were combined and the patient was under skillful medical supervision that the best results could be expected. As it was not possible to find proper air in large cities, it became necessary to resort to properly equipped sanatoriums in the rural districts, and he firmly believed that philanthropists who would give of their abundance for the establishment of such sanatoriums were more worthy of esteem and lasting remembrance than those who embellished costly churches, built libraries, or founded universities.

**Retinoscopy.**—D. H. WIESNER (New York) presented this paper, because, as he said, the method was simple and well adapted to the needs of the general practitioner. The instrument employed for retinoscopy consists of a plane mirror of glass, about 1½ inches in diameter, having a central aperture and a long handle. With a suitable light the background of the eye is illuminated, and then by observing whether or not the movement of this spot of light is with or opposite to the motion of the mirror in the vertical and horizontal meridians, a very good idea is obtained of the refractive condition of the eye. Thus, when the illumination moves with the rotation of the mirror in both meridians the eye is hyperopic. When the movement is opposite to that of the mirror, it denotes myopia.

**The Physician and the Ophthalmoscope.**—FRANCIS VALK (New York) was of the opinion that the rarity with which the ophthalmoscope was used in general practice was to be explained by the fact, that the practitioner who essays to use this instrument became discouraged at the outset by certain difficulties which, with a little instruction, might be readily surmounted. To this end the following method of procedure was advised: The source of illumination is arranged so as to allow of illumination of the background of the eye. If the orange-red reflex ordinarily observed is not visible under these circumstances, a +6 glass should be brought before the aperture in the mirror, as this would enable the observer to secure a good view if no opacity were present. In order to make it easy for the observer to adjust his eye to the rays of light reflected from the eye under examination, it would be found a very great help to make use of the concave lenses, or those marked in red. These should be brought successively before the aperture until the best result was obtained. Sometimes it was necessary to dilate the pupil, and then by the use of a little cocaine or homatropin this could be done without special inconvenience to the patient.

**Incomplete Transverse Congenital Occlusion of the Vagina.**—SAMUEL M. BRICKNER (New York) presented in abstract a report of four cases of this kind. He was of the opinion, from a study of this subject, that transverse vaginal septums were due to embryonal folds, and that the condition was really an example of a reversion to a former type.

**Some Scientific and Practical Details Regarding Vaccine and Vaccination.**—PETER H. BRYCE (secretary of the Provincial Board of Health of Ontario) at the outset made the statement that vaccination conferred complete protection against smallpox in all persons for ten years, and in many individuals for double that period. He pointed out that the investigations carried on by certain French scientists pointed to the bacterial nature of vaccinia, though the specific micro-organism had not been isolated. The continued opposition to vaccination, even at this late day, he endeavored to explain on the ground that it was compulsory, and expressed the opinion that the same fate would have been meted out to the antitoxin treatment of diphtheria had it, too, been made obligatory on the people. Nevertheless, he was a firm believer in compulsory vaccination, and gave the following cogent reasons for the faith that was in him: (1) The theory of immunity conferred by vaccination is based on indisputable scientific evidence; (2) the infectiveness of smallpox had been shown repeatedly to be uncontrollable by the best sanitary organization, though yielding readily to vaccination; (3) vaccination can afford complete protection against smallpox after exposure to that disease, even if done so late as the fourth day, and can so reduce its severity as to avert a fatal issue when vaccination is done concurrently with exposure. With regard to vaccine and vaccination he said that the effectiveness of glycerinated lymph had been demonstrated by a record of 126,000 vaccinations with 98% of successful vaccinations. There was evidence to show that

multiple insertions afforded better protection than a single scarification.

**Treatment of Purulent Conjunctivitis.**—EDGAR S. THOMSON (New York) while expressing the opinion that the only sound guide to the treatment was a bacteriologic examination of the discharge, advocated prompt treatment by energetic measures when there was reason to suspect a virulent infection, such as from the gonococcus. Under such conditions there was no better application than a 2% solution of silver nitrate applied to the upper culdesac, as well as to the other parts of the conjunctiva. For the abortive treatment a 3% or 4% solution should be used, following this, strong application by sodium chlorid to neutralize the effect. In the treatment of ophthalmia neonatorum a 6% solution of protargol was recommended, as it was efficient and nonirritating, but for gonorrhoeal ophthalmia it was decidedly inferior to silver nitrate. Of course, in addition to the use of the applications already mentioned, the eye should be irrigated with boric acid solution sufficiently often to keep it free from the discharge.

**Transportation and the Ophthalmic Referee.**—JUSTIN L. BARNES (New York) considered the means employed by our transportation companies to detect color-blindness among their employes. He had ascertained that about one-third of the railway companies relied upon laymen for these examinations, whereas the public safety demanded that they should at least have an ophthalmic referee for the doubtful cases. The eyes should be tested singly, otherwise color-blindness in one eye might escape detection, and it was conceivable that an engineer might at any time have the good temporarily disabled while at his work. Some color-blind persons were able to distinguish colors quite well by differences in the degree of illumination, but such a method could not be relied on under the ever changing atmospheric conditions present in actual practice.

**Discussion.**—PERCY FRIDENBERG (New York) said that while this question was of much practical importance, there were two sides to it. From the standpoint of the railroad men it was obviously unfair to subject them to tests in matching colors and picking out slight variations in shades when in their work they were only called upon to decide between two or three widely different colors. Persons having defective color sense at the macula were able, by moving the eye, to distinguish correctly the colored wools, whereas with a single point of illumination the result was very different.

**Eye-strain and Headache.**—LUCIEN HOWE (Buffalo) presented an explanation of how eye-strain caused headache. By the term "eye-strain" he meant the pain experienced by some persons when reading, sewing or doing other near work. This pain was referred to the eye itself, the forehead or some part of the head, or possibly even to the shoulders. The proposition which the author sought to prove was, that this pain was due directly to some muscular contraction. According to the theory of Helmholtz, the ligament of Zinn was tense when the eye was at rest, and relaxed more and more in proportion to the degree of accommodation. A better explanation had been offered recently by Professor Tscherning. This observer contends that the act of accommodation is not altogether passive, as Helmholtz believed, and that on looking at a near point the ciliary muscle is contracted. This draws the edges of the lens bends the central portion of the anterior surface further forward, and makes the lens more convex. On this theory that near vision was entirely an active muscular effort it was not difficult to explain the pain in the eyes, which constituted the first feature of ocular headache. Moreover, a certain amount of accommodation always meant a certain degree of convergence of the visual axes, which implied tension of the internal recti and also, to a certain extent, of the superior and inferior recti. The accessory muscles of the forehead and head were called into action when any special effort was required to maintain accommodation, and it was the tension of these accessory muscles which gave rise to the headache. The occipitofrontalis was an important muscle in this respect, and both the anterior and posterior portions were subjected to strain in connection with a special effort to maintain accommodation. This explained the frontal and occipital headache.

**Hydrops Tubae.**—HENRY D. INGRAHAM (Buffalo) reported two cases.

**Sterilized Milk, Pasteurized Milk, or Clean Milk.**—C. W. M. BROWN (Elmira) showed the advantages of pasteurization over sterilization, and the dangers arising from entrusting pasteurization to careless or ignorant persons, or of relying upon it in hot weather when there was not an ample supply of ice for the storage of the milk.

**The Examination of Milk by the General Practitioner.**—HENRY L. K. SHAW (Albany) exhibited and described the apparatus employed. He advised the use of Farrington's alkaline test tablets as a ready and reliable means of determining the acidity of milk. For the determination of the specific gravity of as small a sample of milk as half an ounce—a desideratum in the examination of breast milk—he made use of a small Quvenne lactometer, to which he had added a thermometer in order to facilitate the making of the corrections for temperature necessitated when the milk examined was not at 60° F. He preferred to obtain the percentage of fat by the well-known Babcock method, but to make the method more suitable for physicians he recommended a small hand centrifuge, manufactured by D. H. Burrall & Co., of Little Falls, which was so constructed that it could not only be used for bacteriologic and

urinary work, but could be used with the large regulation size bottles for making the fat test. By means of a convenient device known as Richmond's sliding milk scale, the corrected lactometer reading and the total solids could be read off without the use of mathematical formulas. The amount of proteids could be determined approximately by subtracting the percentages of fat, sugar and salts from the total solids.

**Blood Examination in General Practice.**—IRVING P. LYON (Buffalo) introduced the symposium on hematology by this paper, which showed by a number of illustrative cases how such examinations could be made of service in general practice.

**The Eosinophiles: Their Etiology and Value in Diagnosis and Prognosis.**—THOMAS R. BROWN (Baltimore) the author, was unable to be present. He pointed out the value of eosinophiles as a means of diagnosing trichinosis and of differentiating certain forms of leukemia, and stated that the presence of eosinophiles in a number of the acute infectious diseases was also occasionally of assistance to the clinician.

**Degeneration of the Erythrocyte.**—J. C. D'ACOSTA, JR. (Philadelphia). The paper will appear in a future issue of *American Medicine*.

**The Iodin Reaction and Its Diagnostic Significance.**—EDWIN ALLEN LOCKE (Boston, Mass.) exhibited some illustrative photomicrographs. The method of making the test was to make an ordinary blood smear on a cover glass, dry it in the air and then apply an excess of the iodine solution. The preparation could be examined immediately or after a long time, but the examination should be by daylight, using an oil immersion lens and strong light. The reaction was shown in several ways, viz.: (1) By the presence of brownish granules in the protoplasm; (2) by a diffuse coloration of the cells, and (3) by the presence outside of the cells of round or oval masses of a brown color. The intercellular reaction was never observed in health, and, in general, it might be said that the iodine reaction was associated with some form of toxemia. In doubtful cases the examination should not be put down as negative until at least 100 white cells had been counted.

#### SECOND DAY.

**The Surgeon's Enemy, the Skin.**—ROBERT H. M. DAWBARN (New York) considered as the three main topics, "chemical shaving," "mending rubber gloves," and "a method for excluding perspiration from the operative field." With regard to the first, he recommended as a substitute for the razor in certain hairy regions of the body the application for 10 minutes of a 25% aqueous solution of Merck's sodium sulfhydrate. This would remove the hair as if a razor had been used, and the hair would grow out again after this method just as after ordinary shaving. For mending rubber gloves he advised the use of several test-tubes, two flat-irons and a cautery set such as is employed in burnt leather decoration. When it was required to put in a new finger tip, the tip from the finger of an old rubber glove should be used as a cap. The edges of the rubber having been softened by the cautery, and a test tube inserted into the glove finger bottom up, to serve as a form, the repair is readily made, and the parts are held together by twine until firmly united, when they will stand sterilization by boiling. Flat surfaces are mended in a similar manner, using one flat-iron for laying the work upon and the other flat-iron as a weight to hold the mended parts together. To prevent perspiration in the operative field, the author recommended dusting this area, one hour before operation with a powder composed of lycopodium, talc or zinc stearate, with 20% alum, previously sterilized by heat. The powder should be allowed to remain on the skin until removed by the usual cleansing applications at the time of beginning the operation. Such an application would effectually prevent sweating in this area during the time necessary for the performance of any ordinary operation.

**The Technic of Prostatectomy.**—RAMON GUITÉRAS (New York) advised opening the membranous urethra, inserting the forefinger and separating the prostate from its capsule, meanwhile holding and controlling the prostate by means of an instrument that he had devised for this purpose. This resembles a urethral sound with a sharp double curve. Having removed the gland, artery forceps should be fastened on either side of the wound until the drainage tube had been inserted.

**Periduodenal Abscess Secondary to Perforative Ulcer of the Duodenum.**—WILLIAM SEAMAN BAINBRIDGE (New York) stated that he had found 26 cases of this kind on record, and in 22 cases death had occurred without the diagnosis having been made. One case of his own was reported together with the autopsy findings. There was usually a history of previous gastrointestinal disturbance, the onset was sudden and the chief symptoms were vomiting, pain, tenderness and resistance in the epigastrium and right hypochondrium.

**Some Points Regarding the Treatment of the Functional Disorders of the Sexual Organs in the Male.**—FREDERIC R. STURGIS (New York) said that while he did not pose as an apologist for masturbation, his experience had taught him that masturbation was a comparatively infrequent cause of loss of sexual power, and was no more debilitating than natural sexual intercourse indulged in to the same extent. A more important etiologic factor in the class of cases under consideration was "withdrawal" at the time of coition, and

another was excessive sexual indulgence. In perhaps 50% of the cases the cause was an uncured urethral stricture produced by gonorrhoea. A frequent cause of trouble was the presence of granulations in the urethra. Internal medication was only useful as an adjuvant in these cases; local medication was far more important, and the keynote of success was the use of sedatives. Stimulants should be avoided; in some instances, even coffee should be interdicted. The proper local use of silver nitrate produced an effect which was sedative rather than stimulating. Not much could be done for the relief of sterility in the male, for it was usually dependent upon some obstruction to the mixing of the spermatozoa with the semen, and the ejaculation of the usual quantity of semen was no proof that the person was not sterile, for the semen was largely made up of other secretions.

**Discussion.**—R. H. M. DAWBARN advocated circumcision as means of aiding those who are sexually weak by retarding the orgasm. The tying off of a few of the veins at the base of the penis would also increase the vigor of the erection. A. JACOBI (New York) also thought circumcision was useful, but chiefly because of the profound mental impression which this operation created, and the self-confidence thereby engendered.

**In Memoriam: Rudolph Virchow.**—CHARLES A. L. REED (Cincinnati, O.) delivered this address. He was followed by A. JACOBI, who spoke of Virchow's love for Americans.

**President's Address: Progress, Unity, Liberty.**—HENRY R. HOPKINS (Buffalo) said that unity in medicine was essential to satisfactory progress in that all-important department, State medicine, and naively added that medical unity was not made easier of attainment by dwelling upon the limitations and imperfections in the practice of professional brethren. An epoch-making event in the history of the profession had been the establishment of the system of State licenses, but unfortunately there yet remained that relic of the past, the three examining boards constituting a cumbersome legal machinery wholly unworthy of the twentieth century.

**Plasmiodiophora Brassicæ.**—HARVEY R. GAYLORD (Buffalo) presented a communication on this subject, embodying some preliminary studies of this organism.

**Primary Carcinoma of the Vermiform Appendix.**—ARTHUR W. ELTING (Albany) reported three cases which he had studied. He had succeeded in collecting 40 cases from the literature. The condition was probably more common than would appear from this record, for in several instances the carcinoma had been only accidentally discovered at autopsy, so that many cases were doubtless overlooked. The disease showed a tendency to develop early, but the symptomatology was exceedingly vague.

**The Early Recognition and Symptoms of Arteriosclerosis.**—DELANCEY ROCHESTER (Buffalo) presented this paper as an introduction to a symposium on arteriosclerosis. He classified the cases of arteriosclerosis into: (1) those dependent upon the strain incident to occupation; (2) those resulting from the introduction into the system of poisons from without, *e. g.*, syphilis, lead and alcohol, and (3) those resulting from the poisons generated within the body through faulty metabolism.

**Arteriosclerosis and the Heart.**—GLENTWORTH R. BUTLER (Brooklyn) divided these cases into two groups, depending upon whether or not the coronary arteries were sclerosed. In senile arteriosclerosis, he said, the heart was often not enlarged or the arterial tension increased. Cardiac hypertrophy in connection with arteriosclerosis was usually most marked in cases occurring in middle life. When dilation followed cardiac hypertrophy, the train of symptoms were hardly distinguishable from those observed in connection with ordinary organic heart disease. In advanced cases anginal attacks were common, but true angina pectoris was somewhat rare and was usually associated with sclerosis of the coronary arteries and of the myocardium.

**Arteriosclerosis and the Kidney.**—IRVING P. LYON (Buffalo) discussed, for the most part, those cases arising from syphilis, alcoholism, lead poisoning, and gout.

**Arteriosclerosis and the Digestive System.**—CHARLES G. STOCKTON (Buffalo) said that arteriosclerosis was indirectly a common cause of digestive disturbance, and the opinion was gaining ground that it was more often a direct cause than had formerly been believed. Among the direct effects were attacks of severe abdominal pain simulating gastralgia.

**Arteriosclerosis and the Nervous System.**—WILLIAM BROWNING (Brooklyn) described a very large and varied symptomatology dependent upon arteriosclerosis, but by no means distinctive.

**Arteriosclerosis and Mental Disease.**—ADOLF MEYER (New York) said that arteriosclerosis of the brain was apt to be associated with loss of memory of the immediate past, with transitory delirium and with mental confusion. Persons so affected were sometimes guilty of arson, theft, or of sexual misconduct. There was, however, no justification for speaking of arteriosclerotic insanity, and there was no special treatment for cases of mental disease in which one element was arteriosclerosis.

**Pulsus Infrequens.**—THOMAS E. SATTERTHWAIT (New York) considered this title more accurately descriptive than the more usual terms denoting infrequent pulse. Thus he objected to bradycardia on the ground that in some cases of infrequent pulse the heart was not slow, and indeed, might be quick. The infrequent pulse might occur at almost any period of life, but in

his experience it was more apt to be in middle life or after that period. By common acceptance a pulse below 60 was held to be infrequent. It was rare to meet with a pulse below 40, though most practitioners of long experience had seen instances of it. There were two principal varieties, the physiologic and the pathologic. A French writer had reported a case in which the pulse never exceeded 20. The infrequent pulse was five times more common in males than in the opposite sex. The pathologic variety was subdivided into the temporary and the chronic. They were chiefly due to poisoning by infections, lithemia, digestive disturbances or cerebral disease. The chronic variety was uncommon. The explanation of the infrequent pulse was unsatisfactory because we did not understand thoroughly the physiology of cardiac action, particularly the innervation of the heart. Because of the bearing on prognosis and treatment it was important to determine whether the infrequent pulse was physiologic or pathologic, and whether it was intermittent or deficient. The relation of these cases to mitral disease, especially mitral stenosis, as well as to arteriosclerosis, brain disorder, diabetes and chronic nephritis were commented upon and the danger of giving large doses of digitalis was pointed out. Milder cardiac remedies to the almost total exclusion of digitalis should be employed, and this treatment should be supplemented by hydrotherapy, massage, exercises and electricity.

**Discussion.**—J. J. WALSH (New York) reported a case, occurring in a theatrical dancer, in which, although the pulse was constantly at 30 or less, she experienced no inconvenience from it.

**Some Points Pertaining to the Therapeutic Management of the Uremic State.**—HEINRICH STERN (New York) said that diaphoresis was indicated under certain restriction, in every instance of acute uremia, and as early as possible. Its action was more lasting in cases of chronic parenchymatous nephritis. Venesection produced its best results in uremia following acute nephritis. In children from 100 cc. to 250cc., and in adults from 300 cc. to 500 cc. should be abstracted. The improvement resulting from the withdrawal of this comparatively small quantity of blood appeared to be due to the relief of vasoconstriction in the kidneys and central nervous system. The effect of hypodermoclysis and infusion was more transitory, but might prove useful in certain crises. Morphine was innocuous when given in small doses in the uremia of acute renal disease and chronic parenchymatous nephritis, but was not indicated, and was likely to do harm in the uremia of chronic interstitial nephritis.

**Hepatic Ballotement.**—A. L. BENEDICT (Buffalo) described under this title a method of bimanual palpation of the liver.

### THIRD DAY.

**Cancer of the Cervix Uteri Treated by the X-ray.**—THOMAS S. SCULLY (Rome, N. Y.) said that he had had his interest awakened in this subject by the wonderful relief that he had been able to give an old woman suffering from advanced malignant disease, by three or four applications of the x-ray. Three cases were reported in which the results had been quite satisfactory from the use of an elongated x-ray tube which could be introduced into the vagina or rectum, and exposures of about 15 minutes on alternate days.

**An Operation for Cicatricial Contractures of the Upper Extremities.**—A. H. TRAYERS (Albany) reported a case of very extensive cicatricial contraction, in which a useless arm had had its function restored. The contractions were freely divided, and then repair was effected by a series of flap operations.

**Recommendations to the Advisory Board of the Carnegie Institution.**—Some of the eminent scientists of America have submitted recommendations to the Advisory Board of the Carnegie Institution in reference to certain subjects which they believe should be more thoroughly investigated. Professor Langley, of the Smithsonian Institution, advises the establishment of two laboratories, preferably close to the equator, at the greatest possible difference of altitude, yet within sight of each other where under like atmospheric and other conditions simultaneous observations with reference to the solar constant, the unit of heat exerted by the sun's rays on a given surface at a given time, concerning which there is much discrepancy, could be accurately determined by records. Dr. David Jordan, of Leland Stanford University, recommends a special expedition to study ichthyology in the Pacific Ocean, especially in the vicinity of Peru, Chili, Patagonia, China, Okotsk Sea, and some of the islands of the East Indies and Polynesia. Professor Ladd, of the Yale University, makes recommendations in the realm of psychology. He advocates a bureau of information not only of definite results but of partial results, and attempted investigations in the subject of psychology, with a view to keeping all scientists devoting themselves to this particular branch posted as to what others are doing and have done, thus preventing duplication. Dr. Whitman, professor of zoology in the University of Chicago, recommends a biologic farm as a means of studying heredity, variation, and evolution. Professor Johnson, of the University of Wisconsin, urges the establishment of a biologic experiment station for the study of evolution.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## ALBUMIN IN THE URINE: A PLEA FOR THE EMPLOYMENT OF MORE ACCURATE TESTS.

BY

H. E. MONROE, M.D.,  
of Mattoon, Ill.

This article is written as a result of recent study, my aim being to present a brief review of this important subject.

In quantity the urine varies from 1,200 cc. to 1,800 cc. in each 24 hours, the amount depending on the blood pressure and the condition of the renal epithelium.

Polyuria may be due to any of the following conditions:

(1) Diabetes mellitus and diabetes insipidus; (2) all forms of contracted kidneys; (3) after acute infectious diseases, post-infectious polyuria is a favorable prognostic symptom, and when associated with bradycardia has a special significance in scarlet fever, typhoid fever, and pneumonia; (4) in heart affections, when compensation is established; (5) hydro-nephrosis (here the change from a minimal to a maximal amount is of diagnostic aid); (6) in exudates and transudates of the pleuras and peritoneum, when the fluid has been absorbed; (7) after hysteric and epileptic attacks.

Oliguria is associated with the following conditions: (1) Fevers, in which the blood pressure is lowered, there being usually a slight dilation of the heart and increased cutaneous transudation; (2) heart affections in stages of disturbed compensation (valvular lesions, myocarditis and emphysema); (3) in acute nephritis and acute exacerbations of chronic forms; (4) in obstruction of urinary passages, as stricture of the urethra, hypertrophy of the prostate, atony of the bladder, and stones in the bladder or pelvis of the kidneys.

Anuria is seen in the following conditions: Asiatic cholera, uremia, lead colic, kidney stones, cholera infantum, severe cases of dysentery.

The reaction of the urine is faintly acid when the conditions are normal. This normal acidity is due to ingestion of albuminous foods which are changed to acids (phosphoric, sulfuric, hippuric and uric). After a strictly vegetable diet, the reaction is neutral or alkaline. We find an increasing acidity in conditions in which albumin from the body is oxidized as in diabetes mellitus, in cancer, and in fevers.<sup>1</sup> Alkaline reaction is seen in cases in which there is cystitis or atony of the bladder. These conditions permit a fermentation of urine, the urea being decomposed into ammonium carbonate. This is a volatile alkalinity, and is due to the action of ammonia. The litmus paper turns blue, but returns to a red color on heating. Fixed alkalinity is due to an increased alkalinity in the blood, as seen in cases in which exudates and transudates are absorbed, and in stomach disorders when hydrochloric acid is diminished. Albumin may occur in the urine in one of four forms: Serum albumin, nuclealbumin, albumoses, peptone. Each form has a special clinical significance. So long as the renal epithelium is normal, no albumin can pass its barriers, any alteration of it by irritation or otherwise causes presence of albumin in the urine. This change may be only temporary. We may have a physiologic albuminuria, which is met under the following conditions: 1. After excessive muscular exercise. 2. After exposure to cold, especially after a cold bath. 3. After drinking strong alcoholics. These conditions cause temporary injury to the kidneys, a continuation of which will lead to nephritis.<sup>2</sup> Diseases in which we have albuminuria are the following: 1. Acute infections (here we have the febrile albuminuria due to a cloudy swelling of the renal epithelium. The albumin leaves when the fever abates. In the sediment we find urates). 2. In anemic states, especially pernicious anemia, leukemia and chlorosis. This form of albuminuria is due to a fatty degeneration of the bloodvessels. 3. In jaundice we have mostly nuclealbumin present. 4. In heart affections, in the stage of disturbed compensation. When the urinary amount increases the albumin disappears, which is a good prognostic point. 5. After the use of certain drugs, such

as salicylic acid, pyrogallic acid, carbolic acid, chloroform, ether, turpentine, phosphorus, arsenic, etc., which produce renal hyperemia which if continued will lead to nephritis. 6. In pregnancy albuminuria often occurs in primipara, but usually disappears after parturition. A persistence of the albuminuria after the birth of the child points to a nephritis. This form is due to an autointoxication; the organs having extra work an accumulation of toxins occurs, which produces a temporary insufficiency of the kidneys. 7. In the various forms of nephritis.

A consideration of the clinical significance of each form of albumin is now necessary: (1) Nuclealbumin is not found in normal urine. It is the product of desquamating epithelial cells, and is found in all catarrhal conditions of the urinary passages, such as pyelitis, cystitis, urethritis (chronic or acute). Nuclealbumin is one of the constituents of bile, hence in cases of jaundice its presence in urine may be expected.<sup>3</sup> In suspicious cases of gallstones, when but a small quantity of bile enters the blood, we can get the nuclealbumin reaction, and we can get this reaction when the ordinary bile tests are negative; (2) albuminose are intermediate products of albumin digestion in the stomach. Albuminous food is changed by the action of HCl into acid albumin, then to albumoses, and lastly to peptone. This peptonization is necessary to render albumin absorbable. The moment peptone is absorbed and taken up by lymphatics into the blood it is changed to serum albumin, otherwise the entire amount of peptone would be excreted by the kidneys. Albumoses in urine are readily confounded with serum albumin. Its presence does not indicate renal affection at all. We find it present in scarlatina, leukemia, and stomach and liver disorders; (3) peptone is never present normally in the blood, hence it is not present in normal urine. Whenever there is a destruction of tissue and the destroyed tissue is absorbed, peptone is present in the urine. In phosphorus poisoning, in the absorption of amniotic liquor from a dead fetus, in ulcerating carcinoma and in acute suppurations, peptone is present in the urine. The presence of peptone in the urine is of great diagnostic importance in cryptogenic suppurations, and together with polynuclear leukocytosis, is often the only symptom present; (4) serum albumin is the end-product of albuminous food, and is one of the chief constituents of the blood. When the integrity of the renal epithelium is unimpaired there is no leakage of serum albumin. Any irritation of the kidneys produced by cold, chemic, mechanic or toxic irritants, will cause the presence of serum albumin in the urine. In various forms of nephritis this is the form in which albumin appears in the urine, and when associated with casts, blood and kidney elements, points to one of the forms of Bright's disease.

Having now considered separately the forms of albumin present in the urine, we must look into the methods of detecting each form. There are five tests in active use: 1. The heat test: A small quantity of urine is boiled slowly in a test-tube, a cloudiness may be due to albumin or phosphates. Add a few drops of acetic acid and the cloud disappears if due to phosphates. The disadvantage of this test is that in any of the four forms of albumin it will produce a reaction. 2. Nitric acid test: To a small quantity of urine in a test-tube add a similar quantity of nitric acid. A grayish ring appears on the line of contact if the urine contains albumin. This test is not accurate as bile causes a similar reaction. 3. Potassium ferrocyanid, 10% solution: Take two test-tubes and place a small quantity of urine in each. Dilute the urine one-third with water. Now add a few drops of acetic acid to one tube (using the second tube for a comparison of colors). Now mix the two tubes several times and divide again, having some acidulated urine in each tube. Now, to one tube add one or two drops of potassium ferrocyanid solution. This test is positive if a grayish cloud appears and is accurate and delicate. 4. Add to the urine one-third its amount of a 10% solution of sodium hydrate. Now add a few drops of a 2% solution of copper sulfate. If a purple color appears, the urine contains peptone. Normal urine shows a bluish green color. 5. Add to a small quantity of urine twice the amount of a solution composed of equal parts of diluted HCl and sodium chlorid solution (30%). If albumoses are present, a cloudiness appears and disappears

on heating the solution. When allowed to cool the cloudiness reappears.

Urine containing nuclealbumin reacts to the first and second test. On making the third test we get a characteristic cloudiness after the addition of acetic acid that does not increase on addition of ferrocyanid solution if nuclealbumin alone be present. Should serum albumin also be present, the cloudiness increases. Should we desire to examine a specimen of urine containing serum albumin for peptone we must first remove the serum albumin by heating and filtration and then employ the fourth test. In examining urine for albumin begin with the third test. If it is negative, we have excluded all forms of albuminous substances except peptone and by making the fourth test we can prove its presence or absence. For general office work the third test is sufficient. When reaction from the third test is positive, in the majority of cases we are dealing with serum albumin, but as albumoses alone could be confounded with it, by making the fifth test we can be positive. The great majority of physicians rely upon the heat and nitric acid tests. That they are unreliable and unscientific, is self-evident.

## PELVIC ABSCESS CONSEQUENT TO OSTEOMYELITIS OF THE PELVIC BONES.

BY

W. H. MORLEY, PH.B., M.D.,

of Ann Arbor, Mich.

*To the Editor of American Medicine:*—In your issue of December 6, 1902, Dr. H. A. Wilson, in a paper entitled Pus in the Pelvis as a Result of Bone or Joint Necrosis: Diagnosis and Treatment, calls attention to the difficulty of making a diagnosis of disease of the pelvic bones when the pus incident thereto has burrowed its way downward into the pelvis. Through the kindness of Dr. Peterson I am able to report a pertinent case that was admitted to the gynecologic service of the University Hospital, April 30, 1902.

The patient, aged 22, was single. Her family history was negative. Menstruation appeared at 13, and was regular as to duration and amount up to the time of her present illness. A sharp pain in the left side and back usually marked the onset of her periods. A yellowish offensive leukorrhœal discharge existed for six years prior to her admission to the hospital. The patient had one child with a normal puerperium, and one abortion at two months. Her appetite and digestion have always been poor; bowels and bladder negative.

The present trouble began about seven weeks prior to entrance, when a sharp, shooting pain of great severity in the back and left hip compelled the patient to go to bed, where she has since been confined. She first noticed a lameness in her left leg in May, 1899, a few days before the birth of her child. This lameness was more severe at night, and has existed, with periodic exacerbations, since its onset, being much less severe during the warmer weather. The left leg at entrance was flexed on the thigh, and the thigh flexed on the hip. The patient has had to wear a truss for a left inguinal hernia since the birth of her child, three years ago.

Pelvic examination at entrance showed a stellate laceration of the cervix and the uterus apparently crowded to the right by a large fluctuating mass on the left side. Owing to extreme tenderness the boundaries of the mass could not be outlined, nor was palpation of the adnexa possible. Examination of the blood showed 2,600,000 reds, 20,881 whites, with a hemoglobin of 60%. The urine was negative. Her temperature on the day of admission was 102°, and her pulse 150. Both continued high until a vaginal incision was made two days later, when about 2,500 cc. of a very foul-smelling pus escaped. This was followed by a drop of the temperature to normal, and the patient felt and looked better. Four days later the opening in the culdesac was dilated to afford a freer drainage, as the temperature again rose to 102°. This operation gave no apparent relief, and no marked fall in the temperature was observed. The patient complained at this time of pain in her left side, and lay on her right side for relief. Examination disclosed a semifluctuating mass just above the left iliac crest about the size of an orange. Tenderness could be elicited on pressure over the upper part of the ileum and extended over to and included the left half of the sacrum. Examination of the blood showed 27,000 whites.

On May 9, 1902, an incision over the crest of the ileum, at the juncture of its middle with its posterior third, gave exit to about 2,000 cc. of very foul-smelling pus. A uterine sound with some manipulation was passed over the iliac crest down through the opening in the vaginal culdesac. Examination showed an extensive necrosis of the iliac bone with the usual honeycombed appearance. After a thorough irrigation of the wound with salt solution, a perforated rubber drainage tube was passed from the iliac incision down through the opening in the culdesac. The temperature fell to 98° the next morning. The patient made an uninterrupted convalescence until her discharge, June 30, 1902, 52 days after her admission. At the time she left the hospital the opening in the vaginal culdesac was entirely healed and a small granulating wound marked the site of the former incision over the left iliac crest.

The interesting features of this case were: the enormous size of the pelvic abscess and the absence of signs of bone disease, except the extreme flexure of the leg and thigh on the hip. These latter signs were attributed to the effects of the pus in the pelvis, and it was only after the appearance of the tumor near the left iliac crest that the location of the suppurative process was suspected. The lameness in the left leg about the time of her confinement, its acute onset, and the subsequent flexure of the corresponding leg and thigh on the pelvis, are not the usual symptoms that accompany chronic disease of the appendages. The amount of pus that escaped through the vaginal opening was too large for an ordinary pus-tube to contain. Although free drainage was secured through the culdesac, yet the iliac abscess formed, demonstrating by its rapid onset that the primary pyogenic focus was extra-pelvic, because with good vaginal drainage the pus could not have worked its way upward. Incision of the iliac tumor, the passage of the uterine sound down into the vagina, and the necrosis of the iliac bone, confirmed the diagnosis of pelvic bone disease.

## HEMORRHAGIC PANCREATITIS.

*To the Editor of American Medicine:*—The accompanying is a copy of a letter written by my father to his brother in the year 1810, when both were medical students. As describing the lesions of a hemorrhagic pancreatitis it may interest your readers.

G. M. SWIFT.

New York City.

LANCASTER, July 10th, 1810.

Dear Brother,

Last Friday died in this town a Mr. Aaron Rugg, about 50 years of age, whose death was supposed to have been occasioned by a tape worm or tenia, as he had once expelled a part of one & as some of the circumstances attending his sickness and death seemed to favour this opinion. For the satisfaction of the last attending physician, & of the family & friends of the deceased, Saturday morning Dr. Atherton and myself, after preparing the necessary instruments, went to ascertain the fact. We found the family in tears—expressed our sorrow for their affliction—diverted their attention by questioning them about the circumstances of the man's death &c.—got them to furnish us with water, cloths, thread for ligatures, &c. & then entered upon our business. (We had two men in the room with us). The cavity of the abdomen being laid open, its contents exhibited a very morbid appearance. The omentum, mesentery and pancreas were very much decayed. There were two Introsuptions in the ileum, both were judged to be not less than six inches. After this discovery the Dr. gave me the scalpel—we took out the intestine, ran out the canal—found seven common worms, but no tenia. There was a small induration in the liver—the gall bladder was large—the spleen small. Being satisfied, the viscera which had been taken out were replaced; with a large, crooked needle, I stitched up the dissection & we left the body, as nearly as possible, in the same state in which we found it. We then washed and scrubbed in water, vinegar, &c.; & assafœtida that day, for the first time smelt sweet.

When we got to the house we found a sponge had been forgotten; but it proved to be of no consequence as the vessels seemed to be almost entirely free from blood. The Dr. said he could not have a gill in his whole body. It seems that young Dr. Carter, who had been attending Mr. Rugg, & at length confessed he did not (know) what was the matter with him; about three months since, finding him with a flush in the face, "said he had too much blood in his brains"! & accordingly most *injudiciously* diminished its quantity, when there was already too little to keep up a proper circulation! The patient felt himself weakened, said it was wrong and continued to say it, while he retained the use of his reason, which he lost about three weeks before his death. Nos cavemus.—

Yours &amp;c.

W. SWIFT.

## ORIGINAL ARTICLES

## DIFFERENTIAL DIAGNOSIS OF CERTAIN DISEASES OF THE LIVER.\*

BY

CHARLES G. STOCKTON, M.D.,

of Buffalo, N. Y.

Professor of Medicine, University of Buffalo; Attending Physician, Buffalo General Hospital.

In presenting this paper I do not attempt a full discussion of each of the subjects considered, nor do I dwell upon the differential diagnosis in a general sense. It is my aim to bring before you the consideration of certain familiar diseases of the liver and its appendages, so arranged as to contrast most sharply the clinical picture of one as compared to that with which it is, in my experience, most commonly confused.

*First, Between Cirrhosis of the Liver and So-called Syphilitic Cirrhosis of the Liver.*—Some obscurity exists in the current use of the term cirrhosis of the liver. In the broadest sense a liver may be said to be cirrhotic when the connective tissue is present in relative excess. So it happens that the liver is by some called cirrhotic because of the connective tissue ingrowth that follows chronic congestion from stasis in the hepatic veins, or, when it becomes small as a result of chronic perihepatitis and contraction of the capsule and consequent atrophy of the parenchyma; or when the interstitial elements are multiplied in consequence of chronic obstruction of the biliary ducts. In a more specific sense, the term is employed to describe a condition in which the connective tissue increases either within the lobules, or in the perilobular spaces, which follows either infection or the long-continued irritation produced by toxic substances that reach the liver through the portal blood.

No little discussion has ensued relative to the use of the term hypertrophic and atrophic cirrhosis. Histologically, when the round-celled infiltration is especially intralobular, it is said to be characteristic of hypertrophic cirrhosis, and clinically, in such cases, one would expect to find the liver increased in bulk and ascites absent. On the other hand, when the connective tissue grows for the most part in the interlobular spaces around the radicals of the portal veins, and to some extent cuts off the supply of portal blood to the liver, it is said to be characteristic of atrophic cirrhosis, and clinically, one would expect to find in such cases the liver decreased in bulk and ascites present. When one comes to study the subject at the bedside, and later in the dead-house, he finds that this distinction between atrophic and hypertrophic cirrhosis is, for the most part, an academic question. This is so for the reason that in the average case abnormal connective tissue is found in excess both within and without the lobules, and clinically, there may be marked intralobular connective tissue without the liver being appreciably increased in size, and on the other hand, when there is marked increase of the perilobular connective tissue and great obstruction of the portal radicals, the liver may be considerably enlarged as the result of an accompanying fatty infiltration.

I shall use the term cirrhosis of the liver in the more specific sense, applying it to those cases in which the connective tissue ingrowth results from the infections or toxemias, whether this leads to change of intralobular or perilobular tissue. In point of fact, as has been said, both states are actually met, and in both there is found, as Councilman has pointed out, an atrophy of the parenchyma of the organ quite proportionate to the connective tissue increase, and there is strong reason for thinking that the parenchymatous atrophy takes place before the ingrowth of interstitial tissue. Having said this in the interest of a better understanding, I will now make

some comparison between the disease as one ordinarily encounters it—coming about from causes that cannot be isolated or labeled—and a form of chronic hepatitis which occurs in the later stages of syphilitic infection. In the latter condition we have a diffuse round-celled infiltration of the liver in which the new formed elements replace, to a considerable extent, the parenchyma, and at the same time result in increasing the connective tissue about the portal branches. Frequently there is augmentation of the process in a particular area and a gumma is formed. Clinically, the liver is, in my experience, always enlarged; in a few exceptional cases much enlarged; occasionally, when a gumma exists in a region of the liver accessible to palpation, a protuberance may be felt. Ascites may be present or not, and the same is true of jaundice, but the latter is encountered in the majority of cases. Often there is a slight, and sometimes marked, elevation of temperature, and usually there is a decline in weight at times accompanied by an increase in the elimination of urea. In some cases the cachexia of late syphilis is clearly evident, but in others one searches with little success for the familiar late syphilitic stigmata.

Now, if we compare so-called syphilitic cirrhosis of the liver with ordinary hepatic cirrhosis we shall see that there are many points of resemblance. Even when the history of syphilis is undoubted it is generally impossible to exclude simple cirrhosis, for one cannot be sure that the factors which lead to the latter affection may not be operative in a syphilitic patient either with or without an accompanying syphilitic infiltration of the organ. How, then, is one to make the differential diagnosis? To begin with, the fact that the liver is large, that it is frequently bosselated, or at least has an irregular contour, that it is sometimes accompanied by a friction rub would excite suspicion. Moreover, the history of syphilis is always a matter of importance, especially when there are arterial sclerosis, periosteal nodosities or characteristic cutaneous lesions; a history of fever not easily accounted for, the temperature following a course that suggests sepsis, or malaria, or typhoid; but the blood examination excluding all of these should lead one to inquire as to syphilis; and, finally, comes the therapeutic test—the administration of mercury and the iodids. This criterion is altogether the most important, but one must not be too hasty in forming conclusions. It is a wellknown fact that mercury and the iodids occasionally produce a transient beneficial effect in cases of simple cirrhosis of the liver, and on the other hand, cases of syphilitic cirrhosis fail to respond to treatment as promptly as one might expect; also, one finds not a few cases in which there is a blending of the two elements of simple and syphilitic cirrhosis acting at the same time. A careful record of a case before and after the resort to drugs, in a great majority of cases, would settle the diagnosis; and in the syphilitic an apparent cure will ensue in a large proportion of cases. Sometimes the liver is too thoroughly diseased to admit of great benefit no matter how thoroughly the treatment is applied. There may be improvement, but the liver will remain incompetent. In other cases the patient will be restored to comparative health and remain in this condition for some years, when the disease will recur and may remain very resistant to treatment. I have now under observation such a case which I have not hitherto reported.

The patient, a woman of 46 years, entered my clinic in November, 1900. She had drunk freely of whisky for a number of years, denied syphilis, but had suspicious lesions of the skin. The liver was uniformly enlarged two fingers' breadth below the free border of the ribs, slightly irregular and somewhat tender to pressure; she had lost considerable flesh, had ascites, edema of the lower extremities and jaundice. Urea was eliminated in relative excess; there was slight albuminuria, with granular and hyaline casts; the arteries were somewhat sclerotic, and the left heart was slightly enlarged. Mercurial inunction was applied for a period, followed by a similar period of the internal administration of potassium iodid in large doses. Improvement was

\* Read before the Rochester Academy of Medicine, January 7, 1903.

noticed after the second week, and at the expiration of one month there was a marked change for the better. In the early part of February, 1901, the patient considered herself well. The jaundice and ascites had disappeared, the liver had resumed its normal size, and she had regained her flesh. She returned home to resume arduous household duties, and continued well until October of the present year, when she again appeared in the ward with the return of her old symptoms in a more aggravated form. During the past two months she has been under the old plan of treatment; the first month without appreciable result. The ascites became so embarrassing that she was tapped on the first of December.

At the present time she is improving slowly, but it seems to me improbable that she will be restored to a condition such as followed her first course of treatment. In this case we likely have to deal with a mixed form of cirrhosis, partly alcoholic and partly syphilitic. I have met several such cases.

This amount of space has been given the subject for the reason that it calls attention to a group of cases which is amenable to treatment and which is likely to be overlooked. In a paper on syphilis of the liver,<sup>1</sup> which I read before the last meeting of the American Medical Association, there followed a discussion which showed that the subject possesses more than usual interest, and is worthy of still further study.

*Between Cholelithiasis and Cancer of the Liver.*—A frequent and important question in differentiation arises between cholelithiasis and cancer of the liver. The careful study which has been given to cholecystitis and gallstone during the past few years has placed us in a position where we can identify the affection more easily. Formerly the question of differentiation offered at times very serious difficulties, and these are not altogether removed as yet. We have learned that gallstone cases are common, and in their history we find great variation. The liver at some stage of the process of development of gallstone shows at least transient enlargement, but when the patient appears for diagnosis, the enlargement may have disappeared. When there is active cholecystitis, angiocholitis, or obstruction of the biliary ducts by calculus, the liver will be found enlarged. In the absence of these, and with a calculus present in the gallbladder, or movable in the ampulla of Vater, no enlargement of the liver may be found. Jaundice also is frequently absent. Of 720 cases in which laparotomy for gallstone was performed by Hans Kehr, jaundice was absent in 80% or more. In some of these there was a history of past attacks of jaundice. When inflammation of the gallbladder extends into the biliary passages and obstructs these by swelling, jaundice results, as it generally does, from angiocholitis from any cause. Jaundice is to be expected in an intermittent form when the gallstone is at the outlet of the common duct causing transient obstruction. Exceptionally, a stone is so firmly incarcerated that the jaundice is persistent, but this is rare. A more continuous jaundice, and yet one usually attended with periods of remission, is produced by a concretion held in the cystic duct near its junction with the hepatic duct caused by an accompanying inflammatory swelling. A stone thus located is usually accompanied by at least an icteric appearance which, from time to time, is intensified. A stone thus located is more likely to be accompanied by jaundice than when it is passed onward into the common duct.

In the early stages of cholecystitis, with or without the presence of gallstone, the gallbladder is likely to be enlarged. If the inflammation has been prolonged or repeated, one or more concretions are almost invariably present in the gallbladder. As a result of thickening of the walls of the gallbladder and subsequent contraction, the gallbladder is frequently small and entirely covered over by the right lobe of the liver. Only exceptionally in these cases do we find hydrops or empyema of the gallbladder. When a stone is held at the juncture of the cystic and hepatic ducts, the gallbladder is even less likely to be enlarged, and when the concretion is retained at the outlet of the choleductus, enlargement of

the gallbladder is almost invariably absent. Courvoisier first called attention to this fact. Whether jaundice is present or absent under these conditions, the gallbladder is not increased in size. This is contrary to the teachings in the older editions of our textbooks, and for that reason is here emphasized, as was admirably done by Cabot's<sup>2</sup> recent paper. The presence of jaundice, with enlargement of the gallbladder, suggests cancer. On the other hand, with the history of gallstone and with the gallbladder not palpable, it suggests stone in the common duct. This practically is Courvoisier's law.

With acute cholecystitis we often find severe fever, not infrequently accompanied by chills and a marked leukocytosis. This is illustrated in the post-typhoidal cases which I reported at the State Medical Association in 1901.<sup>3</sup> We should not forget that intermittent fever, which suggests a quotidian malaria or marked septi-cemia, may arise from a gallstone present in the cystic or common duct. This latter form of fever is not apt to be seen when the stone is in the gallbladder, save in the early stages when there is acute cholecystitis. Even then the fever differs somewhat in character. In a case of cholelithiasis in which a stone becomes incarcerated in one of the biliary passages, fever may be excited, and this is sometimes unaccompanied by leukocytosis. Such attacks of fever are characterized by the suddenness of the onset, the severity of the rigor, sometimes by high temperature followed by profuse sweating. The disappearance of the febrile attack is often prompt, and it may recur at regular or irregular periods. Such attacks of intermittent fever are rarely seen in this disease except when the stone is engaged in one of the biliary passages.

Gallstone is usually accompanied by pain. This is sometimes inconspicuous, yet is rarely altogether absent. It frequently is located in the epigastrium, but tenderness is usually found in the region of the gallbladder, at the juncture of the ninth rib and cartilage, and, as Boas has pointed out, at a certain point just to the right of the twelfth dorsal vertebra. Vomiting commonly forms a part of the symptom-complex of gallstone.

When cancer affects the liver, it is usually secondary, and some information may be gained by locating the primary growth. In rare cases in which the liver is primarily affected, the organ is usually large before our attention is called to it. More often the gallbladder or biliary ducts are involved, and not infrequently some of the larger branches of the portal are obstructed. As a result, we expect in cancer of the liver to find jaundice, perhaps ascites, and the gallbladder is usually enlarged. The history of the characteristic hepatic colic of gallstone is lacking except in those cases in which cancer is super-added to cholelithiasis. There is also the history of loss of weight, absence of fever and the presence of the cachexia of cancer to assist us in differentiation. In cancer there is often very little evidence of inflammatory reaction, which state is so commonly observed in cholelithiasis. We must not expect to make a positive diagnosis in all cases, even when one of the affections is unaccompanied by the other; but if we remember what has been said about the diagnosis of gallstone, and recall that in cancer we generally find the liver large, jaundice present, the gallbladder increased in size and palpable, a marked secondary anemia and cachexia present, fever and biliary colic absent, we should usually be able to distinguish between the two affections.

*Between cholecystitis with angiocholitis and abscess of the liver* one of the most trying questions in differential diagnosis is occasionally encountered. When a case of cholecystitis, accompanied or not accompanied by gallstone, is complicated by angiocholitis, the symptom-complex may very closely resemble certain cases of suppurative hepatitis. When we come to analyze the subject carefully, we will see that the embarrassment really lies in the fact that in either case there is present an inflammatory process in the region of the liver; and

the difficulty is to locate the seat of the inflammatory reaction. With acute cholecystitis, the fever may be of the continuous type, although accompanied by remissions. If there is a stone engaged in the biliary passages, the fever may be characterized by periods of brief and marked rise in the temperature, to be followed by a stage of sweating. Still there is usually a little difficulty, as has been seen, in understanding the nature of the process when angiocholitis is present. When the latter process appears the liver increases in size, and sometimes the enlargement is relatively localized; over this area there is usually some tenderness upon pressure and often a limited perihepatitis, in which case pain is to be expected, especially on deep respiratory movements. As a matter of course, in case of angiocholitis, jaundice would be an ever-present symptom, but, occasionally, when the inflammation is limited, the jaundice is slight. In angiocholitis, associated with disturbance of the gallbladder or with obstruction of the larger ducts, the enlargement of the liver would appear for the most part at the lower border, so that this region would become palpable. When one meets abscess of the liver it is likely to be single; or, if multiple, there is one which far outranks the others in point of size. The location of such an abscess is usually near the upper, rather than the lower, border of the organ; more often in the right than in the left lobe. As a result, the liver is enlarged upward rather than downward, and there are signs of the invasion of the right pleural cavity, either in the ascent of the diaphragm and the consequent retraction of the lower border of the lung, or in extension of inflammation through the intercommunicating lymphatics, and the setting-up of a diaphragmatic pleurisy with its characteristic signs. This difference in the location of the enlargement of the liver is of importance in the differentiation in question, although it must be remembered that the rule is far from invariable. The fever which occurs in abscess of the liver follows no constant rule; while sometimes of a severe grade it is occasionally surprisingly mild in character, and while it is sometimes marked by remissions and intermissions, it is, on the other hand, sometimes continuous and resembles typhoid. Jaundice is less frequently encountered than might be expected; it may be present as a result of pressure upon some of the larger bile ducts, but more frequently from an accompanying angiocholitis. The pain in abscess of the liver is not usually great unless perihepatitis is present, and even when that is the case, it in no way resembles the pain of cholecystitis. Occasionally it radiates to the right shoulder, but that is equally true of cholelithiasis; in either condition a leukocytosis will be found, and in proportion to the other symptoms it is likely to be greater in hepatic abscess; but even the acute, nonpurulent cholecystitis often gives rise to a marked leukocytosis, and the patients sometimes have a septic appearance even when there is no pus in the gallbladder. The symptoms of acute cholecystitis, owing to the extreme tension which accompanies the inflammation of the viscus, are of a more acute character than those of hepatitis, unless the infection should happen to be of an unusually virulent type. The history of the case should be of assistance because in one we may have an account of previous attacks of pain and the other phenomena of cholecystitis, whereas in the other we may have the history of some antecedent trouble as, for instance, dysentery, from which a hepatic abscess would be likely to spring. When an abscess becomes so conspicuous as to cause edema or bulging of the superficial structures, the nature of the process becomes almost self-evident. It is then not likely to be confounded with anything else, unless it be with suppurating hydatid cyst. Finally, when we suspect abscess, we may have recourse to puncture, and the point of selection would show that we had to deal with abscess of the liver and not empyema of the gallbladder. Aside from the pain which it occasions, I have not seen

any injury come even from repeated punctures of the liver, but when the abscess happens to be small, it is not always easy to find. Still, when available, this diagnostic measure is so valuable that it should not be omitted. On the whole, in reviewing the subject of abscess of the liver, we should array before us these facts: enlargement of the upper rather than the lower border of the liver; inflammation of the pleural cavity, jaundice possibly severe, more likely slight, or absent; tenderness, possibly perihepatitis; fever of varying type; leukocytosis; the history as to causation; and finally, the outcome of puncture.

*Between Sclerosis of the Liver Following Chronic Biliary Obstruction and the So-called Hanot's Cirrhosis of the Liver.*—The question of biliary cirrhosis of the liver, as described in the textbooks of the day, is practically left in inextricable confusion. Osler's Practice presents a distinct picture of Hanot's cirrhosis, and from his description one is able to form a reasonable concept of the condition. Most writers, while possibly implying that a difference exists between the ordinary biliary cirrhosis described by the French and the cirrhosis of the Hanot type, nevertheless discuss these two conditions as though they were speaking of a common disease, and the impression is left upon the reader's mind that the diseases closely resemble each other, if, indeed, they are not identical. In reviewing the literature of the subject one almost comes to feel that the reason for this confusion lies in the fact that the writers depend for their views upon the descriptions which they have found in the French. A few years ago very much was written in France on *Cirrhose hypertrophique avec ictere*, and we have not quite recovered from the results of the foreign discussions concerning the nature of different types of enlarged cirrhotic livers accompanied with jaundice. Undoubtedly the confusion was worse confounded by Charcot's discussion of Hanot's cases in which he attempted to account for the change in the liver by the angiocholitis that existed, and explained the increase in size of the liver and the fatal termination by the retention of bile which resulted. It is a remarkable fact that there is no uniformity in the several textbook accounts either as to the morbid anatomy or the clinical history of the conditions in question. It is possible that this is explained by the fact that many clinicians feel what Eichhorst unhesitatingly acknowledges in these words: "The classifications suggested therefore scarcely indicate more than that every case of cirrhosis of the liver may possess peculiarities of its own and should be carefully examined. Upon what these peculiarities depend has, however, not yet been explained." While there is some truth in this bold avowal it does not do justice to our present knowledge of the subject, and at any rate there can be no doubt as to the separateness which exists between so-called hypertrophic cirrhosis of the liver and Hanot's cirrhosis of the liver. In the former we have to deal with a condition which results from obstruction to the bile ducts from any cause whatsoever: from obstructing gallstones, adhesions, pressure from tumors or long continued inflammatory processes involving the biliary channels, and no matter from what cause we have a resulting stasis of bile, moderate enlargement of the liver, jaundice, with the usual symptomatology of cholemia. Some cases are complicated by connective tissue changes, such as occur in simple atrophic cirrhosis, and in such instances ascites appears. On the other hand ascites may be absent while the jaundice remains intense. The features that are characteristic are continued jaundice, usually marked in character, moderate enlargement of the liver, with little or no change of the spleen.

Compare this now with what is observed in uncomplicated cases of Hanot's cirrhosis of the liver. The disease is usually seen in the young, often in children. The history of alcoholism is generally absent, the onset is

often acute, although the disease is usually protracted. In the beginning there is pain, often severe, in the region of the liver, and probably a temporary elevation of temperature. The patient is found to be moderately jaundiced, the liver is very large; the spleen is also very large, and pigmentation of the skin may be present over and beyond that occasioned by jaundice. There are intervals without pain, but pain recurs without apparent reason, lasting sometimes a few hours and perhaps a few days, usually attended with temporary exaggeration of the jaundice, occasionally accompanied by an elevation of temperature. In the intervals, aside from a sense of hypochondriac pressure, perhaps occasioned by the weight of the liver, and the symptoms of moderate cholemia, the patients make little complaint, and are sometimes for months exempt from all acute symptoms. Eventually, although, perhaps, not for five or ten years, the jaundice deepens, the temperature rises, and the patient ultimately dies from icterus gravis. It is only necessary to see and study a case of Hanot's cirrhosis in order to feel certain that one is dealing with a condition quite distinct from the ordinary hypertrophic biliary cirrhosis of French, and following them of English, German, and American observers. I hope hereafter to report some cases of Hanot's cirrhosis in which the details of the affection may be dwelt upon more fully. For the present it will be necessary only to recall these facts: That a young person is suddenly attacked with abdominal pain, with a very large, sharp-edged, smooth liver, having at the same time a very large spleen and accompanying jaundice, but no ascites; that he afterward improves, but the liver and spleen continue increasing in size, the jaundice never quite disappearing, but increasing from time to time, usually synchronously with elevation of temperature. Observe that this is a very chronic condition, that it is free from a history of alcoholism, or other known cause of disease, and that though it may persist for several years, the fatal outcome in *icterus gravis* is assured, if we are to be guided by the history of recorded cases.

## THE SIGNIFICANCE OF THE PRESENCE OF STREPTOCOCCI IN MARKET MILK.

BY

RAYMOND CLINTON REED, PH.B., D.V.M.,

of Ithaca, N. Y.,

Instructor in Comparative Pathology and Bacteriology, New York State Veterinary College, Cornell University,

AND

ARCHIBALD ROBINSON WARD, B.S.A., D.V.M.,

of Berkeley, Cal.,

Instructor in Veterinary Science and Bacteriology, University of California.

The infectious properties that are alleged to be possessed by milk containing streptococci warrant an inquiry into their significance in comparative pathology. Of particular importance are facts concerning their presence in the cow's udder in health or disease and concerning the etiologic relation of streptococci to gastrointestinal disorders in children.

Moore<sup>1</sup> has found streptococci associated with suppurative cellulitis in the feet and legs of cattle and sheep, in fistulous withers, omphalophlebitis, septic pneumonia, strangles, and brustseuche in the horse, and in sporadic and rapidly-spreading infections of the cow's udder. Moore also called attention to the fact that streptococci exist in the water, the soil, and on the normal mucosa of the mouth, throat, nares, intestines, and vagina. One of us has isolated streptococci from the bronchioles of the horse.

The task of differentiating the streptococci and of

determining their true pathologic significance constitutes one of the great problems which confront the comparative pathologist. Moore<sup>1a</sup> has defined the problem as follows: "1. Are the streptococci which are encountered in different kinds of lesions, such as acute inflammatory processes, abscesses, septicemia and the like, different species? 2. Is a single species of pathogenic streptococcus capable of producing disease in different species of animals, or different kinds of disease in the same species?" The classification of streptococci is far from satisfactory, for there are not yet discovered sufficient characters to differentiate satisfactorily the species of this genus. Klein,<sup>2</sup> von Lingelsheim,<sup>3</sup> Kurth,<sup>4</sup> Pasquale,<sup>5</sup> and Moore<sup>6</sup> have made attempts to place the classification upon a firm basis.

The role of streptococci as the cause of mammitis in the cow and the probable relation of this affection to digestive disorders in infants are both of vital interest to the sanitary dairyman. Mammitis, commonly called garget, is undoubtedly the most common disease of dairy cows. The investigations of Nocard and Mollereau<sup>7</sup> first, and later those of Hess,<sup>8</sup> Nencki,<sup>9</sup> von Freudenreich,<sup>10</sup> Guillebeau,<sup>11</sup> Zschokke,<sup>12</sup> and Moore,<sup>1</sup> all lead to the conclusion that streptococci stand in a causative relation to infectious mammitis. Inflammatory conditions of the udder apparently due to organisms other than streptococci have been observed by workers in Switzerland, but this fact does not concern the subject under consideration.

The affection may occur in isolated cases with or without recognizable sources of infection and with little or no tendency to spread to adjacent animals. In other cases the outbreak may spread to a large proportion of the cows in the stable. In view of the widespread association of streptococci with affections of the domestic animals, the occurrence of cases of sporadic infectious mammitis is not to be considered as surprising.

Infectious mammitis appears without specific symptoms. Sometimes white caseous masses are noticed in the otherwise normal milk, and often the milker first becomes aware of the existence of udder inflammation by noticing the masses of casein lodged on the milk strainer. Sometimes the disease is recognized by the disagreeable salty taste of the milk, caseous masses in the teat canal interrupting the milk stream. Pus is always present in the milk of cows suffering from this affection, but it is not always present in sufficient amount to impart its characteristic appearance to the fluid. The general condition of the animal is not usually disturbed, although the quantity of milk secreted is lessened in the more serious cases. The udder is sometimes swollen and hard, but not always. The congestion of the udder after parturition causes an appearance readily confused with that noticed in cases of streptococcus infection.

The infected milk possesses no constant appearance by which the disease may be diagnosed without a microscopic examination. The streptococci in a sample of such milk adhere to the pus cells and are therefore present in the purulent sediment precipitated from a sample after standing. A microscopic examination is necessary for the certain diagnosis of this infection. The salty taste of the milk is due to an admixture of blood plasma and is not characteristic, for it is also noted in other sorts of udder catarrh. The color may be normal or present a variety of shades due to the presence of a variable quantity of pus or of red blood-corpuscles. A deficient amount of fat brings about the watery appearance frequently noted.

The chemic reaction of the milk varies. The streptococci themselves bring about an acid reaction of the fluid in their vicinity while the serum may be neutral. That is, the streptococci adhering to the pus may cause an acid reaction in the purulent sediment alone. If the sample has stood for some time at a temperature favorable for the multiplication of the streptococci, the whole may become distinctly acid in reaction.

The insidious onset of infectious mammitis renders it exceedingly difficult for even the most conscientious milk dealers to exclude infected milk from the product marketed by them. One of us has repeatedly observed in the Cornell University dairy ephemeral cases of mammitis in which its existence was first called to attention by the presence of white shreds on the milk strainer. In several such instances bacteriologic examination of a sample collected at the next milking when the secretion was apparently normal, showed the presence of streptococci. Slight catarrhal conditions of the udder mucosa without implication of the stroma of the gland, may thus readily pass unnoticed.

Physicians are inclined to designate streptococci as an important cause of infantile digestive disorders. The allusions to streptococci are generally indefinite, no effort being made to differentiate the species of this genus. In the cases in which streptococci have been charged with inciting intestinal disorders in infants, the assertion is based upon the fact that streptococci have been isolated from the milk. This lack of information concerning the association of streptococci with the morbid processes is unavoidable except in cases coming to postmortem examination.

G. Leslie Eastes<sup>13</sup> writes as follows: "I have also not the slightest doubt that unboiled milk containing streptococci is also to be held responsible for some of the cases of infantile diarrhea and mortality." Holst<sup>14</sup> observed a series of cases of acute gastric catarrh which he attributed to the ingestion of milk containing streptococci. He reports cases of gastric disturbance in four families, apparently caused by raw milk, for only those members of the families that partook of the raw milk were affected. In each instance he found that the patients had partaken of milk from cows suffering from inflammation of the udder.

Niven<sup>15</sup> reports extensive poisoning among the patrons of a single milk dealer. The patients suffered from "diarrhea, sickness, and abdominal pain" and only those persons who had partaken of the milk were seized. A bacteriologic examination revealed the presence of *Bacillus coli communis* and streptococci. It was ascertained that one of the cows in the dairy supplying the milk had been suffering from garget for some time, and on the day when the milk which caused the sickness was produced, the inflammation of the udder of that cow was most marked. While the author considers streptococci to be the cause of the trouble, yet he does not present conclusive evidence in support of that belief.

Wm. Royal Stokes<sup>16</sup> writes: "The prevalence of the acute intestinal disorders among children using cow's milk is well known and many of these conditions are caused by the organisms of suppurative. It would seem therefore that milk from diseased cows, containing these germs, might often be the cause of intestinal troubles especially in young infants.

Busey and Kober<sup>17</sup> hold similar views based upon the authority of Kruger,<sup>18</sup> Nocard and Mollereau,<sup>7</sup> Bang<sup>19</sup> and others.

Bergey<sup>20</sup> observed sickness in an infant fed on milk from a first class dairy and an examination revealed the presence of streptococci in the milk. "This result led to the employment of milk from other first class dairies and the examination of each yielded the same results, viz., the presence of large numbers of streptococci."

Nothing definite can, as yet, be stated with regard to the significance of the presence of streptococci in the milk of healthy cows. Beck<sup>21</sup> believes that they are closely related with the streptococci which Escherich found in infantile enteritis.

Hirsch<sup>22</sup> has described in minute detail the progress of a fatal case of gastroenteritis in an infant, in which streptococci was the etiologic agent. He found the organism like *Streptococcus involutus*, described by Kurth, and found it to be pathogenic to white mice only. Lib-

man,<sup>23</sup> Tavel and Eguet,<sup>24</sup> and de Cerenville<sup>25</sup> have made similar observations.

Apart from gastrointestinal disorders, streptococci have been found associated with various widely differing affections in man. Among these are erysipelas, phlegmonous inflammation, septicemia, puerperal fever, the various forms of angina and tonsillitis. They are constantly found on the mucosa of the upper air passages in health, a fact of interest in connection with our observations concerning their presence in the healthy udder.

In the winter of 1897-1898 one of us<sup>26</sup> while studying the bacterial flora of the udders of several of the cows in the Cornell University dairy noticed the constant presence of streptococci in the freshly drawn milk of one cow. The fact that she was not suffering from mammitis and that she had not so far as known shown symptoms of that affection, lent special interest to the observation. Moreover no streptococci were found in cultures made from the milk of the other seven cows under observation.

The cow under consideration had during the years 1895-1896 headed the University herd in butter production. The fact that the milk record of this cow shows a steady increase since 1892 indicates that she has never suffered a serious attack of infectious mammitis.

Since the presence of streptococci in the udder of this cow was first noted in 1897 their persistence has been observed at varying intervals up to the time of her slaughter. Cultures were made from the milk of the four quarters on November 4, 9 and 23, 1897. On the first two occasions streptococci were observed in overwhelming predominance. On the third examination some micrococci, which had been observed to be present in small numbers on the previous occasions, were found in relatively greater numbers. Agar plate cultures made from the fore milk of all of the quarters on February 2, 1898, showed streptococci in great numbers, almost to the exclusion of other forms. They were found again on several test examinations in 1899.

Samples of milk collected March 27, 1900, showed streptococci to be present in the strippings of all four quarters, as well as in the fore milk.

On April 12, 1900, a sample of the strippings from one quarter was plated in agar for a quantitative determination. On the following day, after incubation, 360 streptococcus colonies were seen, no other species being present. A culture made later in the same manner from another sample of the strippings from the same quarter showed about 150 colonies.

The cow was milked the last time on April 30, 1900, turned out to pasture until July 19, when she was slaughtered. The killing of the cow offered opportunity to study the bacterial flora of her udder<sup>27</sup> by means of cultures made directly from the glandular tissue. At the abattoir the udder was carefully dissected off without laying bare the glandular tissue and was taken to the laboratory, where the cultures were made.

The bacteriologic work upon the udder was carried on under conditions that accorded special assurance of freedom from contamination. For the sake of convenience in recording results, it was decided to designate arbitrarily three regions of the udder and teats to be known as A, B, and C. Region A includes the teat and milk cistern. Regions B and C include equal portions of the glandular tissue. The different quarters, right fore, right hind, etc., were abbreviated RF, RH, etc.

In one of the quarters an incision several inches deep was made, extending from the region farthest from the teat down to the base of the teat. From the sides of this gaping incision bits of the glandular tissue were detached with scissors and transferred to tubes of cool liquid agar which were shaken and the contents poured into petri dishes. Two agar plate cultures were made from each of the regions A, B, and C. One bit of tissue from each region was placed in bouillon also. The same procedure was repeated in each quarter in succession.

Examination of the cultures after incubating over night revealed the presence of streptococci in overwhelming predominance in all the cultures. While the color and general appearance of the streptococcus colonies on the agar plate cultures were sufficiently characteristic, yet at least two bouillon subcultures were made from each plate. Numerous coverslip preparations were made directly from the colonies. The bouillon subcultures after 24 hours' incubation were all slightly clouded by flakes distributed throughout the medium, and showed a grayish-white, viscid sediment. Microscopic examination of each of these 50 cultures revealed the presence of streptococci growing in long chains. Direct microscopic examination of the bouillon tubes that had been implanted with bits of glandular tissue detached from the udder, revealed the presence of long chain streptococci, together with a few other micrococci.

Besides the streptococci, the plates showed a few orange-yellow colonies of micrococci and some growing in white colonies. Their presence is not regarded by us as indicating an abnormal condition of the udder. One of us<sup>23</sup> has examined 16 healthy udders in the manner just described, and these chromogenic micrococci have been found in every case. Moreover these same species are practically always present in milk drawn under conditions that exclude the presence of organisms from other sources than the interior of the udder.

All the cultures except those on gelatin were incubated at 37.5° C.

*Morphology.*—The individual micrococci measure about one micron ( $1\mu$ ) in diameter. In bouillon and other fluid media the chains consist of 10 to 50 or even hundreds of units. Upon agar the chains are short; that is, consist mostly of less than 10 units. The streptococci stain readily with the anilin dyes in ordinary use in the laboratory. They also retain the Gram stain.

*Action of Disinfectants.*—Potassium permanganate in a 1% solution and boric acid in a 2% solution failed to kill after an exposure of 30 minutes. Carbolic acid 5%, mercuric chlorid .1%, lysol 2%, and Marchand's hydrogen peroxid, diluted one-half, all killed in one minute.

*Effect of Sunlight.*—Sterile cover glasses smeared with a drop of a 24-hour bouillon culture were exposed to the bright sunlight for one hour in a sterile petri dish. These cover glasses placed in bouillon failed to develop cultures of the streptococcus. Cover glasses treated in the same manner, except that they were kept in the dark, retained living streptococci after 48 hours, a fact demonstrated by introducing them into bouillon.

*Inoculation Experiments.*—The small experimental animals uniformly failed to succumb to inoculation with this streptococcus. The effect of this streptococcus upon the udder of a dry cow was determined by injecting a bouillon culture through the teat canal. A bacteriologic examination of the fluid contained in her udder showed the presence of a white micrococcus only. After thoroughly disinfecting the udder and teats, a sterilized milking tube was inserted into the teat of the right hind quarter. Five cc. of a 24-hour bouillon culture were introduced by means of a sterile hypodermic syringe inserted into the milking tube. After 48 hours the right hind quarter was enlarged to twice the size of its opposite. Tenderness and local hyperthermia were marked, the lactiferous ducts contained a turbid yellowish fluid, samples of which, upon standing, showed a purulent sediment. Microscopic examination of the pus failed to reveal streptococci, but inoculation of media with pus yielded pure cultures of the organism.

The infection ran a short and mild course, a fact not surprising in view of the absence of functional activity. The contents of the affected quarter, at first purulent, gradually approached the normal until on the tenth day no difference could be noted between it and that of the healthy quarter. However, 20 days later this quarter still retained a slight induration, determined by comparison with its neighbor. Cultures of streptococci

were obtained from the contents of the udder on the third, fourth and sixth days after the cow was inoculated. Fourteen weeks after inoculation the cow was slaughtered and her udder subjected to a bacteriologic examination.

At the same time that we were studying the character of this streptococcus, we were so fortunate as to obtain a sample of milk from a cow belonging to a dairy in which a number of others were also suffering simultaneously from mammitis. This infection had also appeared the previous year in the same herd, and a bacteriologic examination was made at the time by Dr. V. A. Moore,<sup>1</sup> to whom we are indebted for the sample examined by us. No cultural or morphologic characters were discovered by which this virulent streptococcus No. 2 could be differentiated from the one isolated by us from the healthy udder, which we designate as streptococcus No. 1. A rabbit was not visibly affected by the injection into the ear vein of  $\frac{1}{2}$  cc. of a 24 bouillon culture of streptococcus No. 2. Nevertheless this culture injected into another quarter of the same cow, which we had previously inoculated, induced an attack of mammitis identical, clinically and bacteriologically, with the attack caused by the injection of streptococcus No. 1.

We also availed ourselves of an opportunity to study a streptococcus from a so-called sporadic case of mammitis occurring in a cow belonging to the Cornell University dairy. It will be remembered that it was in a cow belonging to this herd that we first noticed the persistence of streptococci in the healthy udder. This streptococcus could not be differentiated from the first two studied. It was not pathogenic to the rabbit, but induced mammitis in a third quarter of the udder of the dry cow which had already been inoculated in two other quarters with the other two streptococci. The symptoms and course of the mammitis induced were identical with the other two attacks.

The behavior of the udder of this dry cow in response to the injection of these three cultures from widely different sources presents some interesting and significant facts. It was somewhat surprising to observe mammitis in a quarter of the nonfunctioning gland induced by the injection of the streptococcus isolated from the healthy udder. Ten days later, after the inflammation had subsided, two diagonally opposite quarters were inoculated with the two streptococci obtained from the diseased udders. Nevertheless these cultures failed to induce a type of mammitis more severe than that caused by the first one. It is interesting to note that the attack first suffered did not confer immunity upon the other two quarters subsequently inoculated.

The presence of streptococci in the healthy udder has its parallels in the case of other organisms. Among these are: the Klebs-Loeffler bacterium, the organisms of pneumonia in man, and the septicæmia hæmorrhagica group causing pneumonia in the various animals, all of which may be harbored in the upper air passages of individuals ordinarily susceptible to the diseases produced by these organisms without themselves suffering from the disease. However, these organisms when communicated to a susceptible individual may produce the disease in question.

It is a matter of common observation that the use of a sterilized milking tube with aseptic precautions in cases of teat obstruction is liable to induce inflammation of the udder resembling that caused by streptococcus infection. One of us has observed a severe case of streptococcus mammitis induced in a milk-fever patient by the injection of potassium iodid solution into the udder, in spite of the fact that the udder was washed in 1:1,000 mercuric chlorid solution and that the milking tube had been boiled. In another case we have observed that a sterile milking tube used after carefully disinfecting the teat occasioned a mammitis associated with streptococci.

These observations concerning the presence of strep-

tococci in healthy udders and concerning the appearance of mammitis after slight irritation, as the careful passage of a sterile milking tube, suggest an interesting field for future investigation.

CONCLUSIONS.

The classification of streptococci is still in an unsettled state on account of the lack of reliable differential characters. At the present time the species of streptococci are largely designated by the lesions with which they are found associated, a fact which causes the greatest confusion in the study of this genus. It is noted with regret that many writers refer to streptococci rather loosely without apparently recognizing the necessity for a more specific nomenclature.

The common prevalence of mammitis in the cow constitutes an important source of streptococci in market milk. The insidious onset of the disease is responsible to some degree for the marketing of infected milk by dealers with innocent intentions. The results of the common method of milk handling in the stable deserves mention. The milk, directly after drawing, is usually strained into a 40-quart can, or even larger receptacle. The existence of udder inflammation is frequently first brought to notice by curd-like masses lodged on the strainer after the infected milk has been mixed with the wholesome milk. The ignorance or greed of the milker, or both, may prevent the rejection of the infected lot.

From the references available to us, it is evident that the medical profession regards the presence of streptococci in market milk as dangerous to public health.

The transition from the condition in which a few streptococci remain after a mild attack of mammitis to one in which streptococci are found in a healthy udder is a slight one. We have been unable to discover characters by which the streptococci found in the healthy udder can be differentiated from those associated with active inflammation of that gland.

We believe that recent investigations indicate that streptococci are found in the healthy udder more frequently than was formerly believed to be the case.

In order to understand the conditions under which these streptococci harbored in the healthy udder may become virulent will require a further study of the pathology of mammitis.

TUBERCULOSIS OF BRONCHIAL GLANDS; TUBERCULIN; CHEST PAIN.<sup>1</sup>

BY

G. W. McCASKEY, A.M., M.D.,  
of Fort Wayne, Ind.

Professor of Clinical Medicine, Fort Wayne College of Medicine.

The extensive prevalence of tuberculosis in all civilized countries makes every question connected with its diagnosis and treatment of paramount importance. The germs of tuberculosis are ubiquitous and are probably inhaled by every member of every civilized community in the world, but susceptibility and immunity are the factors which determine the results of infection in individuals. Immunity is perhaps for the most part practically synonymous with the high resistive power incidental to a first class nutritional state, and this may be either natural or acquired. While it is of the utmost importance that this acquired immunity should exist in time to prevent the initial infection, yet it is not too late in many cases, probably in most cases, after such infection has occurred, provided that the primary local infection has not progressed too far. Herein lies the vital importance of early diagnosis. In order that this acquired immunity may be bestowed upon the tissues, the individual must have ample nutrition, outdoor life, and all other suitable auxiliaries early enough to limit the tuberculous process to its original site, and make of it a purely local and, to a large extent, innocuous process.

The difficulty of early diagnosis, together with our therapeutic impotency in the very late stages of the disease, constitute the *bête noir* of tuberculosis. In order to afford a reasonably fair prospect of limiting the disease by the measures just indicated it is desirable to make the diagnosis long before either physical signs or constitutional disturbances are available for diagnostic purposes. Tuberculin affords the only means of establishing a diagnosis sufficiently early to meet these indications. In spite of the demonstrations of its usefulness along this line it is neglected altogether too much in dealing with obscure cases of nutritional disease. In the last two or three years I have been making tuberculin injections for diagnostic purposes in a considerable proportion of such cases referred for diagnosis. Whenever the pathology is obscure and the case refractory from a therapeutic point of view, the advisability of using tuberculin to clear up the diagnosis is always considered, and is frequently resorted to. In quite a number of such cases it has given most gratifying results. The initial dose depends altogether, in my own practice, upon the character of the case. I rarely give so small a dose as 1 milligram,

<sup>1</sup> Read before a joint meeting of the Wabash and Miami County Medical Societies, at Peru, Ind., September 3, 1902.

and when the patient is robust and the evidences point to a circumscribed area of involvement, I begin with 5, 7, and exceptionally in cases in which time is important, 10 milligrams. On the other hand, if the constitutional disturbance is marked and the indications point to an extensive morbid process which may possibly be tuberculous, I then begin with 2 or 3 milligrams, repeating the injection if no decisive reaction is obtained in three or four days, increasing the dose as rapidly as circumstances seem to warrant, until the maximum dose of about 30 milligrams has been given, or somewhat less for patients who are not very strong, when, if no reaction has been obtained, tuberculosis is confidently excluded from the case. There is, in my opinion, absolutely no danger if the same discrimination and clinical judgment are used in dealing with this as with any other potent chemic factor which is to be introduced into the circulation. Care must be taken that successive doses are not sufficiently close together to produce immunity instead of reaction. The increase in dosage, however, can be made so rapidly in most cases as to make this extremely improbable. It is needless to say that active syphilitic disease should be excluded in estimating the value of the febrile reaction.

The other point to which I desire to call attention is the treatment of certain types of tuberculosis with tuberculin. During the initial stage which exists when this early diagnosis has been made, I believe tuberculin to have a positive value as a therapeutic agent. Later, when extensive disease has occurred, with the usual mixed infection, it is irrational, and can only add to the number of chemic poisons which the circulation has to dispose of. These points were clearly defined and insisted upon by Koch, but too generally ignored by his reckless, if not dangerous, followers.

The following case, the report of which is the principal motive of this paper, is presented because of its bearing on these points, and also as an illustration of a form of tuberculosis the early recognition of which is rare:

Mrs. E., aged 41, was first examined May 22, 1901. She complained of substernal pain together with dyspnea on slight exertion which had become quite extreme. The patient was mildly cyanotic at the time of her first visit to my office. Some of the paroxysms of dyspnea had been alarmingly severe, and were undoubtedly due to attacks of acute dilation of the heart, during which she felt as "though her chest would burst." There was a history of slight dyspnea on going up stairs for a period of ten or twelve years, indicating some chronic weakness of the heart.

Her bowels were obstinately constipated, never moving without laxatives. There was also marked distress after meals with extreme gaseous distention of the stomach, especially severe if she was careless with her diet.

Physical examination showed a very weak heart, vascular tension as estimated by Gaertner's tonometer being about 40 mm. of mercury. The heart sounds were correspondingly weak, and the left border of the heart extended about two inches too far to the left. The pulse was weak, and about 100 per minute. There was, however, no evidence of valvular incompetency, the heart weakness being apparently due to the atonic state of the myocardium.

The liver was considerably enlarged and easily palpable. Examination of the fasting stomach showed the usual debris of chronic gastritis, and the Ewald test-breakfast revealed the absence of free hydrochloric acid although there was a total acidity of 100 degrees. There was also severe chronic colitis with large quantities of mucus, epithelium, and leukocytes. Urinary examination: total quantity in twenty-four hours, 1,000 cc.; urea, 3%; chlorids, 0.4%; phosphates, .15%; no albumin or sugar but a considerable quantity of "indican."

On the basis of this examination the symptoms were supposed to be the result of myocardial atony and probable degeneration resulting from chronic toxemia of gastrointestinal origin, and the patient was placed upon a line of treatment based upon this diagnosis. She was given local stomach treatment, including intragastric faradism, together with colon lavage and faradism, and was, in addition, placed upon a course of Nauheim baths, which resulted in a cure in about three months so far as the principal features of the case were concerned. The heart gradually improved in tonicity (Gaertner's

tonometer indicating 100 mm. of mercury), and at the end of three months its area was nearly normal. The gastrointestinal atony had been largely overcome, stomach digestion was improved and the bowels were acting without laxatives a part of the time, which had not been the case for years. The dyspnea had also ceased to be troublesome. The patient could walk up stairs without any marked discomfort.

At this point, however, improvement ceased, and certain symptoms remained which at first were regarded as due to pressure of the dilated heart, but which now that the heart had practically resumed its normal relations and tonicity still persisted. These symptoms consisted for the most part of diffused pain in the upper part of the chest and a very slight irritative cough; and, in spite of the improvement in other respects, they seemed to grow progressively worse. Moreover, physical examination of the chest repeated again and again revealed nothing whatever by auscultation or on percussion so far as the lungs were concerned. The patient's temperature having been taken every three hours for a number of days and once or twice during the night was found to be strictly within the normal range. Tuberculosis was suspected and 4 milligrams of tuberculin were given at the first dose. No reaction ensued. At intervals of about three days the dose was increased by 5 milligrams each time until a little over 20 milligrams had been reached. The third dose produced a slight reaction and the fourth a temperature of 103°. As there was no other apparent explanation of the febrile reaction—lues being positively excluded—the existence of tuberculosis was assumed, and on the basis of the clinical history (slight dulness over bronchial glands and absence of pulmonary signs) was thought to be located in the bronchial glands, and probably limited to them.

Treatment by tuberculin injection was then instituted beginning with 0.05 milligram and carried out systematically over a period of about six weeks. It is unnecessary to enter into the details of dosage, but several times during the course of treatment, if the dose was increased a little too rapidly, fever ensued, thus further corroborating the primary diagnostic test. Guaiacol carbonate with a tonic, and suitable diet and hygiene, constituted the balance of the treatment. At the end of this time the symptoms had not improved materially, although the failure on the part of the system to react to large doses of tuberculin showed that immunity had been established. It was not long, however, before symptomatic improvement occurred, and now, eight or ten months after cessation of treatment, there is no indication of tuberculous disease. The chest pain and cough have disappeared. It is not supposed, of course, that the tuberculous glands have disappeared, or that they have ceased to be tuberculous, but they have probably become somewhat smaller (a change which Birch-Hirschfeld and others admit), and the tissues have become adjusted to their presence. They still constitute, however, so many foci of latent tuberculous disease which may remain latent or may become a source of metastatic infection, depending on circumstances; in other words, depending on whether the patient's resistive power is able to maintain the artificial immunization which was apparently produced by the tuberculin.

#### CHEST PAIN.

The diagnostic value of superficial chest pain in its relations to disease of the thoracic viscera may well arrest our attention for a moment. The incipient stage of many intrathoracic diseases is shrouded in obscurity. In some of them, notably those involving the contents of the general mediastinal space, there often exists pain in the distribution of the intercostal nerves. Such pains are so commonly the expression of diathetic states that they are too likely to be summarily dismissed with that label attached. That this is often an error, and a costly one to both patients and physician, needs to be empha-

sized. The earliest manifestation of a serious intrathoracic lesion may consist of a pain of this character, and if to this we add the possibility, or even probability, of associated disturbances, the difficulty of assigning such pains to their proper source becomes sufficiently apparent.

The "expression" of a pain at a considerable distance from the irritative lesion which causes it is a familiar fact in the physiology of disease. A detailed consideration of these phenomena would lead me too far, and I will only remark that the "transfer" may take place along the direct line of a nerve trunk, as in the knee pain of hip-joint disease, or in commissural paths in the spinal cord or elsewhere, as occurs in the superficially referred pain of visceral disease.

The accompanying diagram (Fig. 1) is intended to schematically express the neural paths through which such painful impressions could be referred to the spinal nerve routes and thence to the spinal cord and the sensory areas which are represented in it. There are perhaps other relations of the sympathetic and vagus of equal interest and importance with those in the diagram, but these are sufficient for our purpose, and, besides, have a special bearing upon the case herein reported. It will be seen that the various nerve filaments passing between the structures at the root of the

irritative cough, pain, disturbances of cardiac rhythm, etc. The pain of cardiac disease, which we know is not located in the heart but in the distribution of superficial sensory nerves, is explained somewhat similarly by Gibson.

It is not at all surprising that the bronchial glands should be the primary seat of tuberculosis. The fact is

Fig. 2.—Modified from Symington's cross section of human body, showing relations of bronchial, principal neural and vascular trunks, and lymphatic structures at level of bifurcation of trachea. M.S., Manubrium sterni. L., General outline of lungs. A.A., Arch of aorta. D.A., Descending aorta. Aes., Esophagus. R.B., Right bronchus. L.B., Left bronchus. R.V., Right vagus. L.V., Left vagus. L.R.L.N., Left recurrent laryngeal nerve. L.G., Lymphatic glands. (All irregular heavily shaded areas, not otherwise designated, are lymphatic glands.)

Fig. 1.—Diagram illustrating the neural relations of bronchial, vagus nerve, cervical sympathetic, and spinal cord. 1, 1, 1, Filaments connecting cervical sympathetic with spinal cord segments. 2, Cervical sympathetic ganglion. 3, 4, Filaments connecting ganglion with others above and below. 5, Sympathetic fibers to bronchi. 6, Fibers connecting sympathetic with vagus. 7, Vagus fibers to bronchi. 8, Pneumogastric nerve. 9, Trachea. 10, Right bronchus.

lungs, and the vagus and sympathetic are related to the anterior roots of the spinal nerves by filaments from the sympathetic ganglion. Irritative lesions implicating the visceral nerve fibers referred to may, and probably do, produce impressions not primarily painful in character, but passing through the spinal cord they are transmitted into painful impressions, which, in accordance with well established physiologic laws, are referred to the sensory areas, which find their representation in the segment of the cord thus related.

The next diagram (Fig. 2), modified from Quain (Symington), shows the relation of the various structures concerned in the case reported, by a transverse section of the thorax at the level of the bifurcation of the trachea. It will be seen at a glance that enlargement of the bronchial and neighboring lymphatic glands can easily produce in the nerve trunks referred to irritative or paralytic phenomena, either by direct pressure upon them or indirectly by encroachment upon the bronchial walls, hence

well known that in adults they are commonly found blackened by the interception of carbonaceous matter which is taken up by bronchial lymphatics and carried to the glands. Specific infection can reach these glands in precisely the same manner, and probably does so very much more frequently than is recognized. Their close relationship to other mediastinal lymphatic structures makes extension of the disease easy.

It must always be difficult to recognize such processes unless they have involved some of the structures to which attention has been called in such a way as to produce symptoms that are somewhat characteristic. This, however, is very apt to occur in the progress of the disease. In one case reported by Olliver and Ranvier the vagus and recurrent laryngeal nerves were involved in a mass of glands weighing 700 grams. The early diagnosis of this condition is of the utmost importance, and my principal object in reporting the case is to call attention to the early symptoms which may lead to their recognition and proper treatment.

## THE NERVOUS CARDIAC SYMPTOMS DUE TO HIGH ALTITUDES. <sup>1</sup>

BY  
F. SAVARY PEARCE, M.D.,  
of Philadelphia.

Professor of Nervous and Mental Diseases, Medico-Chirurgical College of Philadelphia; Neurologist to the Philadelphia and Howard Hospitals.

It was my privilege last year to present the subject of the Influence of Climate upon Nervous Diseases Considered from a Physiological Standpoint, <sup>2</sup> in continuation of a series of studies begun during extended travel through New England, Canada and the West, which observations were first brought together in a paper entitled The Climatology of Neurasthenia <sup>3</sup> and presented before the Medical Society of the State of Pennsylvania, September, 1900. It has been satisfactory to see that the

<sup>1</sup>Read before the American Climatological Association, June 9, 1902, at Los Angeles, California.  
<sup>2</sup>New York Medical Journal, October 5, 1901, and Transactions of the American Climatological Association, Vol. 17.  
<sup>3</sup>Medical News, January, 1901, and Transactions of the Pennsylvania State Medical Society, 1900.

line of thought presented has met some approval by the profession. The interest of the subject is only surpassed by the difficulty in determining accurate scientific facts. Nevertheless we feel that certain physical conditions, as regards atmospheric pressure, winds, altitude, etc., do influence materially the normal human body and very much more pronouncedly the sufferer from disease, particularly of the nervous system, functional or organic.

*The Effect of Altitude Upon the Heart in Normal People.*—The physiology of the normal person is so nicely adjusted and resilient, so to speak, that changes of altitude in healthful countries when not made suddenly and to too great height, say up to 5,280 feet, about that of Denver, will certainly not cause the least disturbance. I have noted this from personal experience and from that of many others. Even at the altitude of Las Vegas, New Mexico, which is 6,398 feet above sea level, I have known normal people who experienced no discomfort whatever. At the altitude of Pike's Peak, over 10,000 feet, we all know that many do experience disagreeable sensations and palpitation of the heart. However, as we ascend, the increasing altitude tends to produce a more easily excitable heart in normal persons, owing in a measure to the increased peripheral circulation through the lessened vis-a-fronte, and this continued through generations may be the cause of dwarfism as shown in the Thibet men, probably on account of the fact that the important organs of body metabolism, such as the liver, are less constantly kept flushed with fresh blood and that therefore the important chemic changes necessary for bodily growth do not occur. *A priori*, it seems patent that the best type of physique will be produced by individuals whose ancestors have for many generations lived by hard manual work associated with acute mental calculations and on moderately high plains as of our Western States at the foothills of the Rocky Mountains. The theory recently promulgated by Loeb and Matthews tending to prove an electric energy as nerve force, if found to be correct, may awaken renewed investigation toward solution of this perennially interesting problem of functional nervous disease and consequent functionally perverted action of the heart herein considered.

*The Effect of Altitude Upon the Heart in Functional Nervous Disease.*—While the successful treatment of disease of the mind and nervous system depends so much upon remedial measures to which drugs are important adjuncts, it is likewise true that changes of season, climate, etc., are fundamental conditions controlling many diseases. In a consideration of possible affection of the heart due to altitude, we must bear in mind at the outset that the "nervous heart" so-called is entirely dependent upon the condition of the nervous system; *e. g.*, in neurasthenia the rapid irritable heart is a frequent accompaniment. As this form of cardiac disturbance frequently occurs in nervous exhaustion, it follows that the favorable or unfavorable effect of altitude in disease of the mind and nervous system, especially in this particular disease, neurasthenia, will also be coincident with an effect upon the disturbed heart. "It is almost axiomatic that an altitude of over 2,000 feet is unsuitable for the neurasthenically disposed or convalescent patient. Any very 'stimulating' climate should be avoided. Other conditions to be avoided are districts menaced by high winds and frequent fogs; cloudy saturated atmospheres with but slight movements of air current, low country (sea level) with continuous nonvarying although moderate heat, as where the effect of the Gulf Stream is strongly felt. Thus the Bermuda Islands and Florida are enervating localities. Ideal conditions for the neurasthenic include sea-air in a well-wooded country far enough from the coast to avoid its fogs. A sea voyage is, as a rule, an excellent preliminary to other climatic measures. Provided the voyage be not stormy, it acts both physically and psychically in soothing the nervous system. In order to obtain the full benefit of correct climatic conditions

the patient must have good food. Without this important adjunct the desirable climatic change may be entirely defeated in its effect on the patient."<sup>1</sup>

A paper on the Blood Count in High Altitudes, by Dr. W. A. Campbell, assisted by Dr. H. W. Hoagland, read before the American Climatological Association at Niagara Falls, gives some further clue to the solution of the effects of high altitudes upon the cardiovascular system, and as stated in the discussion of that paper I still believe that the sensible perspiration carrying off much of the waste products of the body produces great benefit to nervous individuals when autointoxication is coexistent. Also that at high altitudes increased sensible and insensible perspiration occurs according as the air is moist or dry, and that as a rule, therefore, cases of idiopathic nervousness or essential neurasthenia will do better at the lower altitudes suggested. The decrease of atmospheric pressure at altitudes above 6,000 feet certainly does in some as yet unknown way tend to weaken the inhibitory ganglions of the cardiac muscle. Yet it is not fair either to compare physical experiments with actual facts as determined by clinical observation in the effect of heat loss, since the human body is entirely different from any inorganic mass; *e. g.*, if in a phial of water it is found that the liquid loss is more rapid at sea level, then the human body will likewise lose; the element of complete metabolism is so interwoven with health that the effect of height with its associated winds and temperature will prove of value only as they are constant and active agents toward aiding better internal absorption of food products.

Nor does it necessarily follow that an irritable heart which the patient describes to us will ultimately prove to be a truly irritable heart by the *continuance* of the same climatic conditions, among them altitude, which latter seems to be and often is the etiologic factor for this condition. In some cases it may be that this disagreeable affection of the cardiac muscle will have to be tolerated until the patient can come to a fundamental condition of otherwise good nervous health. I have a case at the present time, that of a young lady suffering from hysteroneurasthenia with a disagreeable and at times dangerous herpetic eruption upon the vocal bands, in which Dr. E. B. Gleason excluded any organic disease of the throat, and in which the rest treatment associated with mental therapeutics had greatly bettered the condition. We sent the patient to Las Cruces, New Mexico, at an altitude of 3,730 feet above sea level, where an irritable condition of the normal heart muscle was shown to have been produced within a week; although her general nervous health, it may be stated, was definitely improved, probably due to the dryness of the atmosphere itself. A letter received May 26, 1902, gives a better report, namely, that the heart symptom has abated, the condition of general nervousness is much improved and the attacks of laryngismus almost ceased. It took about ten weeks for the young lady to become accustomed to the great physiologic change in her system, and I advised her to continue for a year or so in the climate and altitude which seem to be doing her such great good. An analysis of this case would seem to justify the conclusion that the neurasthenic condition was an *essential* one, *i. e.*, not due to any tangible toxic or other cause, and that the altitude of over 3,000 feet which as I have stated is not as a rule good for the nervous individual or his cardiac symptomatology, must have in this patient through the dry atmosphere favored better metabolism and lessened the expenditure of nerve energy in that direction. It is true, however, that in a simple case of neurasthenia with irritable heart, a patient will usually experience considerable palpitation and cardiac distress when ascending above 2,000 feet; but if high winds do not prevail the patient will be ultimately benefited if the general nutri-

<sup>1</sup> Climatology of Neurasthenia, Med. News, January, 1901.

tion improves as shown by gain in weight taken in actual week-to-week records.

In hysteria alone, the effect on the heart will depend therefore very much upon the said condition of tendency toward normal metabolism produced at high, dry altitudes. It has been my experience in partial proof of this that among people living at moderate heights in the coast region or mountains in the north-western United States, that a moderate altitude of say 1,000 to 1,500 feet has more quickly and permanently produced palpitation and tachycardia, owing undoubtedly to less active metabolism in this moist climate. In comparison, at an altitude of 2,000 feet, as at Tim Pond, Franklin county, Maine, the dryness of the climate produces the better effect in nutrition, and nervous people there do not experience any cardiac distress; while the same altitude in the Adirondacks associated with greater moisture is unfavorable to nervous disease and the irritability of the heart action which I have found to be a prominent feature in the cases studied in the Empire State. The pine regions of Georgia and North Carolina back from the coast and at an altitude of somewhat less than 2,000 feet do not cause any nervous cardiac symptoms; while the damp, low country in Florida will produce both mental distress and at least a subjective feeling of cardiac weakness.

*Effect of Altitude Upon the Heart in Organic Disease of the Nervous System.*—The affection of the heart in organic diseases will depend upon the site of the lesion in the brain or cord, with reflex implication of the cardiac muscle or endocardium in association. Taking first the sclerotic diseases of the cord, it is certain that the heart will be more profoundly disturbed in these diseases, particularly in ascending scleroses, such as in amyotrophic lateral sclerosis, glossolabiolaryngeal paralysis, or even in cases of chronic multiple neuritis; in which latter, by continuity of the inflammatory process, the pneumogastric or phrenic nerves may be susceptible to the continuance of inflammation to them, and therefore pneumocardiac control.

Any change of altitude, therefore, should be considered very carefully in relation to the rhythm of the heart, absence of cardiac disease, etc. With a normal heart and degeneration of the lower cord as in tabes, a moderate altitude, as 2,000 feet, will do good only in relieving the heart from overwork, through the increased peripheral circulation; therefore, in any organic disease of the brain or cord, in my opinion, high altitudes should be avoided. It seems to me that altitude will have a favorable effect on the heart in cases of hypertrophy when due to resistance in the course of the circulation peripheral to the capillaries, as in Raynaud's disease and angioneurotic edema. In disease of the endocardium, as in valvular disease without loss of compensation, moderate altitude should be insisted upon. In cases in which there is loss of compensation, as shown by edema, chronic gastritis, renal congestion, etc., an altitude of 2,500 feet or more in a dry climate will undoubtedly prove of value in the vast majority of cases. Cyanosis, therefore, is not always a counterindication to moderate altitudes.

It is not necessary to urge here the importance of the hygienic bearing of the case of heart disease in any altitude, and especially should this be kept in mind by the physician when the patient changes his environment. Emphysema, particularly if associated with asthma, will often be benefited by a high dry altitude, since the interchange of oxygen by the more rapid respiration induced will the better oxygenate the blood and in this way relieve the over-acting heart muscle.

**To Prevent Child Insurance.**—A bill to be introduced in the New York Legislature in the near future prohibits the insurance of children under 16. Statistics have been gathered showing why such a bill should be enacted, and it is believed favorable action will be taken.

REPORT OF 250 ADDITIONAL CASES IN WHICH NITROUS OXID WAS USED ALONE OR AS A PRELIMINARY TO ETHER OR CHLOROFORM ANESTHESIA.

BY  
DAVID H. GALLOWAY, M.D.,  
of Chicago

Over a year ago I reported to the Chicago Medical Society 50 cases in which nitrous oxid was used as a preliminary to ether anesthesia. Since that report I have used this gas in 250 cases and can speak with greater confidence of its advantages. My experience with it has been so favorable that I think writers on the subject have underestimated rather than overestimated its value. If found, the ideal anesthetic will be devoid of danger to the patient; will produce profound anesthesia without producing any unpleasant sensations to the patient in the administration, and will cause no bad after effects. Nitrous oxid is not an ideal anesthetic, and I do not believe such an anesthetic will ever be discovered, but it approaches these conditions more nearly than any other drug known at present. There has been one death from nitrous oxid in about 600,000 administrations, this indicating that it is about 100 times safer than ether. It is my opinion also that ether is safer when preceded by this gas, for then the complications which arise at the beginning of ether anesthesia are practically absent. The question of safety is of course the paramount one, but there are other things to be said in its favor: 1. Nearly all patients have heard of "gas" and regard its inhalation as having little if any danger; they are therefore less apprehensive when taking it. This attitude of mind is itself a powerful factor for safety. 2. It produces no distressing symptoms and is so quick in its action that there is little time for the patient to become frightened after the administration is begun, and there is no delay in getting ready for the operation. This element of time is particularly valuable in clinics where under the method commonly in vogue the second patient is anesthetized almost as soon as the operation is well started on the first. If, as often happens, the first operation is unexpectedly prolonged the second patient is kept anesthetized an unnecessarily long time. 3. Less anesthetic is used and therefore recovery takes place quicker and the after effects are correspondingly less.

The time required to prepare the patients for operation in these 250 cases was as follows:

30 seconds.....	1 case
45 ".....	2 cases
50 ".....	1 case
1 minute.....	10 cases
1 1/4 minutes.....	3 "
1 1/2 ".....	34 "
1 3/4 ".....	3 "
2 ".....	126 "
2 1/4 ".....	22 "
2 1/2 ".....	2 "
2 3/4 ".....	36 "
3 ".....	1 case
3 1/2 ".....	3 cases
4 ".....	3 "
5 ".....	1 case
10 ".....	1 "
11 ".....	1 "
13 ".....	1 "

The average time being 2 1/4 minutes.

In no case, when ether followed, was gas continued for more than three minutes. In the case requiring 10 minutes the patient had a heavy beard, and this probably admitted air under the inhaler sufficient to produce the excitement and struggle during which the patient partly revived and had to be anesthetized with ether as if no gas had been used.

In one case it seemed impossible to relax the patient with ether, though there was no outcry or struggle, and after trying for 12 minutes I changed to chloroform with the result that anesthesia was quickly completed. In one case the patient, a woman, knocked off the inhaler before she was unconscious and it required 13 minutes to get her completely anesthetized with ether.

The calls for these 250 anesthetics were from 44 operators and I have demonstrated the method in 19 hospitals in Chicago.

When an operator has experienced or even witnessed the distressing effects which are often produced when a struggling patient is being anesthetized with ether, particularly if the patient is being "stified," as so many anesthetizers do it, and then has seen the quick and quiet way in which gas does its work, one would expect that he would never again allow ether to be used alone in his practice when it was possible to get gas.

I believe it was Dr. Joseph Price who defined an anesthetic as "an agent with which the patient is carried to the edge of death and held there while the surgeon does his work." To be carried to the edge of death is sufficiently terrifying at best and no pains should be spared to rob the process of as much of this terror as possible. Nitrous oxid is a potent agent for cutting short if not abolishing this agony.

I cannot refrain from carrying Dr. Price's figure of speech further and urging that the anesthetizer should not hold the patient too far over "the edge of death" by the use of an overwhelming amount of the anesthetic. He should not relax his attention or vigilance an instant lest the patient slip from his grasp and fall into the abyss from which no power can rescue him. Furthermore the patient should not be brought into this perilous position until the operator is ready to proceed with the operation and he should not be maintained there one minute longer than is necessary to perform the operation expeditiously. Every minute the anesthesia is prolonged the danger increases both from the immediate and the remote effects. I do not consider it justifiable for the operator materially to delay or suspend the operation, after the patient is anesthetized, in order to lecture to a class of students. The lecture would be just as impressive if delivered on a previous or later occasion. I was once obliged to keep an old man lying on a wet table and covered with wet towels, under the influence of ether, for 25 minutes while the operator talked to a class of students about the operation.

If the anesthetizer could be made to realize that he is holding a fellow being in a slender grasp over the brink of a precipice down which he may be hurled by any lapse of attention or slip of judgment, surely he would have little heart for assumed or real indifference or for idle gossip with those around him.

## CARE OF THE EYES OF SCHOOL CHILDREN.

BY

LINN EMERSON, M.D.,

of Orange, N. J.

Attending Oculist and Aurist to the Orange Memorial Hospital Dispensary; Assistant Surgeon to the Manhattan Eye and Ear Hospital, New York City.

The most potent factor in preventive medicine is the education of the public. This, of course, must be done by the medical man, but along certain lines it seems that the medical profession itself must first be educated before its members can or will perform their duty to society.

I refer particularly to the much-discussed subject of the eyes, more especially those of school children.

When we consider the fact that Risley found in the schools of Philadelphia but 11% of children with normal vision, is it surprising that specialists on diseases of the eye look with disfavor on the inattention and even ignorance of the general practitioner regarding this subject? Exhaustive papers are read by able men before our various society sections, but the topic is so broad and so manifestly within the sphere of the specialist that reports are seldom read by the busy general practitioner, to whom the topic is of so little interest.

Since an appeal to the public by the specialist would be taken as the act of one with an ulterior motive, it

becomes his duty to excite the interest of those who are in the best position to bring these facts before the public, viz., the medical profession in general and the teachers in our public schools.

Not only should every opportunity be taken to address the profession, but effort should be made to obtain cooperation of boards of education, so that lectures setting forth means of detecting ocular disorders may be given to the teachers at the beginning of each school year. In many of our larger cities where school inspection is in force, little or no attention is paid to the condition of eyes or ears, but the physician's entire duty seems to be to discover the appearance of acute infectious diseases; and while this is absolutely essential, he should go further. One unable to distinguish between trachoma and ocular infection due to eyestrain should never be made a medical inspector of schools.

There are about 18,000,000 boys and girls of all ages in the various schools of this country today. In two or three decades the affairs of the nation will be administered very largely by these same pupils. The time is rapidly approaching when the tradesman and mechanic will be required to have more than a "common school" education. Many a bright, energetic young man has found when his opportunity for promotion presented that he was unable to fill the position offered him because of insufficient education. Why did he leave school at an early age to take employment in some shop or factory, or behind the counter? Simply because he did not seem to take to his books. Other children in the family got along rapidly in school, but he just could not learn. It made his head ache to study, and when he tried to study at night it made him so sleepy that he had to give up and go to bed. So much concentration being required to fix his mind on his book, his interest could be maintained for a short time only. Soon his mind wandered to the out-of-door sports in which he excelled, and when recitation came he was unprepared. To the oculist is not this the typical picture of a case of uncorrected hyperopia or astigmatism? The same may be said of girls in this sphere of life, but as much less education is required of them, it is passed unnoticed.

These are cases of facultative hyperopia in which little or no danger is done to the organ of vision, but we find even in this class cases of intractable headache, and neurasthenics of the most pronounced type. Of cases of hyperopia in which convergent strabismus ensues, and astigmatism of high degree is left uncorrected until puberty or later, resulting in permanent amblyopia, little need be said, as the resulting condition is too manifest to necessitate further comment.

While the pernicious results of uncorrected hyperopia are not to be gainsaid, how much more deplorable are the results of myopia. While in myopia asthenopia is not so often present as in hyperopia, how much more terrible are its ravages when it results in divergent strabismus, nystagmus, keratoconus, posterior staphyloma, detachment of the retina, intraocular hemorrhage or cataract.

Unfortunately moderate grades of myopia in the young often cause little inconvenience. Never having had perfect vision for distance the visual acuity possessed by others is not realized, and they go on for years choosing the occupations, recreations, and pleasures to which their short sight best adapts them.

Myopes who reach adult life never having worn correcting lenses seldom take kindly to glasses. When given correction their sense of orientation is impaired, their undeveloped ciliary muscle prevents working at short distances with comfort, and in many cases I have seen glasses thrown aside even when the patient was aware of the danger involved in so doing. The time for the correction of myopia is before the tenth year, and in many cases much earlier. If at the beginning of school life these congenital anomalies of refraction could be carefully corrected by suitable glasses we should hear

much less complaint of the harmful influence of school upon the eyesight. No organ of the body is so easily injured by inappropriate or excessive work, and no organ has less power of readjustment.

M. Le Roux, a French lecturer, speaking of his American audiences, says: "I had but one regret as I looked down into their faces, I saw too many spectacles. They have worked so hard that their sight is failing. They should not let their love for knowledge impair their vision." In comment one of our leading medical editors, himself an ophthalmologist of international reputation, says:

Americans have not worked their eyes harder than other nations, their love for knowledge has not impaired their vision, and their sight is not failing. *Tout au contraire* our eyes are far less diseased than those of Europeans, who have yet to learn that proper spectacles prevent more serious ocular and also systemic disease. Our people have good leather shoes instead of going barefoot or wearing sabots, but the fact is not proof that our feet are weaker or more diseased than those of the French peasant. . . . They also have secured scientific care of the teeth, but that does not prove that carious teeth are superior to filled ones or that no teeth are preferable to artificial ones.

Unfortunately the opinion prevails to a large extent among the laity, and I blush to say to a considerable degree in the medical profession, that the eyes of the present generation are not so good as those of former generations; and what is still more deplorable, that the use of glasses is excessive, and perhaps we oculists are in a measure responsible for this last named state of affairs.

Why a young person with a hyperopia of 1.00 D. or less, or a hyperopic astigmatism of .50 D. or less, who suffers from asthenopia only while at his books should be burdened with glasses for constant use during the balance of his life is beyond my comprehension. While I am aware that many oculists of reputation and ability insist on the full correction of any and all errors of refraction manifest during cycloplegia, I am constrained to say most emphatically that many cases of refractive error of moderate grade need be given correction for close work only. Many patients when chided for delay in seeking relief reply: "Well, doctor, every one who consults an oculist is given glasses, and I feared you would give me glasses." Is this a desirable state of affairs?

A young adult under stress of college life or similar ocular strain breaks down with accommodative asthenopia. He consults an oculist, who finding a moderate grade of hyperopic astigmatism consigns him to the use of glasses for the balance of his life. The patient completes his work which has been the exciting cause, and then leading a less strenuous life and finding the glasses disagreeable, throws them aside and goes for years never feeling the need of them. Is it surprising that his confidence in the oculist is impaired, or that when some other member of his family (who perhaps has absolute need of glasses) is advised to wear them that the advice goes unheeded.

Hotz, of Chicago, in a recent communication calls attention to the misuse of glasses, their being prescribed in cases of asthenopia with associated blepharitis in which the asthenopia is entirely due to the pathologic condition of the conjunctiva and lids. In the minds of most public school teachers glasses are the panacea for all ocular disorders, and many children are sent by their parents to incompetent opticians, by whom glasses are given when local treatment is all that is required.

In the recent investigations carried out by the Board of Health of New York, two public schools taken at random showed 15.5% and 19.2% respectively of communicable eye diseases. While this percentage may seem large, let us console ourselves with the thought that this class of cases has been reduced 47% during the past 30 years, largely because of improved sanitation and medical school inspection.

It is my firm belief that there should be an examina-

tion of the eyes of all children applying for admission to the public schools, and the following facts ascertained, so far as possible, from each individual pupil:

1. Does the child fail to read a majority of the letters on the XX (20) line of the Snellen test types with either eye?

2. Do the eyes and head habitually grow weary and painful after study?

3. Are the lids or eyes habitually inflamed?

4. Is the child cross-eyed, or do the eyes diverge?

Upon an affirmative answer to any of these questions a letter of warning should be sent to the parents.

### VITAL STATISTICS: A PLEA FOR ACTUARIAL ADMINISTRATION AND CONTROL OF THE GREAT RESOURCES OF PREVENTIVE MEDICINE.

BY

JOHN S. FULTON, M.D.,

of Baltimore, Md.

[Continued from page 223.]

#### MUNICIPAL REGISTRATION.

In respect that the practice of registration in cities is more general and is rapidly spreading, and that municipal registration ordinances are usually effective, this phase of the subject is more encouraging. There is nevertheless somewhat to criticize. The worst faults of State registration grow out of neglect, but registration in cities is subject to positive abuses. The extreme diversity of methods and practice which we noted in State registration is less apparent in city registration, but in the mathematics of municipal registration we find vagaries of every sort, insomuch that the statistics of hardly two first class cities in the country are comparable, and many cities cannot safely compare their own records for different periods.

Popular interest in the vital statistics of cities has grown so far as to demand the publication in the daily press of yearly, monthly, and even weekly summaries, bringing their so-called rates into comparison with the similar statements of other cities, and with their own earlier statements. The confiding public assumes that the figures are as trustworthy as the market reports. The uninitiated citizen cannot be expected to know that the deathrate is affected by several ever-active and variable factors besides the mortality; but he knows how to calculate interest, and he believes that the deathrate is obtained by counting the deaths in a given period and dividing their sum by the population for the same period. It is a pity to disturb this ingenuous faith in municipal arithmetic, but the people ought to know how the deathrates are obtained. The city registrar's arithmetic is seldom so simple. His permutations and combinations are perhaps not usually dishonest in intent, but the results are nevertheless misleading. If one will examine the death certificate of a city it will almost invariably be found that more space is devoted to the place of death than to any other single item. Certain apparently subsidiary data are required under this head, *e. g.*, "Place of former or usual residence;" "How long resident at place of death;" "If in a hospital or institution, give its name." These are proper inquiries. It is quite right that a great city should keep a separate account of the deaths which do not diminish her population, and almost all city registrars count off the deaths of transient visitors and of those who are brought to the city for medical treatment. There is no agreement among city registrars, and a wide diversity of practice is followed in solving the question between resident and nonresident. At the pleasure of the city registrar one may be counted out of the death register if he die within a week, or a month, or a year after coming into town. In a true registration area, where every death must be counted somewhere, the solution of this question may be effected with fairness and without appreciable

vitiation of local statistics; for the proposal to exclude a death from record at one place invites consent to admit it to record at another. But in a nonregistration area there are not two parties to the question.

When, on the other hand, bonafide residents of the city die outside the corporate limits, what shall become of the record? If the death happens in a nonregistration area and the body is not brought into the city, the occurrence never comes to the knowledge of the city registrar at all. If the body is brought into the city, the certificate is presented to the city registrar and the death may or may not go into the home mortality account, as the registrar decides. If he counts off the intra-urban deaths of nonresidents he should, by parity of reasoning, count in the extraurban deaths of those who at the time of death were component units of the population. But under existing conditions the city registrar's own sense of honesty must direct him in this course. The matter lies in his own undivided confidence.

Most large cities maintain outside their corporate limits large institutions where dependent citizens are cared for, and among them a considerable annual mortality occurs. These extraurban deaths enter into the mortality accounts of some cities, but is that the practice in all large cities? One looks in vain through the health reports for information on this point.

But the number of the dead is only one factor of the death-rate. The population is the other, and the modes of estimating population for intercensal years are likewise subject to curious variations. The statistical reports rarely contain a word of explanation on the subject. Some registrars take the difference between the results of the last two decennial enumerations and find its ratio to the population of the earlier year. One-tenth of it is said to be the ratio of annual increase over the population at the beginning of the new decennium. The assumption that the ratio of the last completed decennium will govern is perhaps reasonable, but the yearly ratio is not one-tenth of the decennial ratio, for the increment is compounded each year. One should find, therefore, what rate will yield the ten-year increment at compound interest, and apply this each year to his new principal.

Another plan of estimating the population is to multiply the number of children attending school in each successive year by a constant factor. In the same way the number of inhabited houses is sometimes used as a basis, the other factor being the average number of persons per house as determined by the preceding census. Again, the number of registered voters is multiplied by an assumed factor, the result being taken as the population for the year. In Southern cities the voters are divided according to color, the number of colored voters being multiplied by a higher coefficient than is applied to the white voters. In conversation with city registrars I have learned that there are yet more curious modes of arriving at estimates of population; *e. g.*, to ask the publisher of a city directory or the inquiry department of a daily newspaper.

The first named method is the best, but every chance to correct it or to test it should be availed of, and when a new census shows that the estimates for intervening years were too large or too small, the corrections should be applied to all the ratios which are brought forward from year to year for purposes of comparison. It very seldom happens that official estimates of the population of large cities are too small, and the federal census has once or twice been almost persuaded that its own enumerations have been too large.

From what we have said it seems clear that one of the factors of a deathrate is never exactly ascertainable and that the other factor is not the sum total of the deaths that occur in the population or in the political bounds of a city, but is a derivative of this sum total. Moreover it is derived not according to a fixed rule, but by various methods at the unchallenged and often inconstant discretion of individual registrars.

There is not in the country a single city which has not two mortality lists for every year, and a few, very few, of them publish an account of both lists. That an account of the deaths which do not enter into the rates is so seldom published seems rather significant. The people, who trust too much in death-rates, and whose interest in the subject is far too little enlightened, have a right to know how the factors of the deathrate are

determined, and what rate of increment is assumed in the population, and what proportion of the deaths happening in the geographic limits of the city and among its enumerated citizens has been considered to represent the net mortality justly chargeable upon the population. If the people have the right to know so much, still more are the 400 municipal registration offices entitled to this information, for if units of weight, volume and value should be familiar and of common use, no less should the balance sheet of life and death conform to a sealed standard.

Of the many cities whose published statements concerning mortality stagger one's faith, not all, possibly, are grossly erroneous, but whether right or wrong, all ought to display the elements of their computations. In every American city of 100,000 population whose claimed or imputed deathrate is below 17 per 1,000, the rate has been obtained by some avoidable error such as (*a*) discounting too heavily the gross registration deaths on account of intraurban deaths of nonresidents; or (*b*) failure to debit the mortality account with the extraurban deaths of residents; or (*c*) overestimating the population; or (*d*) combining all or any two of the foregoing errors.

Or else the deathrate is explained by (*e*) a peculiar age distribution which reduces the influence of infancy or of old age, or of both upon the gross mortality. The city may be too young to have acquired a considerable population above 60 or normal marriage and birth rates; or (*f*) with a normal sex distribution, the birthrate may be excessively low, the population being recruited chiefly by the immigration of young unmarried adults; or (*g*) a continuous high birthrate may have given the city an unusual proportion of population between 10 and 40 years of age; or (*h*) the low general deathrate may be due in a normal population to an extremely light infant mortality.

It is just possible that one or two large municipalities may owe a deathrate of 17 per 1,000 to natural advantages plus good sanitary administration, but without a single probable exception all deathrates below 17 per 1,000, in cities 40 years or older, are delusions, and a percentage of them are statistical fictions.

In one or two large cities the official registrars have such skill in marshaling figures to prove what is untrue that one might infer equal ability to demonstrate the truth. But such an inference is not necessarily correct, for in vital statistics it is peculiarly difficult to avoid beginning an inquiry with a definite idea as to what the figures will show. Vital data are so complex and variable, and the processes are subject to so many corrections and interpolations that a rigid conscience and inflexible logic will hardly keep one true to the mathematical line. Statistics are to many minds highly intoxicating, and some registrars seem to be habitually exhilarated.

#### REGISTRATION OF BIRTHS.

If we have so far made out our case for the complete, uniform, and systematic registrations of deaths, and for temperate and logical utilization of the accumulated data, we must at the same time have shown that statistics of death alone will not under any circumstances suffice to indicate the sanitary or vital conditions of the people, for all the ratios derived from the death returns vary from time to time and from place to place, in obedience to influences which have little or nothing to do with sanitary administration. To analyze death records according to cause, age, sex, season, locality, race, occupation, social condition, and to apply the numerical results to a living population which has not undergone a similar analysis for the purpose of ascertaining the vital conditions of the people, is about as logical as if one should undertake to estimate the motive power of a great railroad system by a complete and exhaustive examination of the scrap heap. Without knowledge of the sources of population, the mortality statistics can never be made to yield the information which the sanitarian most needs and which, if one may judge by the popular appetite for statistical hokey pokey, the people most demand. This does not belittle the very large independent value of mortality statistics, but emphasizes their superior importance as an articulated part of a comprehensive and logical plan of accounting in the vast business which we call government. Public hygiene has long outgrown the sanitary bookkeeper; its needs exceed the capacity of the expert accountant, and its affairs can only be

reduced to precise order by the highly developed skill and perfect grasp of the actuary.

All the rates derived from the mortality returns are properly called crude ratios, and should be corrected by all the determinable causes of variation. It is an idle saying that the variable minor factors neutralize each other. Some sources of error may be negligible, but none should, without test, be neglected. Of first importance in this connection is the birth-rate, which is not in any degree less important than the death-rate. The private interest of the citizen in registration of births is indeed superior to his interest in registration of deaths, for a great proportion of his privileges and immunities, rights and duties, turning upon the question of his age and his parentage, are definitely conserved by the registration of his birth.

The defectiveness of American statistics of birth is so great that outside of New England probably not a State or city can determine a fairly approximate birthrate for any year. Many States and all the registration cities have more or less ineffective laws upon the subject. In some places the records of births are obtained by annual or semiannual enumeration, but this method is no more successful in the registration of births than in the registration of deaths. Chapin says that in Providence skilled enumerators obtain by semiannual enumeration records of but little more than 60% of the births. Local laws usually require births to be reported by the attending midwives or physicians, but the time limit for making the return is usually very liberal, and penalties for neglect are either not provided or else never enforced, so that the results are always far short of the true number. Even in those States where the legal provisions are most effective it is found necessary to supplement the returns by enumeration and by consulting the church registries of baptism.

In the registration of births it has always been found expedient to consider the confidential relations of physicians and midwives, and the private interests of parents, not only in respect of illegitimacy, but also with regard to the date and even the place of birth. Leniency upon these points opens the door for lax practice in other respects. The element of compulsion enters practically not at all into American practice, and perhaps there is no place for it. In respect to a birth the State cannot compel, as it can in regard to a death, the testimony of any witness.

The key to a complete registration of all legitimate living births is the conditioning of future rights and privileges upon the record of births, as is done in Germany; but it is doubtful if this could be done anywhere in America. A certain degree of pressure could, however, be brought to bear upon the subject, and the means are already available in the laws. For instance, the right to attend the public schools and the right to vote both depend upon attained age. If it were necessary to accompany every application for either of these privileges by some sort of signed testimony as to the age of the applicant, a copy of the birth certificate would offer the simplest means of meeting such a requirement. Thus gradually the birth certificate might come into habitual, though not exclusive or enforced, use in establishing citizenship. Many difficulties undoubtedly attend the registration of births, but satisfactory results have long been obtained in England, Germany, and France, and in at least one American State—Massachusetts.

Among the various methods of obtaining birth records we may speak of those employed in Massachusetts as well conformed to our republican ideas and as the most successful. Physicians and midwives are required to report monthly the births occurring under their care. Parents also must report in 40 days. In order to keep the physicians reminded of this duty a ruled sheet, 4 inches by 14 inches in size, is mailed each month to every physician with a request for a list of the births attended in the preceding month. This sheet is divided into ten vertical columns for the ten required items of information, so that the record of each birth occupies one line across the sheet. The data provided for on the sheet are the date of birth, sex, color, name, place of birth, names of parents (mother's maiden name), residence of parents, father's occupation, birth-place of father and mother.

These record sheets hardly meet the private needs of the citizen, being inconveniently preserved and difficult of refer-

ence, but they do serve the purposes of vital statistics with which we are at present concerned. Once a year an enumeration of births is made, and the returns of parents, physicians and midwives are thus supplemented. It is also found advisable to consult the pastors of certain religious bodies in order to get the records of births occurring among foreign born people under the care of foreign midwives.

In some places, as in Cincinnati, the sanitary police call once a month upon clergymen, physicians, and midwives for their returns of births. The success of such visitations depends upon finding the certifier at home and at leisure, so that the usefulness of this plan, except in a supplementary way, is doubtful.

A difficulty which often places a wide interval of time between the birth and its record is the item of Christian name. Now, the name of the child has no statistical importance, and, provided that the right to a completed record is secured to the new citizen, there is no reason for delaying the report for want of that item. Indeed, the experience of my own State seems to indicate that parents are easily impressed with the importance of sending in this final bit of information, and in about 65% of instances do complete the record by sending in the name.

The data required upon a record of birth for statistical purposes do not all appear upon the Massachusetts blank. Thus the ages of the parents should be given, and the number of the children (first, second, third). Items of doubtful value or of merely curious interest are sometimes asked for. In some certificates the hour of birth is asked for. In Wisconsin the certificate asks for the day of the week and for the names of the other living children of the same parents. In contrast with Indiana's impious pursuit of a death record by means of a mattock and spade, the birth certificate of the city of Mobile meets the unborn babe with an impudent inquiry; "*What part presented?*" There is no room on a birth record for any inquiry which is not of definite use to the citizen or to the community, and the difficulty of obtaining careful records increases in proportion to the number of separate inquiries. Thirteen items suffice for all the legitimate uses of a birth certificate.

By bringing several sources of information under tribute, and employing two or three agencies of collection, restricting the scope of each inquiry to the unquestionable needs of the public, and by keeping always in the foreground the private and personal interest of the citizen in the registration of births, it should be possible to realize in any American community a registration of births as complete as is obtained in Massachusetts. When several sources of information are interrogated especial care must be taken to avoid duplication of returns, but any good plan of registration will always include the supervision of the returns by a special officer, who will take whatever pains are necessary to find out whether two records which resemble each other belong to one event or two.

We have alluded in our discussion of mortality statistics to some of the more important uses of birth statistics, and shall mention here briefly some other sorts of information derivable from the study of birth records. As the birthrate has its measurable effect upon the deathrate, so the deathrate has at times an appreciable effect upon the birthrate. Birthrates in general obey the marriage rate, which always rises in times of prosperity; but when the infant mortality is high the fecundity of marriage is raised by abbreviation of the suckling period, so that the explanation of a marked rise in the birthrate for a given year may be found in the statistics of the previous year, and not in the marriage rate, but in the infant mortality.

The effects of a high birthrate during a period of years are to be looked for not only in an increased gross deathrate for approximately the same period, but may sometimes be traced to a diminished deathrate at a much later period when the growing children have made unusual additions to that part of the population which furnishes the least mortality (10 to 40). In the same way a period of high reproductiveness leads to an increase of the relative proportion of women of the childbearing age at a later period, so producing a second wave of reproduction.

War, by taking away vigorous young men, depresses the

marriage rate and the birthrate, abstracting at the same time from the home population those lives which contribute least to the mortality rates. After the return of peace this loss is not compensated, for war has its evil influence not only upon the lives of those engaged but upon their virility and upon their inclination and ability to marry.

Prosperity increases the marriage rate, but not, in corresponding degree, the birthrate. The birthrate is generally higher among the poor, and as families rise in the social scale the production of offspring tends to be more and more controlled. This condition is now generally observed throughout the civilized world and is not without serious significance. Long continued prosperity brings a decline of the marriage rate with a greater average age at marriage, thus further depreciating the reproductive energy of the people. Nations as well as men may therefore find sweet profitableness in the uses of adversity.

The annual rhythm of fecundity which has sometimes been noted is quite curious. If constantly looked for it perhaps might be often observed. Thus in the experience of Hamburg for ten years (1881-1890) the months of February and March gave the highest percentage of births, while June was the month of lowest percentage. A similar observation in Berlin for 1895 showed that January, February, and March gave the highest percentage, November the lowest. The birthrate is also influenced by density of population, by divorce, by race, and by religious belief.

Still-births and illegitimacy bear quite irregular relations to the general birthrate. Indeed the still-births appear to obey the illegitimate rather than the general birthrate. Illegitimacy does not, as might be expected, rise as the average age at marriage increases. On the contrary, in England, with the fall of marriage under age, illegitimacy has also declined.

Still-births have not received due recognition in registration. The Eleventh Census included still-births in the mortality and so charged against the population the deaths of those who were never in any sense a part of the population. In the comparative rates published by the Twelfth Census the figures of the Eleventh Census have been corrected for still-births. In England still-births are not recorded at all. In France and Belgium all children who die before their births are reported are registered as still-born. The birthrates for these countries must therefore be corrected before they become comparable to the birthrates of Germany and Italy, where only the infants delivered in the last two months of gestation, and dead without having breathed, are registered as still-births. The birthrate may for certain purposes be stated, as the deathrate is, in ratio to 1,000 living population, but such a ratio is crude in a more obvious way than our customary crude deathrates.

The ratio of births to the number of living females of child-bearing age is a more generally useful form of statement. Where populations differing materially in social conditions are to be compared the ratio of legitimate births to married women of child-bearing age must be determined.

#### STATISTICS OF MARRIAGE.

The registration of marriage is quite generally and effectively provided for in this country, 45 States having laws upon the subject. In all the States license must be obtained before the ceremony is performed, but return of the fact of marriage is not provided for in the laws of four or five States. In the New England States the license itself becomes a certificate. The items of information noted in the license suffice for the needs of vital statistics, but the records are often in the form of stubs, and are not generally available for the uses of vital statisticians. Provision for the return of the event has usually been made no stronger than will meet the private interests of the contracting parties, so that the records of marriages are not so complete as they would be if the interests of the State were fairly secured by the laws of the subject. Still, tolerably effective machinery is provided for the collection of statistics of marriage and it is only necessary to direct our present plea to the better utilization of existing data. It is highly desirable that returns of marriage with all their items of information should be brought, if not under medical supervision, at least into the hygienist's general store of vital memoranda.

#### STATISTICS OF SICKNESS.

When the fact that crude deathrates are comparatively unmeaning has been firmly grasped, and when we have realized the need of detailed information concerning the composition and movements of population, the sources of their natural and their actual increase, and the influences which lead to death and decay, we shall find that the productive energy of the people is not more closely related to the chief events of individual history (birth, marriage, and death) than to a multitude of minor occurrences which are more or less disabling.

Perhaps the most dangerous fallacy in the use of mortality statistics arises from the assumption that the mortality obeys the morbidity, and that the prevalence of sickness may therefore be approximately estimated from the recorded mortality. The two curves do indeed correspond in a rough way, but the intervals are so variable that different statisticians have furnished coefficients as far apart as three and nine, for the purpose of estimating general morbidity from general mortality.

Long ago an eminent English actuary, Mr. Neison, reduced this assumption to an absurdity by showing, from the records of medical charities, that in London in a year of favorable mortality there were no less, probably more, than 35 cases of illness to each death. Neison also showed that in 16 selected occupations, whose mortality was low, the sickness rate was high; while in other occupations, whose sickness rate was low, the mortality was high. He also worked out a table of ratios of mortality to sickness by age periods, finding the lowest 1.5%, in the age period 10 to 15, and the highest ratio 62.5%, in the age period 85 to 90; so that age distribution plays as important a part in the disability rates as in the deathrates.

Rumsey found that "deaths in a younger population are associated with less sickness than deaths in an older—in a male population than in a female—in an agricultural than in a manufacturing population." Newsholme testifies to the same effect, and more vigorously: "It is fallacious to assume any fixed ratio between sickness and mortality. Death returns are silent about the large mass of common sickness, which, although it may disable a man, is not 'unto death.' From an economic point of view this sickness is *more important* than deaths."

It has always been cheaper to bury a dead man than to support a sick one, and the contingent and remote effects of sickness have always been of more practical concern to the sanitarian than the number and causes of death. This view is very ancient, and has always had a strong political influence. The most convincing argument which Chadwick was able to urge in his movement for a general registration law in 1837, was that the cost of sickness was the heaviest item in the poor rates.

Registration of all sickness, or even of all disabling sickness, is impossible. The boundaries between health and disease are exceedingly vague, and the nature of much disabling sickness is indeterminate. But, because the registration of all disabling sickness is impossible, it does not follow that we should be content with the small amount of information which the notification laws afford. These laws attempt to cover only the more dangerous communicable diseases, the special agents of untimely death. The presumed intent of such laws to limit preventive operations to these diseases is by no means acquiesced in by the practical hygienist, and no small stir has been created now and again by attempts to include within the scope of the notification laws diseases whose infectious nature have been more recently recognized.

The efforts of preventive medicine must, in general, be directed against those diseases which cause the highest mortality, and every success against one cause of death simply transfers the debit to another account whose settlement we may or may not be able again to postpone. The winnings of hygiene have not as yet probably altered the age constitution of living populations to a measurable degree, or brought clearly into view the increased power of those tax-gatherers into whose hands our disputed accounts have fallen. But it is certain that what we win in one age period, or against one agent of death, we shall have to contend for again in a later period and against another agent, so that we must constantly readjust ourselves to shifting phases of the contest. Advance information will enable us to do this promptly, and such

information is to be sought, not in the mortality returns, but in returns of sickness.

Of several attempts to collect statistics of sickness in this country, but one has survived a considerable period and yielded approximately uniform results. The Michigan weekly returns of prevailing sickness are sent in by a number (usually about a hundred) of voluntary observers in various parts of the State. They report simply the presence or absence of certain specified diseases, without any details as to the amount or intensity of such sickness as is observed. This work has been kept up for 25 years. While this plan furnishes but a small part of the information needed by the sanitarians, the accumulated data have, nevertheless, a surprising accuracy, and would seem to indicate that the assay method of estimating the amount and kind of sickness may be satisfactorily applied to such data as are already in many places available.

The establishment in connection with boards of health of bacteriological laboratories furnishing physicians, free of cost, valuable assistance in the diagnosis of certain infectious diseases, has brought public hygienists into possession of amounts and sorts of information which could not be obtained under notification laws. Born of necessity, this movement has made astonishing progress. Within a decade twelve or more such laboratories have been established under the control of as many State boards of health, thus making small communities and rural districts contributors to the statistics of sickness. There are besides fifty or more such laboratories in connection with city boards of health, and in some of them the number of records concerning separate cases of disease mount well up in the thousands each year. Besides the definite information furnished by these reports, whose immediate use has been of surpassing value, the accumulated data will doubtless yield under statistical treatment results hardly less profitable.

With the advent of the public laboratory a new bond of mutual helpfulness has been created between public health officers and practising physicians, and the advantage of such a fortunate circumstance should not be lost. Since every man is supposed to contribute to the support of the commonwealth, there is a natural inclination on one hand to dispense, and on the other to accept, the benefits of the public health laboratory as if the State's whole concern in the matter were limited to the need of the moment. One has already heard practising physicians declare that the city or State is not entitled to the information asked for on laboratory blanks, and some physicians endeavor to evade the manifestly proper inquiry as to street address. What is worse, health officers seem inclined to condone such defaults. This is to lose the smaller but cumulative profits which the State should realize upon such an investment. It fosters, besides, a light esteem of professional privilege which will in time take on the characteristics of parasitism. The commonwealth is well within its right in requiring of every physician, who avails himself of the proffered aid, careful attention to the details of information which are provided for on the clinical and laboratory blanks.

Of the total amount of sickness occurring in any city, 40% at least is treated wholly or in part at public expense, and it has often been proposed to make the records of such sickness available for statistical uses. Hospitals and dispensaries have always manifested a decided opposition to such propositions, and have always been able to defeat them. It is nevertheless perfectly just and proper to make statistical use of the records of all sickness treated at public cost, and while municipal registration offices do not anywhere come into possession of such data, many hospitals and dispensaries do at the present time report at definite intervals both the kind and amount of sickness coming under treatment at the charge of the municipality. Some of the data required for sanitary purposes are not found in these reports, but the missing items are usually on record either in the hospital memoranda, or at the police station, or with the boards of charities. To obtain at least the temporary use of information from such sources does not, therefore, involve any increase of clerical work at hospital or dispensary, but requires simply a modified form of municipal accounting, which could often be secured by mere consultation and at no considerable expense.

Another new arm of municipal hygiene, which adds much

and might add more to the statistics of sickness, is medical inspection of schools. In Boston, where this practice is the oldest (since 1894), the returns for a year include upward of 10,000 cases of sickness falling under 100 or more nosologic heads. The inspectors' reports are made monthly to the board of health. In New York the inspectors report to the board of health daily. If the teachers were instructed to supplement the inspectors' reports with the results of inquiry concerning absenteeism a more satisfactory view would be obtained of the sickness prevailing among children.

By easy arrangements boards of health might secure the temporary use, if not the permanent possession, of all needful data concerning the causes of disability among a very large part of the population, and timely needs would be served in this way. But, as we have already seen, the details of present sanitary history are sure to be needed again and again in tracing the causes of remote events, and for such purposes they must come complete into the permanent possession of boards of health. Never was a day so auspicious for the acquisition of such property. In no aspect of modern medicine is the scientific spirit more strikingly manifest than in the completeness of medical anamnesis. It is an age of exhaustive histories, of systematic and minute note-taking, of graphic memoranda, of indexes and cross-indexes. The few and simple data required for the broader purposes of preventive medicine need only to be abstracted from heaps of manuscript, and so far as these relate to sickness treated at public cost, their appropriation to the service of preventive medicine needs no apology. On the contrary, failure to so appropriate them must inevitably become a reproach both to medical charity and to municipal government.

A comprehensive plan of collecting statistics would include reports of sick benefit associations and the disability returns of corporations, such as mining, transportation, and industrial concerns. In England the Factory and Workshops Act furnishes a great deal of useful knowledge concerning industrial hygiene, and in Germany the Allgemeine Krankenkassen make regular reports to the health officials. In time such sources of information may be brought under tribute in America. Farr's original plan was yet more ambitious. He confessed an ultimate aim to register all the sickness among the civil population as completely as is done in the Army. Our own remote ideal may be as great as that, but meanwhile our plea is for the instant seizure and conversion to the uses of hygiene of every scrap of information coming within official reach.

[To be concluded.]

**The Enno Sander Prize of the Association of Military Surgeons** for 1903 will be awarded to the author of the best essay on "The Differential Diagnosis of Typhoid Fever in Its Earliest Stages." The board of award will consist of Dr. Austin Flint, of New York; Colonel Calvin DeWitt, of the Army; Prof. Victor C. Vaughan, of Ann Arbor. Competition is open to all persons eligible to active or associate membership in the Association of Military Surgeons of the United States. Two prizes will be awarded, one a gold medal of the value of \$100, and the other a life membership in the association of the value of \$50. Full information concerning the contest may be obtained from Major James Evelyn Pilcher, Carlisle, Pa., secretary of the association.

**"Medical Library and Historical Journal."**—We have received Vol. I, No. 1 of this publication, which marks a new departure in medical journalism. An idea of the character of the journal can be obtained from the following titles appearing in the original article department: "Jacobus Berengarius Carpensi and His Commentaries on Mundinus," by Lewis Stephen Pilcher, A.M., M.D., LL.D., of Brooklyn, N. Y.; "The Medicine and Doctors of Juvenal," by Eugene F. Cordell, M.D., of Baltimore, Md.; "The Book-Worm," by Frederick P. Henry, A.M., M.D., of Philadelphia; "A Brief Account of the Library of the Medical Society of the County of Kings," by James MacFarlane Winfield, M.D., of Brooklyn, N. Y.; "A Few Hints on Medical Library Administration," by John S. Brownne, of New York City; "A Practical System of Classification for Medical Libraries, Large or Small," by Albert T. Huntington, of Brooklyn. This journal, which is now the official organ of the Association of Medical Librarians, is designed to fill the unique function of supplying to medical historians, medical librarians and medical bibliophiles an exclusive medium of intercommunication. The aim of the editors, as set forth on the title page, is to publish a periodical "devoted to the interests of medical libraries, bibliography, history, and biography." The journal will be issued quarterly. The subscription price is \$2 yearly; single copies, 75 cents.

## THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

February 7, 1903. [Vol. XL, No. 6.]

1. How Not to be Nervous. HUGH T. PATRICK.
2. The Scientific Exhibit and Its Future. FRANK B. WYNN.
3. The Year's Progress in Therapy. GEORGE F. BUTLER.
4. Cardiac Stimulants. JOSEPH M. PATTON.
5. Adenoids. W. FREUDENTHAL.
6. Chlorosis. C. F. WAIRER.
7. Is the Adenoid Operation a Justifiable Surgical Procedure; and, if so, Shall it be Done in Accordance with the Rules of General Surgery? GEORGE L. RICHARDS.
8. The Diagnosis of Carcinoma of the Larynx. OTTO T. FREER.
9. Uniformity in Medical Practice Acts. N. R. COLEMAN.
10. Note on Malarial Vertigo. THOMAS J. MAYS.

1.—See *American Medicine*, Vol. IV, No. 18, p. 687.4.—See *American Medicine*, Vol. III, No. 25, p. 1060.5.—See *American Medicine*, Vol. III, No. 25, p. 1048.6.—See *American Medicine*, Vol. III, No. 25, p. 1049.7.—See *American Medicine*, Vol. III, No. 24, p. 992.8.—See *American Medicine*, Vol. III, No. 25, p. 1056.

9.—**Uniformity in Medical Practice Acts.**—Coleman points out the necessity for a more uniform definition of the practice of medicine, as few of those included in the laws are adequate to meet all the methods devised for their evasion. He suggests the appointment of a committee with one member from each board of medical licensure to frame a definition and report. State examining boards should make a specific definition of what is meant by four full years of study and by four full courses of lectures each in four separate years, and then exact it from all who apply for examination. In case of graduates in dentistry, pharmacy, and veterinary medicine advanced standing in the medical course should be withheld unless their literary training is equivalent to that leading to an A.B. or B.S. and their work has included that of the first year in a first-class medical college. It is regrettable that some States still admit undergraduates to examination. Night schools and summer schools should not be recognized. There is no necessity or excuse for such institutions. Time should be devoted at each annual conference of the National Confederation to outlining and agreeing upon the extent and character of the ensuing examinations in the several States in order that they shall all be equally difficult. Adequate time should be given applicants for full answers. A uniform standard of grading should be adopted. Let the members of the confederation agree to a uniform course of action and in a few years our laws would be in accord. [H.M.]

10.—**Malarial Vertigo.**—Mays has found this symptom mentioned by few recent writers. It is sometimes the first thing to draw the patient's attention to his condition. In apparent health his gait suddenly becomes insecure and he staggers or falls, but consciousness is not dimmed. The attacks come in daytime and intermittently. In all of the author's cases there was a history of intermittent fever, latent for some time, perhaps for years, before the vertigo appeared. Quinin should be administered in doses large enough to cause ringing in the ears. [H.M.]

## Boston Medical and Surgical Journal.

February 5, 1903. [Vol. CXLVIII, No. 6.]

1. On Paratyphoid Fever and its Complications. JOSEPH H. PRATT.
2. Typhoid Fever at Boston City Hospital in 1902. GEORGE G. SEARS.
3. Typhoid Fever at Massachusetts General Hospital. HERMAN F. VICKERY.
4. The Clinical Diagnosis of Typhoid Perforation. JOHN C. MUNRO.
5. Diet in Typhoid Fever. FREDERICK SHATTUCK.
6. Typhoid Fever in Private Practice. J. T. G. NICHOLS.
7. Upon Presence of Typhoid Bacillus in Urine and Sputum. MARK W. RICHARDSON.

1.—**Paratyphoid Fever.**—The paratyphoid bacilli are members of a group which includes meat poisoning bacilli, *B. psittacosis* and the hog cholera bacilli. They produce typhoid symptoms in man. Pratt reports a case, the only one in which orchitis due to this bacillus is recorded. He also reports a case of Richardson's, unique from the occurrence of cholelithiasis four years after the fever. In the 84 cases recorded *B. paratyphosus A* was the causative organism in 12, and *B. paratyphosus B* in 69; in the others the species was not determined. The disease is a general infection in which local lesions may be

absent. Fatal cases were all due to *B. paratyphoid*. It may present all the clinical aspects of typhoid fever. The number and frequency of complications is striking. The author gives a list of these. The diagnosis is made by cultures from the blood. These have also been made from urine, feces, vagina, rose-spots, and sputum. If the organism cannot be recovered, diagnosis is justified if the bacilli are agglutinated by high dilutions of the blood, while typhoid bacilli are not agglutinated or only by very low dilutions. The serum reaction is a special, not a specific test. The mortality is apparently much lower than in typhoid fever. [H.M.]

2.—**Typhoid at the Boston City Hospital.**—Sears reviews the symptoms, etc. in 203 cases treated in six months, with a mortality of 12.8%. The great majority developed insidiously, but an unusual number of cases began with severe headache, a chill, or diarrhea. Diarrhea and constipation were about equally present. Defervescence occurred in two cases by crisis. In one case a temperature of 107.5° was reached without discoverable cause, and without interrupting the patient's progress toward recovery. Hemorrhage occurred in 14 cases, four of which ended fatally, and perforation in three—all fatal. In operation is the only hope of cure, but Sears does not advise this method until the diagnosis is clear. In some cases of the disease there was noted a marked increase in the amount of urine voided at the time convalescence set in. Three women were pregnant, but recovered without aborting. Psychic disturbance developed in six cases. The prevalence of relapse depends on the interpretation of the recrudescence of the fever. In this series the relapses were estimated at 20. The Widal test was positive in 168 and negative in 33. It is of great value in cases with misleading features. [H.M.]

3.—**Typhoid at the Massachusetts General Hospital.**—Vickery reports 49 cases, with a mortality of 6%; 41 gave a positive Widal reaction. The diazo reaction was of little assistance in making a diagnosis. One profoundly toxic case exhibited striking improvement upon subcutaneous administration of normal salt solution, one pint twice daily for 13 days. [H.M.]

4.—**Typhoid Perforation.**—Munro, of Boston, reports 26 cases, 21 of which came under his own observation. Of the entire series 21 were operated upon, and all but two died. Two patients died and three recovered without operation. Fatality in a number of cases was due to refusal of operation on the part of the patient or friends until the operative time had passed. The author prefers ether to local anesthesia as a rule. He insists that the surgeon be called earlier in consultation, and believes the ideal plan in hospital practice is for the surgeon to see, with the physician, the typhoid patients each day. Early surgical interference is insisted upon; and attention is called to the fact that symptoms differ much in different cases; in many cases the classic symptoms do not appear at all. Two of the patients recovering without operation, he believes had perforation which healed spontaneously. He knows of no definite means of differentiating perforation from hemorrhage. All cases exhibiting signs of additional peritoneal infection should be operated upon. Naturally in some perforation will not be found, but to wait for definite and conclusive signs is to lose to many patients the only hope of recovery. [A.B.C.]

5.—**Diet in Typhoid.**—Shattuck feeds his patients according to their digestive power rather than according to the name of the disease, avoiding anything which can leave a residue irritating to the ulcerated surface. Under exclusive milk diet he had a mortality of 10% in 233 cases, while with enlarged diet the mortality has been only 8.45% in 246 cases, and relapse has been 2.9% less. The evidence is sufficient to warrant further trial. Hemorrhage and perforation are no more frequent, the patients are more comfortable, and have a shorter convalescence. [H.M.]

7.—**The Typhoid Bacillus in Urine and Sputum.**—According to Richardson, the bacillus is present in the urines of 21% of cases, frequently in enormous numbers, persisting for weeks, with danger to both patient (cystitis and possibly orchitis and epididymitis) and public. Disinfection should be rigid. Urotropin is generally sufficient. Obstinate cystitis may require vesical irrigations. No patient should be discharged until his urine is proved free from bacilli. He has

isolated this organism on three successive days from the sputum of a case complicated by pneumonia. In 15 cases without pulmonary complications results were negative. It is almost invariably associated with other organisms, and is to be regarded rather as a secondary invader than the primary cause of the complication. [H.M.]

### Medical Record.

February 7, 1903. [Vol. 63, No. 6.]

1. Theory and Practice of Spinal Cocainization. G. K. DICKINSON.
2. Essential and Paroxysmal Tachycardia. J. J. MORRISSEY.
3. Hemorrhagic Appendicitis as the First Manifestation of Purpura Hemorrhagica. NATHAN JACOBSON.
4. Subcutaneous Abscesses Due to the Gonococcus in a Child Two Years of Age. MILTON A. GERSHEL.
5. Imbalance and Insufficiency of the Eye Muscles. R. C. MATHENY.
6. The Maternal Impression Supersition. EDWIN TAYLOR SHELLY.
7. Paraffin Injection in a Case of So-called Saddle-nose. FRANCIS ALTER.
8. The Army Cartridge-belt. LOUIS L. SEAMAN.

**1.—Spinal Anesthesia.**—Dickinson says until 100,000 cases have been observed and properly recorded it will be idle to condemn or laud this method. Cardiorespiratory complication is the main danger to be apprehended, but from his experience in a series of over 200 cases, no anxiety need be felt. There was no distress from dyspnea nor palpitation. Blanching of the skin and consequent nausea were observed at times with vomiting in a few cases shortly after puncture, or later when disturbed by being transferred to bed. In his earlier cases, when but few drops of the spinal fluid was lost, or perhaps due to faulty choice of cocain, the nausea and vomiting was more frequent and persistent, but in the last 135, with removal of the same quantity of fluid as the amount injected, this phenomena has been quite unusual. [Eucain B is prepared by many surgeons, as it can be sterilized without decomposition by boiling.] [A.B.C.]

**2.—Tachycardia.**—Morrissey reports two cases, one of which was due possibly to myocardial degeneration, and the second to profound shock of the nervous system. Tachycardia is a symptom. When associated with definite pathologic changes in the myocardium it should be classified as essential; when due to outside disturbances in the nervous system, alimentary tract, etc., the name reflex should be applied. Rapid action found with organic heart disease is an entirely different phenomenon. In some hearts attacks of tachycardia may precipitate all the consequences of advanced disease. The pathology is very obscure and the treatment unsatisfactory, due probably to so many diverse conditions giving rise to the same symptoms. [H.M.]

**3.—Hemorrhagic Appendicitis as the First Manifestation of Purpura Hemorrhagica.**—Jacobson reports the case of a woman of 37 who suffered for several days from general abdominal pain, confined mostly to the right side. The pain became most pronounced over the appendix, and existed to a less degree over the gallbladder and at a point to the right of the umbilicus. Right-sided abdominal rigidity could not be definitely determined on account of a very thick belly-wall. Temperature rose to 104.5°, and the pulse to 132. Operation showed the appendix apparently inflamed. Microscopic examination of the removed organ showed it had sustained numerous intestinal hemorrhages, but no blood extended into the lumen. Two days after operation pain became marked in the right chest. Two days later a hacking cough developed, which raised a quantity of bright blood, followed by a profuse nasal hemorrhage. The next day petechial spots appeared on the left leg, followed by numerous ecchymoses on both calves; petechias also appeared on the abdomen. There was no vomiting. The heart and joints were normal, and there were no hemorrhages from the bowels or kidneys. For some three weeks she daily expectorated more or less blood. Then suprarenal extract was given, and from that time there were no expectoration of blood. It may have been a coincidence. After about six weeks the patient was discharged cured. The author knows of no similar case, and his search in the literature has been fruitless. The point of greatest interest is hemorrhage occurring in the appendix as the first manifestation of purpura hemorrhagica. He therefore, in consequence of

the similarity in symptoms to inflammatory appendicitis denominates it hemorrhagic appendicitis. [A.B.C.]

**4.—Subcutaneous Abscesses Due to the Gonococcus.**—Gershel reports the case. A male child of two years was suffering from typhoid fever. Acute anterior urethritis developed. A week later a subcutaneous abscess developed at the left of the anus; a few days later a similar abscess developed at the right of the anus. There was no communication with the rectum or prostate. Bacteriologic examination from both abscesses and from the urethral discharge proved all to be of gonococcal origin. The source of the urethral infection could not be determined. The abscesses were considered by the author to be the result of lymphatic conduction. A study of the literature on the subject showed 11 other somewhat similar cases reported so far as origin of the abscess is concerned; only two, however, were subcutaneous. [A.B.C.]

**6.—Maternal Impressions.**—It seems incredible to Shelly that our modern textbooks should contain such antiquated ideas on the subject of maternal impressions as he quotes from Hirst, Dorland and others. The grounds upon which the old theory of maternal impressions producing physical marks upon the unborn child rests are untenable, both anatomically and physiologically. As soon as the ovum is expelled from the Graafian follicle, the solution of continuity between the ovum and the mother is complete. This fact is conspicuous even in the arrangement of the placenta, whereby the blood of the mother and that of the child do not mingle directly, only by osmosis; and the gap between the nervous systems of the two extends throughout the whole length of the umbilical cord and the thickness of the placenta. That it is possible for a nervous or mental influence to bridge this chasm and produce physical abnormalities, is absurd. The prevalence among medical men of such a delusion is a stigma upon the profession and the source of many hours of anxiety to expectant mothers. [W.K.]

**7.—Saddle-nose Corrected by the Subcutaneous Injection of Paraffin.**—Alter reports that a man of 55 had a marked saddle-nose, the result of a luetic infection at 22. He had many relapses from the original infection, due to inadequate treatment. Subcutaneous injection of paraffin was done with good results, the correction being almost complete from a cosmetic standpoint. The material used consisted of one part of solid to three parts of liquid paraffin, the mixture having a melting point of 40° C. (104° F.). The antitoxin syringe, as suggested by Heath, was used. A strong, perfectly-acting syringe, with shoulder or eyelets should be employed, as it requires a surprising amount of force to drive onward the paraffin. The point is inserted at the apex of the glabella. Some blanching will be noticed, which soon subsides. Molding is easy and should be followed up by rubbing a small piece of ice over the surface. [A.B.C.]

**8.—The Army Cartridge-belt.**—Seaman, late Major and surgeon, First U. S. Volunteer, makes grave complaint against this belt. He asserts that in the tropics 80% of the soldiers are sooner or later afflicted with some gastrointestinal disorder. The cartridge-belt, weighing from 10 to 12 pounds, is suspended from the waist, and changing its position at every step, acts practically as massage to the abdomen. This, if the viscera be at all inflamed, is the very antithesis of what is needed, and in his judgment is a causative factor in producing visceral inflammation. The belt should be suspended from the shoulders, as is the practice among the armies of all other civilized nations. [A.B.C.]

### New York Medical Journal.

January 31, 1903. [Vol. LXXVII, No. 5.]

1. The Treatment of Acute Septicemia by the Intravenous Infusion of a Solution of Formaldehyd, with Report of a Case. CHARLES CLIFFORD BARROWS.
2. Rectal Fistula Curable without Operation. A. ROSE.
3. Report of a Case of Intestinal Obstruction Due to Meckel's Diverticulum. J. S. PRICE.
4. Fourteen Cases of Smallpox from the Buffalo Epidemic of 1901-1902. D. E. WHEELER.

1.—See editorial *American Medicine*, Vol. V, No. 6, p. 232.

2.—**Rectal Fistula.**—Rose reports a case of rectal fistula in a man of 34 cured by the application of carbonic acid gas. The patient had hemorrhoids, suffered from constipation and did

not have complete control of the sphincter vesical. He had been unable to sit down long enough for his meals, and had suffered thus for years. A current of gas was passed through the external opening into the rectum, filling the bowel up to its full capacity and causing thereby the agreeable sensation of warmth that is noticed when the gas is introduced directly into the rectum. From the first application the sinus began to close, and with the third very little, if any, gas passed into the rectum. At the end of two weeks the fistula was completely and entirely closed and healed. The rectal cone was used to reduce the hemorrhoids, and compound licorice powder to regulate the bowel. Following the closure of the fistula the rectum was inflated daily with carbonic acid gas to heal the internal ulceration. [C.A.O.]

**3.—A case of intestinal obstruction due to Meckel's diverticulum** is reported by Price. Upon opening the abdomen it was found that a loop of ileum about 15 inches in length had been caught by the diverticulum which was about 3 inches in length. The knuckle of strangulated gut was gangrenous in three or four places and very much distended. To relieve the pressure it was necessary to open the bowel and allow about a quart of liquid feces to escape. The gangrenous areas were inverted under a double tier of running Lembert sutures. After replacing the intestine it was surrounded by iodoform gauze and the wound left open. The operation was performed in a negro cabin. Uninterrupted recovery followed. [C.A.O.]

**4.—Smallpox.**—Wheeler gives pictures illustrating, and reports in full 14 cases of smallpox from the Buffalo epidemic of 1901-1902. Of 409 cases reported up to the time of writing, only six had ended fatally. Most of the cases had been among the Poles, especially those under the school age. Of the 409 cases, a vaccination history was recorded in 374. Of the subjects of these, 295 were never vaccinated. Sixty-nine professed to have been vaccinated, by no means all of them successfully, or within seven years. There is only one case reported in this epidemic of smallpox in a person successfully vaccinated more than once. This was a very mild case of varioloid. [C.A.O.]

2. Eye-strain. A. C. BARDES.
3. A Fatal Case of Polyarthritides Complicated by Choreiform Symptoms and Vegetative Endocarditis. AUGUSTUS A. ESHNER.
4. Prostatic Calculi: With Report of a Case. JOHN F. ERDMANN.
5. The Facts in a Case of Hematuria. CHARLES H. CHETWOOD.
6. Trap-drummer's Neurosis: a Hitherto Undescribed Occupation Disease. CHARLES J. ALDRICH.
7. Experiments With a New Quinin Derivative. F. PIRKNER.

1.—See *American Medicine*, Vol. IV, No. 18, p. 689.

**3.—Polyarthritides, Choreiform Symptoms and Vegetative Endocarditis.**—This case of Eshner's is interesting on account of the association of these conditions. Various cocci may each give rise to a number of distinct lesions, and it may eventually be found that rheumatism and chorea merely represent different localizations of the same infection. [H.M.]

**4.—Prostatic Calculi.**—Erdmann reports the case of a man of 23 who had been operated upon twice within two years and two tooth-like stones removed from a perineal incision, and the condition diagnosed dermoid cyst of the prostate. A urinary sinus persisted. The author operated and removed 50 small, brownish, highly polished stones from the right lobe of the prostate. The fistula persisted for some weeks, when a second operation was performed for its closure. This was entirely successful. Some sebaceous material, hair, etc., were removed with the small stones, but the author suggests that this may have resulted from the first operation, rather than from dermoid or inversion-cyst origin. The origin of the calculi is a calcareous degeneration of a previous inflammatory condition. [A.B.C.]

**5.—Hematuria for Four Years.**—Chetwood reports the case. An American laborer had for four years noticed that his urine was very dark. No relief followed medical treatment and he was told he had stone in the bladder. Since one year ago he has found it necessary to micturate once or twice during

the night. There have been no chills or fever. On presentation to the author the patient was anemic. A cystoscopic examination showed dark blood coming from the right ureter and clear urine from the left. Operation by right lumbar incision showed the kidney apparently normal. Laying it open a small area of induration was found on a bit removed for microscopic purposes. Three days after the operation the urine was clear for the first time in four years. The urine as previously examined was negative except for blood. The microscopic tissue examination showed some parenchymatous changes only. [A.B.C.]

**6.—Trap-drummer's Neurosis.**—Aldrich's patient stated that each stroke on the pedal required from 5 to 20 pounds pressure, and sometimes a rapidity of movement equal to 150 or 180 strokes per minute. A sense of constriction was felt in the whole leg, and a cramped, distressing sensation of pain and exhaustion in the anterior muscular groups. This is a rare development of kinesthesia in a set of muscles whose centers are very low in the cord, and whose volitional stimuli travel farther than any other in the body. Such a degree of precision and nicety of irregularity is demanded that it is little wonder exhaustion of the cortical centers should occur. [H.M.]

**7.—A New Quinin Derivative.**—Pirkner recommends saloquinin on account of its tastelessness and nonirritating and diuretic qualities. It is especially indicated when quinin must be administered to patients with gastrointestinal irritation and middle-ear disease, and to those in whom severe symptoms of cinchonism are easily produced. [H.M.]

6. An Improved Syringe for Intratracheal Medication. P. S. DONNELLAN.

**1.—Tropical Diseases.**—Kieffer details at length chronic dysentery, which is usually a sequel of acute dysentery, although it may be a subacute or chronic process from the beginning in amebic cases. The great bulk of chronic tropical dysentery is due to the ameba coli. When bacillary dysentery becomes chronic the clinical type is simply one of amelioration of all the symptoms of the intense acute stage. The treatment of chronic dysentery is divided into the treatment of the subacute recurrences and into the treatment of the essentially chronic stages. Bismuth is a valuable remedy administered in the form of betanaphthol bismuth; sulfur has been used by Stengel with prompt and striking success; salol alone or in combination with bismuth is of great value. The local treatment is considered the most rational plan of treatment. Local remedies should not be used in acute or subacute recurrences or recrudescences, in chronic dysentery. In giving local remedies the quantity of the fluid must be such that the irrigation will fill the colon and reach quite up to the ileocecal valve. The remedy of greatest value is silver nitrate. It is administered in a strength from 1 gm. to 2 gms. (15 grains to 30 grains) to the pint. Of this solution three to four pints are carefully injected. Commonly this injection would be repeated at intervals of three to four days; but in certain cases the silver salt causes marked irritation, and it must be abandoned. Scorbutus and malaria are complications which should always be borne in mind. [F.C.H.]

**2.—The Elevation of the Stomach in Gastroptosis.**—Beyea describes his operation for elevation of the stomach in gastroptosis by the surgical plication of the gastrohepatic and gastrophrenic ligaments. The principle of this operation is that by placing three rows of interrupted silk sutures from above downward and from right to left through the gastrophrenic and gastrohepatic ligaments, a broad transverse fold or plication is formed in shortening these ligamentary supports and elevating the stomach to normal position. The normal ligaments are

shortened without disturbing the physiologic mobility or functions of the organ. The principle of the operation must be considered physiologically and surgically ideal. Seven cases are reported in which the patients have secured completeness of relief by this operation. [F.C.H.]

**3.—A Study of Fifty-five Fatal Cases of Pertussis.**—Hull gives a detailed study of 55 fatal cases. In these the complications were not the primary causes of death. In all of them, particularly in those of very young infants, the danger signal was either a developing stupor or an attack of prostration, from which the patients recovered only temporarily, to go into a state of increasing stupor and exhaustion until death. The average duration of the fatal cases was a trifle over three weeks. The treatment in pertussis is plainly to support the patient, to establish an equilibrium in the nerve centers, and to prevent the further absorption of toxins by destroying the micro-organism producing them. [F.C.H.]

**4.—Irritable Bladder.**—Broter believes that in every case of irritable bladder there is something more than a mere nervous condition. He considers that when one speaks of an irritable bladder, an inflammatory condition of a localized area of the mucous membrane is inferred. In the treatment of this condition, prophylaxis is of paramount importance; a mild diet should be used. Excellent results are obtained by the following plan of treatment: Catheterize the bladder; then wash out the bladder several times with a warm saturated solution of boric acid; then introduce one ounce of a 1% solution of silver nitrate, allowing this to remain in the bladder for three to four minutes; draw off the silver solution and introduce about three ounces of a 2% to 10% solution of ichthyol in water, and allow this to remain in the bladder for at least a half hour. The treatment should be repeated every other day for about three or four weeks. In conjunction with this treatment a simple alkali should be administered daily. [F.C.H.]

**5.—The Significance of the Temperature in the Diagnosis of Extrauterine Pregnancy During the Period of Collapse from Hemorrhage.**—Noble details a case showing that a rise of temperature a few hours after the onset of symptoms of hemorrhage from ectopic gestation does not exclude a diagnosis of collapse from hemorrhage. [F.C.H.]

**6.—An Improved Syringe for Intratracheal Medication.**—Donnellan describes an intratracheal syringe which can be readily sterilized by boiling, or by immersion in alcohol or corrosive solution. With ordinary care the barrel and glass piston are quite durable, but should they get broken they can be easily replaced by the instrument dealers. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

### EDITORIAL COMMENT

**Multiple serositis or multiple progressive hyaloseritis**, as Nicholls<sup>1</sup> prefers to call it, is a disease entity to which more than passing attention should be directed. Nicholls, summarizing his opinion on the subject, says that there is an affection of the serous membranes—multiple progressive hyaloseritis—characterized by the formation of dense fibrohyaline investment in certain regions, and that anatomically two forms exist—the sporadic and the diffuse. The disease is primarily and essentially due to chronic inflammation, and is almost certainly attributable to the action of microorganisms of low virulence. The exact nature of the microbic excitants is in many cases obscure, but cases undoubtedly exist that are due to the tubercle bacillus. Nicholls furthermore believes that apart from tuberculosis only one form of the disorder, namely, chronic hyaline perihepatitis (Zuckergussleber) gives rise to clinical symptoms sufficiently definite to render diagnosis possible; that this form of perihepatitis may exist *per se* but is often secondary to chronic peritonitis, or may be again part and parcel of a generalized affection of the

serous membranes; and that the most important etiologic factors in chronic perihepatitis are, in order of frequency, acute and subacute hepatitis, chronic mediastinopericarditis, chronic peritonitis, and chronic pleuritis.

Two striking features of multiple serositis possess unusual interest in connection with the presumed tuberculous nature of many of the cases—the marked susceptibility of the serous membranes and a certain immunity of the organs. This has led a number of the Italian writers who have studied the disorder carefully (calling it polyorrhomenitis or polyserositis) to insist that not every case of generalized tuberculosis that implicates the serous membranes and gives rise to chronic fibrous lesions belongs to the group under discussion. Thus Picchini<sup>1</sup> states that the cases under discussion differ from the ordinary cases of serous membrane tuberculosis in that in their etiology heredity plays no role; that the disease does not appear to affect especially persons of phthisical or tuberculous habitus; that the inflammations of the serous membranes set in insidiously, much less acutely than do the ordinary cases of tuberculous inflammation; that they may remain latent for a long time; and that the lesions remain localized to the serous investment of the organs and are unassociated with tuberculous lesions of the lungs, as is so common in the ordinary cases. A study of the cases reported in the literature bears out the reasonableness of this view. Nevertheless, as pointed out by Kelly,<sup>2</sup> there seem to be border line cases and cases representing varying degrees of infection with the tubercle bacillus: (1) Cases in which the lesions are confined strictly to the serous membranes; (2) cases in which the lesions involve especially the serous membranes, but in which one or several tuberculous foci may be found in the body (of which several cases have been reported); (3) cases in which the serous membrane disease represents but a part of a general tuberculous infection (usually a distinct disorder rarely presenting the characteristic thickening of the serous membranes). Although the disease may begin in any one of the serous membranes—the pericardium, the pleura, or the peritoneum—the lesions of the pleura or pericardium are frequently for a long time latent; the striking clinical feature of the disease is ascites, which is present whether the pericardial and pleural changes are absent, whether they are slight, or whether they are marked.

The presence of disproportionate ascites, therefore, should awaken the suspicion of the presence of this multiple serositis, particularly as already pointed out<sup>3</sup> in the absence of the etiologic factors and usual physical signs and symptoms of cirrhosis of the liver. Such suspicions will the more likely occur to those who have read the extremely interesting observations of Hale White<sup>4</sup> who, in discussing the causation of ascites, says that the supervention of ascites in uncomplicated cirrhosis of the liver means that the end is near; that if a patient with ascites and cirrhosis of the liver lives long enough to require a second paracentesis, it is in the highest degree probable that either the diagnosis is incorrect or that some cause other than cirrhosis exists to explain the ascites, and that such cases nearly always turn out to be examples of chronic peritonitis with perihepatitis, which is not a special disease, but merely a part of chronic peritonitis. These observations are of special value as indicating the relative unimportance of the liver in the causation of an ascites that persists as long and necessitates as many tapplings as does the ascites in the cases of multiple serositis at present under discussion. Nicholls, point-

<sup>1</sup> Quoted by Kelly: American Journal of the Medical Sciences, 1903, cxxv, 137.

<sup>2</sup> Loc. cit.

<sup>3</sup> Editorial, American Medicine, January 31, 1903, p. 190.

<sup>4</sup> Guy's Hospital Reports, 1893, xlix, 1.

<sup>1</sup> Studies from the Royal Victoria Hospital, Montreal, Vol. 1, No. 3, 1902.

ing out that chronic hyaline periphepatitis, atrophic cirrhosis of the liver, tuberculous peritonitis, and carcinoma of the peritoneum present many features in common, gives an extremely valuable table for differential diagnosis. The chronic perihepatitis (or "zuckerguss-leber") occurs in middle life or later, and affects both sexes equally; often a history of acute pericarditis or perihepatitis may be elicited; alcoholism, syphilis, and heredity are without influence; the disorder becomes insidious or chronic from the beginning and lasts for years; fever is absent except during exacerbations; pain is trifling and indefinite; digestive disturbances are trifling or absent; ascites is constant and extreme; anasarca is constant, but slight; and jaundice is absent in pure cases.

**The Egyptian Medical Congress**, held at Cairo at the close of last year, exhibited in its proceedings a very high standard. Among Americans who read papers were Major W. G. Gorgas, and Charles Wardell Stiles. Major Gorgas' paper was on "Recent Experiences of the United States Army with Regard to the Sanitation of Yellow Fever in the Tropics;" Stiles' on "Uncinariasis (Ankylostomiasis) in the United States." The latter was read by Assistant Surgeon V. G. Heiser. Professor Loos, of Leipsic, made a more detailed announcement of his hypothesis that the ankylostoma enters through the skin, a view to which attention was some time ago called in an editorial in *American Medicine*. Some striking statements were made by Kartoulis, of Alexandria, with regard to dysentery. He expressed the belief that when abscess forms in the liver the attending physician is to blame. He treats his cases with rectal injections of tannin and uses sodium salicylate internally. Other interesting papers were read. These will no doubt soon be printed and will then be reviewed in their proper place.

**The X-ray as a Therapeutic Agent.**—An interesting discussion upon this subject took place in the Cincinnati Academy of Medicine a short time ago. It was called forth by a paper by William Jordan Taylor. From his studies it seems that the first to suggest the applicability of the x-ray to therapeutic purposes was Freund, who employed it to remove the hair from a nevus. According to Taylor, the x-ray treatment is valuable in the following five conditions: (1) In hypertrichiasis, for the removal of undesirable hair; (2) in diseases of the hair and hair-follicles, such as sycosis, tinea tonsurans, favus, and when the removal of diseased hair is essential; (3) in the treatment of inflammatory troubles, such as chronic eczema, in which it is necessary to stimulate the tissues and produce absorption of inflammatory products; (4) in certain affections in which it is desired to cause destruction or absorption of tissues of low vitality; (5) to relieve pain and to produce sleep. This list, however, by no means exhausts the affections for which the x-rays have been and are employed. In the discussion, which was participated in by Ravogli, Shields, and Heidingsfeld, Shields expressed the belief that the results attributed to the x-ray are not due to the action of this agent at all, but to rays of a different sort produced in the tube with the x-ray. He also gave it as his emphatic opinion that the x-ray has absolutely no power to relieve pain. This is in strong contrast with the views of others, particularly with those expressed by Moseley in *American Medicine*, January 31, 1903.

#### REVIEW OF LITERATURE

##### A Peculiar Complication of Pulmonary Hemorrhage.

—Cybalski<sup>1</sup> has seen four cases in which slight pulmonary hemorrhage coming on during sleep was followed shortly after by extreme dyspnea, in one case threatening the life of the patient. Each patient expectorated after a violent coughing

paroxysm a large, branching, grayish-red cast, this being followed by immediate relief of the breathing difficulty. Microscopically the cast was found to consist of coagulated blood, air bubbles, and leukocytes. Evidently one of the larger bronchi had become occluded by the blood clot, setting up the extreme dyspnea. [E.L.]

**Typhoid fever in children of two and one-half years and less** is discussed by Griffith and Ostheimer,<sup>1</sup> who give as far as possible the statistics of 325 cases collected from the literature. [A.O.J.K.]

**Morphinodipsia.**—Dipsomania is often the result of an acute psychic depression, a melancholia, and the reason individuals thus affected use alcohol is that they must find rest from their diseased mental condition. Some, instead of drinking alcohol, make use of ether, chloroform, or chloral; morphin is rarely used by these people. Krafft-Ebing<sup>2</sup> reports the case of an engineer of 35 who had learned to know the effects of morphin during an attack of trifacial neuralgia. Later he employed the drug because of sleeplessness brought on by worry and grief over family matters. After a fall from a horse he developed epileptic seizures, which were attended by dizziness, restlessness, irritability, unconscious wandering, amnesia, and precordial oppression. When in such a condition he sought and found relief in large doses .3 gm. (4½ grains) of morphin hypodermically administered. Between attacks he never used opium in any form, and even wished to fortify himself against its use. The frequent connection between epilepsy and dipsomania is considered. [E.L.]

**The Widal Reaction.**—Pitts<sup>3</sup> gives the history of the Widal reaction, the method of obtaining it, and reports his observations. He concludes that a positive reaction can fairly be expected at some time or other in the course of the large majority of cases of typhoid. As positive evidence it is of decided value; as negative evidence it is untrustworthy. In cases other than typhoid the reaction is probably never present, though partial reactions must be rigorously excluded to avoid possible error. [W.E.R.]

**Hemolytic Blood-plasma.**—Ascoli<sup>4</sup> concludes, after a consideration of the literature on the subject and his own experimental work, that plasma possesses the same blood dissolving properties which are peculiar to the corresponding serum varieties *in vitro* and *in vivo*. This action appears under such circumstances as to exclude positively the interference of osmotic factors. The events in question being absolutely analogous, it is believed the hemolytic and bacteriolytic actions of immune and normal serums depend upon a plasmolysis or plasmoptysis in consequence of changed osmotic conditions, when these fluids are transferred to strange serums. If we consider the supposition that the specific action of serums depends upon the combined action of two substances (amboceptors and complement), assisted by observations conducted with lytic serums, it is also believed these substances are present in unchanged plasma, and that coagulation, leukolysis and postmortem processes have nothing to do with their production. [E.L.]

**A case of subpectoral abscess**, supplemental to the cases reported by Musser<sup>5</sup> is reported by Davis.<sup>6</sup> [A.O.J.K.]

**Abscesses of the Liver Following a Simple Ulcer of the Stomach.**—Leclerc and Tavernier<sup>7</sup> report such a case, which was diagnosed during life as carcinoma of the stomach, not involving the pylorus. Autopsy showed two large abscesses of the liver, and also the cicatrix of a simple gastric ulcer, the latter revealing the probable origin of the abscesses. They had evidently not resulted in the usual way, through the successive production of perigastritis and suppurative perihepatitis; but had their origin in septic matter transported by the portal vein or lymphatics, the process being similar to that which occurs in abscesses developing from dysenteric ulcers of the colon. Liver abscesses develop more commonly from dysenteric than from gastric ulcers for two reasons: (1) The presence in dysen-

<sup>1</sup> Münchener medicinische Wochenschrift, September 30, 1902

tery of a pathogenic germ endowed with special virulence; and (2) the presence of conditions in the lower bowel much more favorable to bacterial development than the acid secretion of the stomach. [B.K.]

**The Frequency of Nursing.**—Neumann<sup>1</sup> reviews numerous statistics from other cities comparing the relative number of breast-fed and artificially-fed infants. They compare very favorably with those he reports from Berlin, where nature's method of feeding children is constantly being less employed. While in 1885 55.2% of children were nursed by their mothers, in 1900 there were but 31.4%. In spite of this decrease in the number of nursed children the mortality from intestinal diseases has diminished steadily, thus showing the great improvement in the quality of the milk used throughout the city as well as in the city's general hygiene. [E.L.]

**Concerning the Assimilation of Fat in the Organism.**—Leo<sup>2</sup> gives the methods and results of his investigations on the digestion of fat. He found that fat is partially changed to glycerin in the stomach and intestines by the action of steapsin. The fatty acids and glycerin are absorbed in the intestines. A portion of the glycerin is absorbed alone. He examined the feces of a large number of persons who had ingested a considerable quantity of glycerin, yet never found a trace of that element. In disturbances of the digestive tract, the assimilation of fat does not always occur, but is discharged in the feces unchanged. On the other hand, persons who indulge in large quantities of fat may develop intestinal disorders without decreasing the fat metabolism. The conversion of fat in such cases may cause diarrhea by irritation of the intestinal mucous membrane. Normally no glycerin occurs in the urine. Leo found glycerin absent in the urine of all pathologic conditions excepting diabetes mellitus. [W.E.R.]

**A New Method to Determine the Quantity of Milk to be Given to Artificially Fed Children.**—Adam<sup>3</sup> describes the method which he uses in the artificial feeding of newborn infants, and which he has found to be extremely valuable in nearly all cases in which artificial feeding was required. He uses in all cases whole milk, diluting it considerably during the first three months. The quantities which his experience has taught him to advise during these months, and upon which the children seem to thrive, correspond closely with those prescribed by others for breast-fed children, sometimes they are even smaller than these. Between the seventh and thirteenth week he advises 800 cc. in 24 hours, and does not increase the quantity to more than 1 liter per day up to the end of the first year. Concerning the quality of the milk mixture the condition of the child must remain the chief guide. The general rule which he followed was this:  $\frac{1}{2}$  of the daily volume of milk corresponding to the age of the child was multiplied by the age of the child in kgrs., and this result corresponded to the amount of whole milk used—a child three weeks old and weighing three kgrs. (6½ lbs.) will usually get 500 cc. (1 pt.) of milk, of this 300 cc. (10 ozs.) is whole milk, the rest is dilution. In occasional cases, during the first few months of life, he considers warm cream mixtures in definite proportions (he gives tables for these proportions) preferable to the above-mentioned milk mixtures. [E.L.]

**The Treatment of Pneumonia.**—Wilcox<sup>4</sup> advises the continuous, persistent, and generous administration of creosote carbonate; the careful adjustment of mechanical conditions; thorough evacuation of the toxins by all possible ways; temporary supplemental oxygen by inhalation; liquid diet until physical signs disappear; and the avoidance of antipyretics, opiates, ill-advised external applications, and slowly-acting heart remedies, as digitalis. His experience with this treatment comprises 33 cases with no deaths. [A.O.J.K.]

**Analysis of Human Milk the Basis of the Artificial Feeding of Infants.**—Meigs<sup>5</sup> reviews the results of his various analyses of the human milk during the last 20 years and gives his clinical experience in the artificial feeding of infants. He reports a method for determining the amount of casein and

sugar in the human milk, and concludes that the human milk contains about 1% of casein. Artificially fed infants should not have the strength of their food increased at frequent intervals, as is generally advised, but the same food should be given with an increase in the amount as the child grows older. [W.E.R.]

**Diphtheria with Persistent Trismus and Opisthotonos: Escherich's Pseudotetanus.**—Snow<sup>1</sup> reports a case of mild diphtheria occurring in a boy aged 7 years, and associated with prolonged contracture of the masseter and dorsal muscles. From the third to the tenth day of illness laryngismus and violent generalized muscular spasms occurred; after the tenth day the disease assumed a tranquil type, with persistent trismus and opisthotonos. The contractures lasted 21 days, unaffected by tetanus antitoxin, but were eventually relieved by morphin. The condition is said to suggest Escherich's pseudo tetanus. [A.O.J.K.]

**The Tanner's Trade in its Relation to Tuberculosis.**—Immunity to tuberculosis is accorded to but few occupations; among these are the coal miners, the lime burners and plasterers, and especially the tanners. The latter have been said to be immune to a number of diseases at different periods of the world's history. It has been claimed for them that they never contracted cholera or plague, but especially in reference to tuberculosis has it been said that the atmosphere of tanyards is a preventive as well as a cure for the disease. Several observers, on the other hand, have collected figures to prove that not only are tanners not free from tuberculosis but it is even a frequent disease among them. Reitter<sup>2</sup> has made inquiries in 50 tanneries in and around Vienna, and reports the observations thus gathered. Diseases of the lungs are said to rarely ever occur in these places, and in a few cases where workmen have had tuberculosis when starting to work in tanneries their condition has improved very much. It must be remembered, however, that these observations are not based upon physicians' statements, but upon laymen's. [E.L.]

**Concerning the Abuse of Boric Acid.**—Dosquet-Manasse<sup>3</sup> reports his investigations on meat preserved with boric acid. He found that this drug, as an efficient preservative, must be used in large quantities. His control experiments proved that boric acid does not prevent putrefaction entirely but that it may conceal the degenerative process. All antiseptics which destroy bacteria also decrease the nutritive value of the food. The aseptic process is the proper preservative method and should be employed in place of antiseptics. Dosquet-Manasse concludes that boric acid is a powerful cell-poison, and should be excluded as a food preservative. [W.E.R.]

### REVIEW OF LITERATURE

**Stab Wound of the Kidney.**—A carelessly thrown weapon struck a bystander, who was leaning forward, in the back, producing a stab wound 5 cm. (2 inches) long, hemorrhage being profuse. Tubenthal<sup>4</sup> saw the patient the following day, and noticed a reddish fluid staining the dressings. The urine was found to be bloody. Upon incision a longitudinal wound of the kidney was found. It was packed with iodoform gauze, the patient making a normal recovery. [E.L.]

**Eosinophilia in Pelvic Lesions and in the Vermiform Appendix.**—Weir,<sup>5</sup> from a study of the subject, concludes: 1. Eosinophiles take a prominent part in the cellular infiltration associated with inflammatory and suppurative processes of the pelvic organs. 2. In such conditions they usually occur in largest numbers in the subacute stage and associated with connective tissue hyperplasia. 3. Eosinophilic infiltration is found in most cases of carcinoma of the cervix of the uterus, and in almost all cases of pyosalpinx and ovarian abscess. 4. In inflammatory conditions of the endometrium eosinophiles occur in small numbers and in but few cases. 5. Eosinophiles

represent a large proportion of the cells forming the stroma of the mucosa in the normal and the diseased appendix. 6. In inflammatory conditions of the pelvic organs associated with an eosinophilic infiltration of the tissues the percentage of eosinophiles in the circulating blood is rarely increased, and usually decreased. [A.O.J.K.]

**A Curious Case of Emphysema.**—The case reported by Taylor<sup>1</sup> was that of a boy of 15, who while running fell and struck the frozen ground just above his right eye. There was no visible external injury nor constitutional shock. A few minutes later the boy blew his nose, when the right upper eyelid immediately bulged out, completely closing the eye. The condition is supposed to have been one of slight, fissured fracture of the anteroinferior osseous wall of the frontal sinus, through which air escaped during the increased nasal tension. [A.G.E.]

**Ligation of the Inferior Vena Cava, Followed by Recovery.**—In a woman of 36, Henzel<sup>2</sup> performed a nephrotomy on account of pyonephrosis, and later a nephrectomy. On account of numerous adhesions to all neighboring structures, operation was difficult and attended by tearing of the inferior vena cava. By means of two circular catgut ligatures the vessel was ligated above and below the wound. Recovery was interrupted, except for a slight edema of the lower extremities. Since then the patient has enjoyed perfect health. [E.L.]

**Bloodless Reduction of Phimosis.**—Graeser<sup>3</sup> after trial approves of Orłipski's bloodless method of overcoming phimosis; he dilates the prepuce in all directions with a dilating forceps several times daily until it will retract over the glans. Even cicatricial stenoses can in this manner be overcome. [E.L.]

**Surgery of the Stomach.**—VanderVeer<sup>4</sup> reports one case of gastrostomy and two of gastrectomy. The first was that of a woman of 56, the diagnosis of esophageal stenosis due to carcinoma being made. Gastrostomy was performed. Nine months later the patient had gained 15 pounds and was taking a normal amount of nourishment, partly by mouth, partly through the tube. VanderVeer is satisfied that more good is accomplished by conservative than by radical operations upon the stomach. Gastrectomy is rarely indicated, though the surgeon is at times led to perform this by his great desire to remove all of a malignant growth. This principle is illustrated by the case of a woman of 42, gastrectomy being performed to remove a carcinoma of the stomach, three-fourths of the organ being involved. The patient died within 24 hours. Gastrostomy would probably have prolonged her life. The third case was a man of 55, gastrectomy for sarcoma of stomach. Excellent results followed this operation, the patient working as a blacksmith nine months later, having gained 31 pounds. [A.G.E.]

**Sarcoma of the Third Cervical Segment.**—Putnam, Krauss, and Park<sup>5</sup> report a case of sarcoma of the third cervical segment occurring in a man of 45, and removed at operation, with marked amelioration of the patient's condition. From a study of the literature of spinal cord tumors, they believe their case to be unique for the following reasons: 1. It is the only tumor of the spinal cord affecting the upper cervical region which has been so far recorded. 2. It is the only cervical cord tumor which has gone on to an uninterrupted course toward recovery. 3. It was definitely located and quickly removed without sacrifice of spinous processes and laminae, and the short incision made a remarkably rapid closure. 4. The involvement of the phrenic nerve added an element of danger, which was quickly removed during the progress of the operation. 5. From the surgeon's standpoint it was located in the most inaccessible portion of the spinal cord, by virtue of the cervical curvature of the spinal column offering a concave field for operation instead of a convex. [A.O.J.K.]

**Rhinogenic Purulent Meningitis and Cerebrospinal Meningitis.**—Struppler<sup>6</sup> reports three cases of fatal cerebrospinal meningitis, two of which were considered epidemic, as no other primary focus could be discovered clinically; lumbar puncture was negative in both cases; the third was believed to

be otogenic, as a large polyp grew from the tympanic membrane. Operation proved this erroneous. Autopsy revealed in all cases purulent leptomeningitis of brain and spinal cord, associated with latent suppuration of the antrum of Highmore. In the third case the ethmoidal sinuses were also filled with pus. [E.L.]

**Tissue Changes Induced by the Röntgen Ray.**—Ellis,<sup>1</sup> from a review of the literature and a study of three cases, summarizes as follows the changes induced in the tissues by the Röntgen ray: (1) Necrosis of cells and trabeculas in varying degree (in addition fatty degeneration in one case); (2) increase of elastic tissue in the three cases examined, both before and after exposure; (3) fewer areas of lymphocytic infiltration in one case after exposure—about equal numbers in the other cases; (4) a tendency to occlusion of vessels by deposits on their inner surfaces; and (5) practically entire absence of infiltration of polymorphonuclear leukocytes. While he believes that conclusions are hardly warranted as yet, the following thoughts suggest themselves: (1) Back and others lay great stress on bloodvessel changes as the cause of the necrosis. While endarteritis is probably induced by the Röntgen ray, the accompanying tissue necrosis seems out of proportion to the vessel changes, suggesting the possibility of these being *pari passu* results of the same influence, instead of cause and effect; (2) the presence of immense numbers of cocci and bacilli in the tissues in one case after 20 exposures to the Röntgen ray would argue against the possession of bactericidal power by these rays. The pathogenicity of the organisms, however, was not proved; (3) the unsatisfactory clinical results, as well as the slight microscopic changes in Case III can probably be safely attributed to the presence of the exceedingly numerous keratinized areas or "pearls." This emphasized the importance of cureting or cutting away diseased tissue, whenever feasible, before instituting treatment by the Röntgen ray. [A.O.J.K.]

**Inflammatory Tumor of the Abdominal Wall Produced by a Foreign Body.**—Wagner<sup>2</sup> removed from the abdominal cavity of a woman, who had passed through two attacks of appendicitis, and was believed to have either a sarcoma of the abdominal wall, actinomycosis, old paratyphlitis abscess, or ovarian tumor, the jawbone of a codfish, which had been swallowed two months before the first "appendiceal" attack. It had become wedged in the cecum, perforated backward, and formed there an abscess the size of a man's head, which had gradually become surrounded by dense granulation tissue. After its removal recovery soon followed. [E.L.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Ovarian Fibroma.**—McCann<sup>3</sup> reports the successful removal of an ovarian fibroma from a patient aged 73. The case is of interest not only on account of the age, but as showing that a solid ovarian growth may increase in size and probably even originate after the menopause, and yet be of a simple character. [w.k.]

**Cesarean Section for Obstruction Due to Fibroid Tumors.**—Lewers<sup>4</sup> reports two cases of cesarean section in women, aged respectively 35 and 42, because of obstruction to normal delivery by fibroid tumors. In both cases the uterus was allowed to remain, and in both the children lived and the mothers recovered.

**Cesarean Section in Eclampsia.**—Guérard<sup>5</sup> reports a case of eclampsia in which cesarean section was performed with fatal result. When first called to the case he found the patient in a state of coma; but as it had only been a few hours since the first signs of labor, it was decided to wait, using remedies other than surgical. Two hours later examination showed a collum five cm. (two inches) long, very firm, with no signs of elasticity, os completely closed, and no signs of

<sup>4</sup> Lancet, January 17, 1903.

<sup>5</sup> Zentrablatt für Gynäkologie, December 6, 1902.

any labor pains. Cesarean section was rapidly performed by transverse incision; but the patient never recovered consciousness, and died a few hours later. Guérard was convinced that the operation should have been performed much earlier, upon the first appearance of coma. In this case there had been no examination of the urine. He believes that in all difficult cases of eclampsia in pregnancy, without the least signs of labor activity, cesarean section should be performed upon the first symptoms of coma. [w.k.]

#### Labor in a Patient Having Double Uterus and Vagina.

—This case is reported by Williams,<sup>1</sup> who examined the patient, aged 26, 18 months after marriage. Leukorrhœa was then present. Two distinct vaginas, each having a hymen, and separated by a wall one-fourth inch thick were found. Two cervixes, into each of which a sound could be passed 2½ inches, were also present. There was no communication between the vaginas or the uterine cavities. Operation was advised and refused. Later the patient became pregnant and then consented to operation. The entire septum between the vaginas and cervixes was removed. Labor at the end of term was normal, the child weighing 7½ pounds. But one placenta was present. Examination two months afterward showed but one cervix and but one cavity to the uterus, the septum in the latter having been entirely obliterated during labor. [A.G.E.]

**Ovarian Embryomas or So-called Ovarian Dermoid Cysts.**—Jelke,<sup>2</sup> from a study of the literature and of three personal observations, concludes: 1. It has been shown in the specimens described that, though each has an anatomy peculiar to itself, still there is much in common among them, and also that they are similar to the cases recorded by Pfannenstiel, Kroemer, Wilms, and others. 2. Structures derived from the three embryonal primordial layers were found in each of them, with the exception of the first, and here the microscopic search for the endoderm was prevented by the great degeneration of the tissues, so that only the coarser structures could be made out. 3. The extent of the development along different lines varied greatly in each case, though all of them were turned to pathologic growth comparatively early when compared with the normal embryo. 4. The structure of the cyst wall was seen to be similar to other cysts derived from Graafian follicles. 5. The size of the cyst was independent of the size of the embryoma within certain limits, but the size of the cyst seemed to vary in direct proportion to the amount of waste matter excreted by the embryoma. 6. The remains of the ovary from which these specimens developed, as well as the organ on the opposite side, were found to be either cystic or to have an abnormally large number of follicles approaching maturity. 7. In none of the specimens were any fetal inclusions, fetal remains, or congenital malformations found, and the rest of the genitalia of the hosts were normal with the exception of the cystitis in Case I, and the tubal pregnancy in Case II. So that the congenital formation of these tumors appears to be extremely doubtful. [A.O.J.K.]

#### Ovariectomy Seven Years After Vaginal Hysterectomy.

—Bantock<sup>3</sup> in 1895 removed the uterus from a woman of 46, the whole cervix being converted into a mass of obstructed mucous follicles. Both ovaries appeared healthy and were left. Seven years later the patient was again operated upon for ovarian disease and a tumor weighing 5½ pounds and very adherent was removed with great difficulty. No trace of the other ovary could be found. This fact supports the theory that after the menopause the ovaries atrophy within three years unless attacked by disease. Bantock says the perfect health of the majority of women after the removal of both ovaries bears eloquent testimony to the fact that no injury has resulted, either mental or physical; and his observation during 25 years has shown the fallacy of the old idea that every woman must undergo certain symptoms at the climacteric; for the majority suffer no inconvenience whatever. [w.k.]

**Endothelioma of the Ovary.**—Lange<sup>4</sup> gives the history of an unmarried woman of 41 who, in 1899, underwent laparot-

omy for the removal of an ovarian cyst on the left side. The right ovary appeared normal and healthy, and was allowed to remain. The recovery was undisturbed. Five months after the operation the patient had not recovered her health, and was now suffering from abnormal conditions in the chest diagnosed as pleuritic effusion with ascites, which pointed to tuberculosis or metastasis. Nothing in the history of the case indicated the former. There were repeated chest and abdominal punctures to withdraw the accumulated fluids, but the patient failed rapidly, and in a few weeks died of apparent pulmonary embolism. Necropsy showed the right ovary enlarged twofold, and the visceral and parietal peritoneum, especially in the region of the right broad ligament, studded with numerous metastatic knots of a grayish color. These under the microscope were found to be endothelioma. The same was true of the right ovary, so that the correct diagnosis was ovarian endothelioma, with widespread metastases. Lange questions the wisdom of permitting, in the case of women above 40, even an apparently healthy ovary to remain when removing the other for any neoplasm. [w.k.]

**Uterine Fibroid.**—Paton<sup>1</sup> reports the history of a case of uterine fibroid giving rise to intestinal obstruction. When he first saw the patient she was suffering from advanced intestinal obstruction and was considerably collapsed. It was, however, decided to open the abdomen and a tumor was found attached to a considerable length of the intestine and mesentery. As its removal so as to clear the obstruction was not practicable it was not attempted and she died in a few hours. The subsequent necropsy showed that the tumor was a transplanted fibroid of the uterus, from which organ it had become entirely separated, but upon the posterior wall of which was a short stalk, and from this doubtless the tumor had been disconnected. Instances of such transplantation are very rare, though two have come under the writer's notice since the one reported. [w.k.]

**Menstruation in a Male.**—Léri<sup>2</sup> reports this unique case as one of pseudohermaphroditism. The subject was 75 years of age, was married, and gave the history, corroborated by a sister, of having menstruated regularly for 37 years, beginning at the age of 18. The breasts were those of a male, the external genitals being partly male and partly female in type. The voice was that of a eunuch. Autopsy showed the presence of undescended testicles. Neither uterus nor prostate was found. No explanation of the apparent menstruation was furnished by the autopsy. [A.G.E.]

**Extrauterine Pregnancy.**—Sittner<sup>3</sup> adds 16 to the previous 126 cases of extrauterine pregnancy which were ended by laparotomy, with the fetus living at the time of operation. These belong to a period since 1813. Of the 16 cases, 1 illustrated the rare form of pregnancy in the hernial sac in the inguinal region; in 7 the fetus had developed to an advanced stage in the original sac, 5 of these in the uninjured tube, 1 in the ovary and 1 in the ovarian tube; in 8 the fetus was outside the original sac, twice through rupture into the broad ligament and in the other cases into the abdominal cavity, where the fetus lay completely free in four instances; in 2 with placenta attached to an abdominal organ. One case was especially interesting, as the fetal sac was found between the liver and right kidney, to which it was firmly adherent. The placenta was about ⅔ attached to the peritoneal fold between the right under surface of the liver and the diaphragm, and ⅓ to the tissue of the under surface of the liver itself. The sac contained a living fetus. The maternal mortality in these cases was about 33%, a very high deathrate, probably largely due to the bad condition of the patient when brought to the hospital. Of the children, 7 had not reached an age to live after delivery. Of the others, 3 died after a few hours, 1 after three weeks of gastroenteritis, and 4 are still living. [w.k.]

**Hysterectomy.**—Morse<sup>1</sup> gives notes on 10 cases of hysterectomy for fibroid disease, and calls attention to cases 8 and 9 as showing that when a fibroid is surrounded by the uterine muscle and compressed by it, it is futile to wait and hope for the menopause at an age when loss of blood is not so well borne nor so rapidly recovered from as in earlier years. ## TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

## EDITORIAL COMMENT

**Substitutes for Potassium Iodid.**—There are a number of remedies of such well proved virtue that they are practically indispensable to the physician, but which, nevertheless, exercise very undesirable secondary effects that interfere seriously with their use in many cases. Such, for example, as potassium iodid, sodium salicylate, quinin, and tannic acid. The skill of the synthetic chemist is, we believe, much more beneficially exercised in the discovery of substitutes for these drugs that shall be free from their drawbacks, than in the multiplication of antipyretic and analgesic compounds of doubtful utility. These substitutes have increased so rapidly within the last few years that it is almost impossible for the busy physician to keep track of them. Many of them have had a brief day and passed to the limbo of dead medicines and canines; but others have proved to be of distinct value. A critical summary of these preparations would prove useful, and without binding ourselves to complete it, we propose to publish from time to time in the near future, editorial comment on the more important ones. This article will be devoted to substitutes for potassium and sodium iodid. The problem of finding some mode of exhibiting iodine in a therapeutically active form without the disturbance of the digestion which is often caused by the alkaline iodids, has engaged the attention of physician and chemist for a number of years. Some of the compounds therefore that we shall consider are, therefore, not new remedies in the strict chronologic meaning, yet they are employed with such comparative infrequency that their discussion in this connection is justifiable. The substitutes for the alkaline iodids of which we shall take note are iodoform, iodol, iodolene, iodalbacid, iodine-eigon, iodized starch, and iodipin.

**Iodized Starch.**—This remedy, although by no means a new discovery, having been employed to a certain extent for many years, is so generally unknown that it seems worth while to call attention to the properties that have been claimed for it. It has been known by various names, as iodamylum and amyli iodidum. The last name is unfortunate, because it would indicate that the substance is a chemic fluidity, which is probably not true. The term iodized starch is therefore much to be preferred, or if we wish to express it in Latin, amylium iodatum under which name it was at one time recognized by the U. S. P. A fairly stable compound at ordinary temperature, it is easily decomposed at a temperature of 100° F., especially in the presence of alkalis, liberating in its decomposition free iodine. It may be employed in the form of a powder containing 5 parts iodine to 95 parts of starch. According to Solomon<sup>1</sup> it has much less tendency to disturb the stomach than the ordinary preparations of iodine. Buchanan has given as much as 15.5 grams (½ ounce) at a dose, increasing gradually to 31 grams (1 ounce). Ordinarily it is employed in doses of from .2 to .6 grams (3 to 10 grains) administered either in capsule or pill. This dose, of course, represents a very small quantity of iodine, but it would seem that the iodine is liberated from the combination in a nascent form and exercises a comparatively much greater effect than the same quantity of the element represented in potassium iodid. It is also useful, according to Solomon, as an external application in certain conditions, such as sluggish ulcers, in which iodine has been found of service.

**Iodoform.**—This is one of the earliest substances recommended as a substitute for the alkaline iodids. Although it is capable of fulfilling all the internal indications of the iodids, it has not become very popular, and its use to-day is almost limited to tuberculous conditions. Glover, more than half a century ago, Shingleton Smith and the editor of this department, during the last two decades, and Jackson<sup>2</sup> very recently have reported a distinctly beneficial action in pulmonary tuberculosis; while Burney Yeo<sup>3</sup> has observed remarkable results in tuberculous peritonitis by the conjoint use of iodoform ointment and pills containing iodoform and creasote, the ointment being absorbed through the skin. It may be given in doses of from 2 to 5 grams (3 to 80 grains) daily. The secret of its tolerance is to begin with small doses and increase gradually. It is given in chronic cases for which chronic treatment is

necessary, hence there need be no undue haste in enlarging the dose. Balsam of Peru is an excellent excipient.

**Iodol**, was originally recommended as a substitute for iodoform externally and seems to be slightly more popular as an internal remedy than its predecessor. Assaky has found it effective in tertiary syphilis in doses of from .4 to 2 grams (6 to 30 grains) a day. Maldarescu employed in the treatment of angina pectoris, the following formula:

Iodol 30 grains (2 grams.)

Extract of Licorice, a sufficient quantity.

Make 20 pills. Two pills twice daily.

**Iodolene.**—A compound of iodol and albumen is an insoluble powder, originally intended for an antiseptic dusting powder. It is placed on the market in two strengths; that intended for internal use, which may be denominated iodolenum internum, contains from 9 to 10% iodol. Jordan has found that it possesses the antisiphilitic properties of the iodids and that although it is generally well borne, it occasionally causes gastric disturbances and iodism. It is asserted that it is eliminated more slowly than potassium iodid and that its action is therefore more lasting, which property according to Rievel makes it valuable in the treatment of actinomycosis. It must be given freely at least 3 drams (12 grams) should be administered in the 24 hours, in doses of about 30 grains (2 grams) each.

**Iodalbacid.**—This preparation is made by the action of alkalis upon synthetically iodized albumen. It contains 10% of iodine and it is stated that it has an effect analogous to thyroïdin. It has also been employed as a substitute for the iodids in syphilitic affections.<sup>1</sup>

**Iodipin** is by far the most important substitute for iodine. The manufacturers state that it is a chemical combination of iodine and oil of sesame. As it is put upon the market it contains 10% of iodine and possesses the oleaginous taste of sesame oil. According to Winternitz,<sup>2</sup> it appears after its internal administration in almost every tissue of the body. Being insoluble it has no effect upon the stomach, but is partially broken up by the intestinal juices and iodine liberated. According to Blank,<sup>3</sup> however, it is in greater part absorbed unchanged and after its absorption gradually decomposed, liberating its iodine very slowly. It therefore exercises a much more persistent and prolonged action than do the alkaline iodids. Gastric disturbance is rarely caused by iodipin and it has been asserted that the drug does not produce the symptoms of iodism. Hoenigschmiedt<sup>4</sup> gave a patient in the course of 10 weeks 590 cc. (20 ounces) of iodipin hypodermically and 11 cc. (¾ ounce) by the mouth, representing 74 cc. (2½ ounces) of iodine, or about 7.5 cc. (2 drams) of iodine per week. Another patient received hypodermically 15 cc. (½ ounce) of iodine daily, representing 1.5 cc. (24 minims) of iodine; in neither case was there any disturbance of digestion or any symptoms of iodism. Iodipin appears to be absorbed with great readiness, Frieser<sup>5</sup> having detected it in the urine and saliva within 15 minutes after its administration by the mouth. It is rarely found in the feces after its ingestion, showing that it is completely absorbed. It would seem that it is absorbed less rapidly after hypodermic administration than when given by the mouth, as Frieser states that it takes two or three days to make its appearance in the secretions after subcutaneous administration. Iodipin seems to be useful for every purpose for which potassium iodid has been employed. The literature of its therapeutics is too large to be reviewed in detail. The reporters agree that in the conditions in which iodine is ordinarily employed, such as syphilis, neuralgia, asthma, arteriosclerosis, and the like, the remedy is fully equal to the iodids. Some observers rate it as superior; thus Klar<sup>6</sup> reports a case of asthma in which potassium iodid, as well as arsenic and atropin, had failed, but which was promptly relieved by the use of iodipin. Kreiblich<sup>7</sup> reports a case of actinomycosis of the cheek cured by local injections of iodipin. The drug is best administered in the form of an emulsion. Either of the following formulas may be employed, the preference being perhaps given to the emulsion made with egg:

Iodipin . . . . .	.60 cc. (2 fl. oz.)
Powdered acacia . . . . .	.30 cc. (1 fl. oz.)
Peppermint water . . . . .	.90 cc. (3 fl. oz.)
Syrup . . . . .	.30 cc. (1 fl. oz.)

Make an emulsion.

Dose: One to two teaspoonfuls.

Make an electuary.

Powdered cacao . . . . .	} equal parts
Sugar . . . . .	
Iodin . . . . .	.48 cc. (13 fl. drams)
Yolk of one egg . . . . .	
Oil of cinnamon . . . . .	.1 drop

Dose: One to two teaspoonfuls a day.

When the patient objects seriously to the taste of the preparation it may be given hypodermically; about 10 cc. being injected subcutaneously rather than intramuscularly into the

<sup>1</sup> Merck's Archives, 1900, Vol. II, p. 484.<sup>2</sup> Merck's Archives, 1901, III, page 338.<sup>3</sup> Lancet, 1901, Vol. I.<sup>4</sup> Archlv. f. Derm. u. Syph. 43 u. 44 Bd.<sup>5</sup> Deutsche med. Wochenschr., Vol. xxIII, No. 23.<sup>6</sup> Die Med. Wochen., December, 1901.<sup>7</sup> Aertz. Zeit., 1901, No. 28.<sup>8</sup> Med. News, Vol. lxxvi, p. 784.<sup>9</sup> Deutsche med. Zeit., 1900, No. 97.<sup>10</sup> Wiener klin. Wochenschr., 1902, No. 4.

gluteal region or the back. The fluid should be warmed previously, as when cold it is a little too dense for ready injection. We cannot dismiss the subject of iodipin without calling attention to its use as a diagnostic agent in determining the motor power of the stomach. Its value for this purpose depends upon the fact that it is not absorbed in the stomach but is very rapidly broken up in the intestine; ordinarily the iodine reaction with starch may be demonstrated in the saliva in 10 to 45 minutes after the administration of a dose of iodipin. If a longer time than this is required there is serious interference with the motor power of the stomach.<sup>1</sup>

**Eigon.**—The eigon preparations are combinations of iodine (or bromine) with albumen or peptone. They have been used in surgery as substitutes for iodoform externally, and have been used in medicine internally as substitutes for iodids. The so-called sodic eigon or sodium iodalbuminate represents about 15% of iodine and has been recommended as a substitute for potassium iodid in syphilis and scrofula. Fischer and Beddies,<sup>2</sup> who have studied the effect of these preparations locally and internally, give them in doses of 3 grams (45 grains) daily, increasing gradually. Sodium-iodine-eigon is specially recommended in scrofula.

REVIEW OF LITERATURE

Preventive Treatment of Pericarditis. — Carrière<sup>3</sup>

believes that the heart should be watched in all infectious diseases which are liable to cause pericarditis. Daily auscultation is necessary in all cases of rheumatism and in all infectious diseases. Rheumatism should be treated energetically, sodium salicylate being the remedy of choice. For 3 or 4 days the patient should be given the following in 24 hours:

Sodium salicylate . . . . .	1 to 3 grams (15 to 45 grains)
Syrup of bitter orange-peel . . . . .	30 cc. (1 ounce)
Water . . . . .	90 cc. (3 ounces)

The quantity of sodium salicylate in this prescription should vary according to the age of the patient. After the fourth day this prescription should be continued in smaller dose. In the other infectious quin is usually employed, in children, as follows:

Quinin hydrochlorate . . . . .	0.06 to 0.6 gram (1 to 9 grains)
Glycyrrhizin . . . . .	3 grams (45 grains)
Syrup . . . . .	10 cc. (2½ drams)
Water . . . . .	50 cc. (1½ ounces)

To be taken in tablespoonful doses in 24 hours.

In adults, quin sulfate should be given in doses of .2 gram (3 grains) four times a day. [L.F.A.] [The importance of continuous rest for some time after convalescence and during the active period, the value of the cold precordial coil or ice-bag, and of blistering below the clavicle as prophylactics against cardiac and pericardiac complications in infectious arthritis, cannot too often be emphasized. s.s.c.]

Treatment of Erysipelas by the Red Light. — Krukenberg<sup>4</sup>

has employed this treatment in 18 cases of erysipelas. The rapid fall of the fever and the mild evolution of the disease after treatment is explained by the absence of chemical rays in the red light. In certain infectious diseases, the active chemical rays predispose to dermatoses, but their action is not well understood. Ichthyol, tincture of iodine, and plasters do good in erysipelas by protecting the skin from the light and particularly from the chemical rays. In negroes this protection is afforded by the pigment of the skin. Däubler and Plehn assert that negroes rarely suffer from erysipelatosus or phlegmonous affections. [L.F.A.]

The Diagnostic Value of the Blood Changes Produced by Syphilis and Mercury. — Justus<sup>5</sup>

reviews the literature on the subject of blood changes in syphilis, and finds most authors to be of the opinion that the untreated disease causes a diminution in the hemoglobin. The percentage begins to fall with the onset of secondary symptoms. The amount of decrease is in proportion to the severity of these symptoms, and a beginning rise in the hemoglobin is a sign of beginning involution of the exanthem. There is considerable disagreement, however, in regard to the behavior of the hemoglobin during a mercurial treatment of the disease. Justus reiterates the claims previously made by him that following the inunction or injection of a full therapeutic dose of mercury there occurs a quick and

decided fall of 10 to 20 points in the percentage of hemoglobin. This loss is recovered in one or more days. If injections are used, the drop may be repeated after each of several injections. Eventually, however, the hemoglobin rises again until it finally reaches a point above that at which it stood before treatment. No such drop in hemoglobin occurs when mercury is administered to healthy persons or to those suffering from other diseases than syphilis. These observations may have failed of confirmation by other writers for several reasons. It is of importance that the hemoglobin count be made sufficiently often, at least once daily. The characteristic fall takes place about 12 hours after inunction, or 8 to 9 hours after injection. The dose of mercury should be large, at least 3 grams of blue ointment, or its equivalent. Internal administration of mercury has no influence on the hemoglobin. The test is useful in tertiary, as well as secondary syphilis. It fails after the symptoms have begun to diminish in severity. [B.K.]

Ethyl Chlorid as a General Anesthetic in Obstetric Practice. — Lepage and Le Lorier<sup>1</sup>

employ ethyl chlorid as a general anesthetic during parturition when the pain is not sufficiently severe to warrant the use of ether or chloroform, but the patient desires to avoid suffering. Under these circumstances, ethyl chlorid presents many advantages: 1. It is easily administered; the doses being always the same. 2. Anesthesia is obtained in from 30 to 60 seconds, and lasts for about four minutes without renewal. 3. The return to consciousness occurs very rapidly without headache, and is accompanied only occasionally by slight vomiting. Inhalations of ethyl chlorid may be employed with advantage under the following conditions: 1. In the course of labor, when it is urgent to extract the fetus with forceps, when an internal version is practised, or when the anterior foot is pulled down in incomplete presentation of the buttocks. In the latter case, anesthesia by ethyl chlorid has the advantage of allowing the patient to awake rapidly and to complete the expulsion of the fetus by her own efforts. 2. During delivery ethyl chlorid may be used when the accoucheur is obliged to remove the placenta from the uterine cavity, or exceptionally to extract the membranes when the greater part of them remain in the uterus and it is necessary to remove them. 3. After delivery it may be used when the insertion of several sutures into the perineum is required. During pregnancy ethyl chlorid may be used as a means of diagnosing pelvic deformities. [L.F.A.]

Treatment of Malarial Hepatitis. — Lemanski<sup>2</sup>

recommends the following treatment of malarial hepatitis: The patient should not be allowed alcohol in any form; this is imperative, for the greater number of these patients are addicted to the use of alcohol. Quinin, arsenic and alkaline salts are the principal drugs used in this condition. They may be employed as follows:

Sodium cacodylate . . . . .	0.01 gram (¼ grain)
Quinin sulfate . . . . .	0.5 gram (7½ grains)
Sodium bicarbonate . . . . .	0.5 gram (7½ grains)

For one cachet. One three times a day.

Purgatives act well in some cases. Hydrotherapy is indicated in all cases, but its application must be carefully watched by the physician. For nervous, impressionable patients the hot spray douche may be used; its application must be short and progressively colder each day. If the liver is not too painful the local hepatic douche with a special apparatus is indicated; a cold jet may be directed against the legs, but never on the abdomen. Two douches a day are necessary. The hepatic douche must be cold and very short, or alternately hot and cold. It is very important that the percussion of this organ be not too violent. This local douche may be followed by a general douche. The administration of from 30 to 100 grams (1 to 3½ ounces) of cooked calf-liver is considered a useful adjuvant to this treatment. [L.F.A.]

FORMULAS, ORIGINAL AND SELECTED.

In Subacute, Atonic Gastric Catarrh.—

Compound tincture of iodine . . . . .	1 cc. (16 min.)
Compound tincture of cinchona . . . . .	60 cc. (2 fl. oz.)

Mix. Dose: One or two teaspoonfuls in water before each meal. [s.s.c.]

**In Diabetes Mellitus with Albuminuria.—**

Gold and sodium chlorid . . . . . .005 gram ( $\frac{1}{12}$  gr.)  
 Uranium nitrate . . . . . .008 gram ( $\frac{1}{8}$  gr.)  
 Codein . . . . . .008 gram ( $\frac{1}{8}$  gr.)  
 Mix. One pill four times daily. [s.s.c.]

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 7, 1903:

**SMALLPOX—UNITED STATES.**

**Changes in the Medical Corps of the U. S. Army for the week ended February 7, 1903:**

CHAMBERS, WILLIAM H., contract dental surgeon, is granted leave for eight days, from about February 1.  
 GEORGE, W. R. S., contract surgeon, is granted leave for two months, with permission to apply for an extension of one month.

BYARS, C. R., contract surgeon, is granted leave for one month.  
 OHLINGER, LORIN B., contract surgeon, is granted leave for one month, from about March 1.  
 LORD, LESTER W., contract surgeon, is granted leave for one month.  
 KENNEDY, JAS S., contract surgeon, now at Chambersburg, Pa., will proceed to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty.  
 SCHUMACHER, FREDERICK, hospital steward, is relieved from further duty at Fort Santlago, Manila, P. I., and will proceed to San Francisco, Cal., and will report to the commanding general, department of California.  
 BROWN, IRA C., contract surgeon, now at Buffalo, N. Y., will proceed to Fort Niobrara for duty.

**Changes in the Medical Corps of the U. S. Navy for the week ended February 7, 1903:**

CURL, H. C., passed assistant surgeon, discharged from treatment and ordered to duty at the Naval Hospital, Mare Island, Cal.—January 31.  
 PLUMMER, R. W., passed assistant surgeon, detached from the U. S. S. Prairie and ordered to the Navy Yard, New York—January 31.  
 FURLONG, F. M., passed assistant surgeon, detached from the Navy Yard, New York, and ordered to the U. S. S. Prairie—January 31.  
 CURTIS, L. W., and PITTS, M. B., passed assistant surgeons, commissioned surgeons from December 2, 1902—February 2.  
 SPEAR, H. R., and GROVE, W. B., passed assistant surgeons, commissioned passed assistant surgeons from November 7, 1902—February 2.  
 SCHWEHIN, L. E., NELSON, H. T., JR., and GRIEVE, C. C., appointed acting assistant surgeons from January 29, 1903—February 2.  
 PARWELL, W. G., medical director, retired, detached from the Marine Recruiting Station, Philadelphia, Pa., and ordered to the Navy Yard and Hospital, Portsmouth, N. H.—February 3.  
 COOKE, G. H., medical director, retired, ordered to the Naval Recruiting Station, Philadelphia, Pa.—February 3.  
 SPEAR, J. C., medical inspector, retired, ordered to the Marine Recruiting Station, Philadelphia, Pa.—February 3.  
 BIDDLE, CLEMENT, surgeon detached from the Naval Recruiting Station, Philadelphia, Pa., and to continue duty at Naval Hospital, Philadelphia—February 3.  
 MORRIS, L., passed assistant surgeon, detached from duty at the Naval Hospital, Philadelphia, Pa., and granted sick leave for three months—February 3.  
 THOMPSON, J. C., assistant surgeon, detached from duty with the Marine Detachment, Dry Tortugas, Fla., and to duty on the U. S. S. Columbia—February 3.  
 DEBRULER, J. P., assistant surgeon, ordered to the Naval Hospital, Norfolk, Va.—February 3.  
 BROWN, G. L., acting assistant surgeon, to duty at the Naval Proving Grounds, Indian Head, Md.—February 3.  
 JUDD, H. W., acting assistant surgeon, to the Naval Station, Key West, Fla., for duty at Dry Tortugas, Fla.—February 3.  
 ROSSITER, P. S., acting assistant surgeon, to the Naval Recruiting Station, Baltimore, Md.—February 3.  
 MURPHY, J. A., assistant surgeon, detached from the U. S. S. Don Juan de Austria, and to duty on the U. S. S. Monadnock—February 4.  
 SEAMAN, W., assistant surgeon, detached from the U. S. S. Monadnock, and to duty on the U. S. S. Don Juan de Austria—February 4.  
 HARMON, G. E. H., medical inspector, to duty at the Naval Station, Port Royal, S. C.—February 4.

**Changes in the Public Health and Marine-Hospital Service for the week ended February 5, 1903:**

GEDDINGS, H. D., assistant surgeon-general, detailed as recorder of board convened to meet at Washington, D. C., for the physical examination of an applicant for the position of second assistant engineer, R. C. S.—January 30, 1903.  
 CARTER, H. R., surgeon, to report at Washington, D. C., February 6, 1903, for duty as temporary member of Sanitary Board  
 BLUE, RUPERT, passed assistant surgeon, relieved from duty at Milwaukee, Wis., and directed to proceed to San Francisco, Cal., and report to Surgeon A. H. Glennan for duty—January 30, 1903.  
 VON EZDORF, R. H., assistant surgeon, granted eight days' extension of leave of absence—January 30, 1903.  
 KERR, J. W., assistant surgeon, to report at bureau for instructions—January 31, 1903.  
 WARREN, B. S., assistant surgeon, relieved from duty as recorder of board convened to meet at Washington, D. C., for the physical examination of an applicant for the position of second assistant engineer, R. C. S.—January 30, 1903.  
 ALEXANDER, E., acting assistant surgeon, granted leave of absence for twenty-seven days from February 1—January 29, 1903  
 HAMILTON, H. J., acting assistant surgeon, granted leave of absence, on account of sickness, for thirty days from December 27—February 3, 1903.  
 HARRIS, B. Y., acting assistant surgeon, granted leave of absence for ten days from February 21—February 3, 1903.  
 SAMS, F. F., acting assistant surgeon, granted leave of absence for fourteen days from February 4—February 3, 1903.  
 KOLB, W. W., pharmacist, granted leave of absence for twenty-eight days from February 12—January 30, 1903.

*Appointments.*

CARTER, HENRY R., appointed acting assistant surgeon for duty at Newport News, Va.—January 10, 1903.  
 GRAY, ROBERT H., appointed acting assistant surgeon for duty Shreveport, La.—January 26, 1903.

VOL. V, No. 8.

FEBRUARY 21, 1903.

\$5.00 YEARLY.

The end of the San Francisco disgrace of concealment of plague is announced in the fact of the declaration of Dr. Buckley of the Board of Health that during the last sixty days no case of bubonic plague has been discovered in the city. The federal quarantine officers also agree, and vessels leaving the port are now given clean bills of health. There are no admissions on the part of those who have denied the existence of plague that their denials were either errors or lies. Perhaps that is too much to expect of human nature, and the profession will be so glad that the past policy is ended that we can afford to let the contention die. The U. S. Marine-Hospital Service deserves the gratitude of the profession and the nation for its long efforts to bring about an end of the policy of concealment and to prevent the spread of the disease. In this aim it has, since the inauguration of the new State administration in California, had the help of the Mercantile Joint Committee and of the State and City Boards of Health. That the United States has been spared the horror of a widely disseminated epidemic of the disease is surely not due to those who have stifled every dictate of conscience, professional and social, in obedience to an execrable selfishness. The lesson, however, must not be lost, and concealment of infectious disease by physicians at the command of commercialism should be an infamy never again possible in this country.

**Blackmail and the Quack Business.**—Doubtless every one has wondered that so many of the advertisements of nostrum venders and quack doctors offer to give treatment and prescriptions free. As it costs money to advertise, there must be a profit obtainable in some roundabout way. An old plan was to put in the prescription some secret drug that could only be had of the advertiser. A New York lay journal astonishes its readers with a clear-cut charge that these "treatment free" advertisers for gullibles usually with sexual disease, have a thoroughly organized business of blackmailing by means of the information they get from the weaklings who fill out the "information blanks" with every sort of nauseous detail about their symptoms, sins, and diseases. These blanks signed by the dupes are used to extort "hush money" from the victims. By comparing the information blanks of different persons the materials of social scandals are put together

and blackmail is again secured. "One advertiser receives a 'blank' from a husband; another in a different city secures a 'blank' from a wife. Put together at the headquarters of the combination, there is a story which those concerned will pay liberally to keep out of the papers." The Postmaster-General should get after these wretches.

The practice of medicine by those only having the proper knowledge, such is the wise demand of a bill now before the Pennsylvania Legislature. According to its provisions every one who shall profess to diagnose and treat disease by any means whatsoever shall pass an examination by the State Board in the fundamental branches of medicine. Four years of study in a recognized college must have been spent prior to examination. The foolish claim that one is not practising medicine because he does not give drugs or practise surgery is thus done away with. The special methods as to therapeutics which an applicant purposes to use are thus not recognized by the law, and hence one may become an eddyite, an osteopath, an allopath, etc., at his pleasure, providing he is outfitted with the requisite knowledge of anatomy, physiology, pathology, chemistry, surgery, and obstetrics. There is no doubt that one who has intellect enough to study these branches for four years and to pass the State Board examinations in them will also have enough to disavow the follies of quackery and humbug. We hope the bill will soon become a law.

The atypical school child is the subject of a most excellent article by a New York teacher, Miss Alida S. Williams, principal of the Girls' Department of Public School No. 33, and which is published in the *New York Commercial Advertiser* of January 17, 1903. It is most encouraging to find teachers meeting the obligations of modern science, both pedagogic and medical, with such broadmindedness and clearness. The normal or typical children constitute, of course, the majority, and ever since the establishment of the modern school system the atypical, the defective, and backward exceptions, already sufficiently afflicted by their physical and mental handicap, have been immolated by the necessities of the system for the good of the more fortunate. Later society must atone for the school sin, as the defective

becomes the pauper, the degenerate, or the criminal, who does not neglect to exact pay for his indiscriminating and neglectful upbringing. There is a just and growing recognition that shifting the burden of responsibility for the abnormal child upon the divinity called Heredity is neither scientific nor curative. The influence of the environment is greater than heredity, and saves valuable lives when fatalistic philosophies only wreck them. As high as 20% of all school children have been pronounced "subnormal in some point" by one authority. In Germany official investigation showed that 8% of the children of the school registration were "defective." In California of 10,000 school children, 10% were "mentally dull" and 3% "feeble-minded." On the whole, it may be said that at least 10% of all school children are "subnormal," and the question is emphatic—What is to be done for and with them by the overworked teacher in the overcrowded school? First, says Miss Williams, "all successful training of atypical children must be physiological." The training of the sensory and motor systems is fundamental. The school inspections by medical men at once determine which children are really unfitted for the work of the graded class. These should form a somewhat separate class (and yet not "herded") in each of the larger schools. These pupils when exhibiting malnutrition, traumatic injuries, and organic diseases, must be cured if possible of their diseases, to enable them to be properly educated. The specialization of these children must be such that no stigma, no reproach of "defectiveness," etc., shall be applied to them. The "neurotics" also form a part of the ungraded or special class, and all classes should be small, to allow of perfect individualization by the teacher. And this teacher must be one specially fitted for and loving her peculiar work.

**Conditions of Practice in Ancient Rome.**—There are many pessimists who affect to mourn for "the happy days of old," supposing that we have degenerated and the discomforts and diseases of modern life have increased rather than diminished. In his fine article on the "Medicine and Doctors of Juvenal," in the *Medical Library and Historical Journal* for January, 1903, Dr. Eugene F. Cordell gives a picture of the circumstances of the medical practitioner's life in Rome which suggests interesting comparisons with those of a modern city.

Owing to the great noise in the streets, none but the rich could sleep, and many an invalid died from want of rest. For a stream of carriages was continually passing in the narrow and crooked thoroughfares, and the drivers were perpetually engaged in noisy disputes and foul abuse of one another. If you were in haste, your passage was obstructed by the crowd. A rich man's litter, borne aloft upon stout shoulders, jostled you aside; those behind pressed upon your back; one man would dig into you with his elbow, another with a hard pole; your shoulder would be struck by a joist, your head by a beam, and a cask thrust against your shins. Your legs were bespattered with mud, on all sides you were trodden on and the nail of a soldier's boot would stick in your toe. The cooks scattered the burning coals as they hurried by with their patrons' meals, and your clothing was torn into shreds. One wagon loaded with a fir-tree, another with a huge pine, shook the streets as they advanced, the ends waving to and fro, threatening the people. Another wagon was loaded with stones from the quarries of the Apennines, and woe betide if the axle broke and the mass was

precipitated on the people. Who could find their scattered limbs or gather up the carcasses ground to powder? Then there were the dangers of the night when broken crockery, thrown out of the lofty windows, made dents in the pavement and threatened to break one's skull. Indeed, there were as many fates awaiting you as there were open windows where you passed. You might thank your lucky stars if they threw only the contents of the basins and pots upon you. Rash would he have been thought who went to supper without having made his will. Or your life was put in jeopardy by some drunken and illtempered fellow, ready to pick a quarrel with the first person he met. He took care to avoid the scarlet cloak and the long train of attendants, the many lights and the brazen lamp, but you whom the moon alone attended he despised. Or you met a worse fate if you fell into the hands of the numerous robbers, driven by the soldiers out of their lairs in the neighboring Pontine marshes and forced to seek refuge within the city's limits.

There are two differences that may be noted in the modern American city: The slums of today are scarcely preferable to the best streets of ancient Rome, but the slums of the old city were doubtless unspeakably worse. The best parts of the modern city are as much better than those of old as they are better than the most wretched. Then, second, betterment is the law of these times in all parts, whereas there was no progress possible for old cities until modern civilization with its social and medical ideals began to reorganize their diseases and evils.

**Large or Small Hospitals?**—Should the profession and lay benefactors encourage large hospitals and dispensaries exclusively, and thus extinguish the small ones, or should the existence of the small ones be stimulated and supported? The question is not easily answered if one ponders well the tendencies of the times and the ever-present evils of hospitalism in both large and small institutions. The difficulty really lies in the worthiness of two views—the scientific and educational, and the charitable or social. The large hospitals and dispensaries are necessary for medical education and must be kept up, because the cause of education and the advancement of science is primary and fundamental. The small institution is undoubtedly preferable for individualizing patients, for keeping a deadly mechanical routine from killing the personal relations of doctor, nurse, and patient, and for preserving the self-respect and gratitude of patients. In the large institution there may grow up a tyranny of subordinates and of patients which is as unprofessional as the quasiprivate ownership of which the small one is in constant danger. The establishment of a small poverty-stricken hospital by the egotistical endower, for the purpose of compelling the worship of his long name, portrait, and ghost, is pretty certain to result in a waste of money, an exhibition of silliness and a doing of evil. Beneficence and conceit do not mix well. Is it impossible to keep the large institution from being a soulless machine devoted to the exploitation of "clinical material?" Is it not equally possible to preserve the small one from the abuses of over-individualism? May the medical politician and the selfish schemer not be kept out of both?

**Child Labor and Disease.**—Continuous and increased zeal is being shown throughout the country in the crusade against child labor. One hesitates to say

anything that may weaken or prevent the good that may arise from the movement, and yet its advocates must remember that no purely anti movement is likely to be of service to humanity in the long run. All real reforms are founded upon desire for positive good, not only to do away with an abuse. There are worse evils than child labor, one of which certainly is vicious child idleness. In place of the labor the child must be given innocent play and helpful education. The reform of our sports is as necessary as the reform of disease-engendering labor. If one will watch several hundred street urchins playing football and exhibiting football morality he will, if not altogether hopeless, admit that they might fully as well be working in factories. If the many thousand messenger boys are left in idleness, uneducated and unguided, to the corruption of their surroundings, the work they do in running errands does not certainly make them worse. However, it is beyond all discussion that the law should stop the engendering of tuberculosis and other diseases, the perpetuation of ignorance, and the stunting of normal growth of body and mind that are the inevitable concomitants of child labor. It is said that there are some sixty special forms of industry coming under the head of "dangerous," and regulated by laws in England and in other European countries. In progressive America there is but one of these, that in reference to the use of emery wheels, with which the law concerns itself, and only seven States think this worthy of consideration. An uncompromising minimum should be demanded—no child labor before 14, and compulsory school attendance up to that age.

**The treatment of astigmatism by wet packs** was thoroughly tried by Darwin during his life of suffering, but his "beloved Gully" (*absit omen!*) was never able to relieve his patient, except temporarily, and then only by interdicting eye work. Later a physician famous in his day, Professor Davis, was accustomed to tell his internes at the hospital to use wet packs on all patients who complained of functional diseases, such as dyspepsia, neurasthenia, headache, etc. One hardly understands how corneal curves can be altered by the packs, yet even in our time there seems to be a slight tendency visible of a return to the therapeutics of Drs. Gully and Davis; hydrophathy is once more lifting up its eyes and even its shivering head among civilized people. It is not much talked about in books and lectures; the sacrifices, as usual, to the old disavowed idols are secretly carried out. It is true that this plan saves much trouble. There is no bother as to the true cause of functional nervous and digestional diseases, and the trend of popular opinion is flattered that all diseases are organic or contagious on the one hand, or imaginary upon the other. It also has another profound reason for being—it gives good ground for scorn of and indifference to all "riders of hobbies." Moreover, wet packs occupy the time and attention, both of the patient and of the interne, until, perhaps, something else may happen. The something else, however, that really happens may be the unexpected diagnosis elsewhere and later of astigmatism and the relief of the eyestrain that caused all the functional trouble of the perplexed patient.

**Adultery and Adulteration.**—It is not generally remembered that these two words are etymologically the same thing. Adultery is adulteration, and historically, the special reason for the heinousness of the sexual crime consisted, it must be confessed, not in the sin of itself, but in the evil consequences. These in adultery are greater than in other forms of in chastity, because in the former "the introduction of a spurious offspring into a family" is "a debasing by admixture of something else." The wrong to the husband who may thus be compelled by the wife's fraud to support the child of another is the cause of the legal and social opinion of the greater sin of this act than when committed under other conditions. It is curious to note that the word adultery is a latinized form which came into use with the beginnings of modern civilization in the fifteenth and sixteenth centuries. The older forms *avouterie*, *avoutrie*, *advoutrie*, etc., passed through the forms *adoultrie*, *adoultry*, *adultry*, to *adultery*. "Advowtry" was used by Scotch and Northern writers as late as 1688. Probably the deception and breaking of her word by the false wife added to the seriousness of the offense and made it much more hated than that of those expressed by the synonyms fornication, lechery, etc. It is also noteworthy that this feeling appears in the fact that the law, at least of some States, recognizes no such a crime as prostitution—a strangely anomalous fact, when the law is used to punish it.

**Hereditary pauperism** is a problem that we have mistakenly supposed concerned only the older nations and cities of Europe, but the evil is growing in our own country. So far back as 1883 the associated charities of Boston published a statement giving the data as to "ninety-one families which form thirty-one groups of cases related to each other by blood or marriage, all paupers in the technical sense, all receiving help from the city authorities. There are many more such groups in the registration files." It is becoming evident to all who have seriously interested themselves in social betterment that as a rule indiscriminate charity serves only to multiply the numbers of those who will take the help, rather than strive to become self-supporting. Both heredity and education unite to make the children of these lazy, shiftless, vicious, or extravagant classes grow up in the same habits and to perpetuate their kind until they form a distinct body encouraged by foolish almsgiving or selfish charity, and becoming genuine and persistent parasites upon the self-reliant and productive classes. The only way to avoid this is to call in the aid of the Society for Organizing Charity. This society makes a business of kind, careful and just investigation, so that the worthy shall be helped and the unworthy shall not cheat both the benevolent and the genuine unfortunate. Pauperism and disease, as we all know, are closely related.

**The Cure Must Not Increase the Disease.**—It would seem that there should be no need for discussion of this most self-evident rule of therapeutics, and yet there is more than enough evidence that in certain social diseases (causing genuine pathologic results in patients)

much of the attempted curing in reality serves to multiply the evil. Instances that might be cited are the increase of pauperism by almsgiving and out-door relief, compulsory legislation based on the idea that prostitution is a crime, some aspects of the drink problem, etc. Take as illustration the second. All careful investigators agree that the amount of syphilis and gonorrhoea in the community is greatly increased by punitive legislation as regards open prostitution. This is because such laws increase clandestine prostitution. The proper cure and one that does not multiply the disease, both social and infectious, is to establish hospitals, reformatories, etc., where every patient suffering from venereal disease may have immediate, scientific, and humane treatment in secrecy and in confidence. The extent of quack treatment, expensive and as unscientific as it is fraudulent, can be only partially estimated by the columns and pages of disgusting advertisements that fill the cheap newspapers of the city and the loathsome ones of the country.

#### The Training in Speech of Deaf Children.—

"The fact that all deaf children after leaving school must live their lives and earn their living among hearing people, and that heretofore so little has been done toward training them until they were of school age, has induced us to try teaching them to talk as nearly as possible at the natural age and then sending them to be educated with hearing people, among whom they must live their later lives." These are the words of Miss Garrett, the founder and principal of the (Philadelphia) home for the training in speech of deaf children before they are of school age. The aim of this beautiful charity is to approach as near as possible the natural home treatment with these unfortunates. It is remarkable how much can be accomplished by giving the same amount of speech and language through the eye as hearing children receive in their homes through the ear. To do this specially trained teachers are necessary if the child's education of this kind has been neglected. Parents should thus constantly speak to the deaf child from the earliest age when deafness has been discovered. Not to do this is to fail in justice to the child, and by doing so there is no limit of what the child is capable.

How little the professional politician cares for the public good is illustrated every day by our legislators. For fifteen years workers have labored to get bills through Congress to prevent adulteration of drugs, and during this time any legislation for politicians' purposes could claim attention and the desired bills secure passage. Now the "Statehood Bill" will again block the way of the drug-adulteration measure. And the farce will go on, no one knows how long. There is time to pass thousands of private pension bills, but none to prevent disease and improve the sanitary conditions of the whole people. The pure food and drug bill has been passed by the House, but until the bosses have their way as to selfish schemes it cannot get through the Senate. And until it does the nostrum and patent-medicine syndicates will be allowed to breed alcoholism and cocaineism and draw their millions from a patient and submissive democracy.

**Newspaper Reporting and Dosage.**—From *The Presbyterian* of January 28 we quote as follows:

Dr. Barrows injected into a large vein of the right arm "500 cubic centimeters of formalin, which is 40% of ordinary commercial formaldehyd gas in water." The patient immediately revived, her temperature dropped, and she showed marked signs of improvement. A test of the blood the next day revealed a diminished number of bacteria. A second injection of 750 cubic centimeters of formalin in the left arm reduced the temperature to normal, where it has remained for two weeks.

With recovery after such doses it is certain that all the laws of toxicology must be revised! It is hardly likely that this dose will be repeated by any physician on the authority of the foregoing report, but the value of the newspaper publication of medical facts is illustrated by the statement as to the percentage, etc., mentioned and the omission of the fact that the strength of the solution used was 1 to 5,000. Even in the medical reports there has been an oversufficient haste to argue a whole summer from a single swallow, and warnings are justified that conservatism as to formalin injections is highly advisable.

## EDITORIAL ECHOES

Two professional casters-out of demons have engaged in an illuminating argument at Philadelphia. One is a native of the place, while the other is a "reformed physician from Chicago." It is a pity they do not agree, because to the unlearned mind their theories and methods seem to be about the same. The "divine healer" from the West has received a good deal of notoriety by summoning the lame, the halt, and the blind to his platform, and then, after formally exorcising the demons which caused these infirmities, pronouncing the patients cured, and hustling them out of sight so quickly that no one could examine just what had been accomplished. According to the claim of his followers, he cast out about 1,000 demons during business hours of one day. This was all very well, but the local "divine healer," who presumably felt the competition, sent out an open letter. "Why don't you heal yourself? Take off your own spectacles, if you can cure other people's eyes." The "reformed physician's" reply is adequate, though it smacks slightly of sophistry. "I am an old man," he said, "and the balls of my eyes have grown flat. But younger persons, under the age of 50, who wear spectacles, are possessed of demons, and if they had proper faith, the demons would jump out of them." This means, apparently, that if one's eyeball gets flattened at the age of 45, it is the work of a demon, but after five years of occupancy the demon can vacate the premises and the eye still remains flat. But if this is true of eyesight, it is true of everything else. Consider the little demon which causes indigestion. Granted that the good and wise man from Chicago can cast him out, does there come a time when the "host," as biologists say, is equally uncomfortable with or without the demon? There is no escape from the dilemma. Either demons cause measles or they do not. If they do, though the patient be 97 years old, the measles go away when the demons do. If not, we must go on believing that the germs are the really important performers, and the demons only incidental.—[*New York Evening Post.*]

**Mortality from Pneumonia in Philadelphia.**—There were 114 deaths caused by pneumonia in Philadelphia for the week ended February 14, making nearly one-fifth of the total number of deaths. For the same period there were 62 deaths from pulmonary tuberculosis, and of all the other diseases recognized officially as contagious but 40.

## AMERICAN NEWS AND NOTES.

## GENERAL.

**Smallpox** as officially reported in the United States from December 27 to February 13 amounts to 7,714 cases with 210 deaths. For the corresponding period of last year there were 15,617 cases with 355 deaths.

**Miscellaneous.**—PENNSYLVANIA STATE VETERINARY DEPARTMENT: A strong movement is on foot to have Dr. Leonard Pearson reappointed State Veterinarian. It is claimed that the department has made more progress during Dr. Pearson's short incumbency than in all its previous history. The high opinion in which Dr. Pearson is held was recently shown when he was chosen by the Federal Government to diagnose the disease of cattle in the New England States which proved to be foot and mouth disease and to organize the work of repression.—AUGUSTA, GA.: Dr. Thomas D. Coleman has been appointed president of the Board of Health of this city. Dr. Coleman has held several different professorships in the Augusta Medical College and now holds the chair of medicine.

## EASTERN STATES.

**Free Vaccination.**—The great prevalence of smallpox in the coke region has induced the C. Frick Coke Company to issue an order stating that they will vaccinate without charge all their employes and their families. As this company has about 50,000 men on its pay-roll, it is estimated that this order will reach about 300,000 people. There has been expended \$10,000 for vaccination virus, and 50 physicians have been engaged to do the work.

**Boston Hospital for Babies.**—A hospital exclusively for babies is to be erected in Boston. There will be 50 beds, plenty of air and sunshine, a baby incubator and all the conveniences of a modern hospital. This building will be one of Harvard's already large collection and will cost \$136,000, of which \$76,000 has already been given. The building is to be erected in memory of Thomas Morgan Rotch, of Boston, a member of the class of 1901, and is given by his classmates. The age limit of babies shall not exceed two years.

**Families of the College Bred.**—President Elliott, of Harvard University, has obtained from the secretaries of the various classes that have graduated from Harvard data that led to the question whether the college graduates have families large enough to reproduce themselves in number. The figures are based upon the vital statistics of the Harvard College classes of 1872 to 1877 inclusive, which comprise the graduates from 25 to 35 years after graduation. It is not likely that these men will have many more children. On the assumption that the surviving descendants are one-half males, these classes have fallen 28% short of reproducing themselves. Of those graduated during this period 28% are unmarried, and those who are married have on an average only two children living.

## NEW YORK.

**Typhoid Epidemic Abating at Ithaca.**—President Schurmann, of Cornell, states that among the students there are 62 cases of typhoid fever, of which only 7 are considered serious, while between 150 and 200 students have been sent to their homes owing to the fact that they showed typhoid symptoms. The last few days has shown a marked decrease in the number of cases.

**Rockefeller Laboratory.**—Announcement has been made that the site for the laboratory planned by John D. Rockefeller, whose experiments in the research of remedies for disease will be conducted by the scientific staff which he has engaged, has been selected. The laboratory will occupy three blocks of land on East river, New York. The site cost \$700,000. It is reported that it is to be placed under the direction of Prof. Simon Flexner.

**Summer Course at Columbia University.**—It is announced that the College of Physicians and Surgeons of New York City will establish summer courses in the department of medicine at the Columbia University. The courses, which will include the work in the various departments and which will cover a period of from three to five weeks, will be of a practical nature and especially adapted to the needs of the senior student and the practitioner.

**Nurses for Public Schools of New York.**—It is announced that the Health Department of New York has assigned nurses to 39 public schools in Manhattan. Necessary supplies are to be furnished to the schools, and principals are invited to give the nurses as much assistance as possible. The nurses are to examine the children as to cleanliness, and to instruct the mothers at their homes how to treat all cases of sickness. The school authorities are pleased with the assignments, and Dr. Maxwell believes that much good will result. The schools selected are in the congested districts of the East and West sides of Manhattan.

**Formalin in Septicemia.**—At a meeting of the New York Pathological Society many physicians expressed themselves as speculative of the results of the benefit to be derived from the injection of formalin in cases of septicemia. It appears from the discussion that in a number of cases in which formalin was injected into the veins of rabbits there followed cramps, convulsions, anemia; hence the physicians regard the procedure as dangerous, and if used at all should be given with greatest caution.

**"Blochisches Centralblatt."**—This journal is published in Berlin under the direction of Ehrlich, Fisher, Kossel, Liebreich, Muller, Proskauer, Salkowski, and Zuntz. The objects of the publication will be:

- A—To report such experiments and observations of physical and employed chemistry which are of importance to the physician.
- B—Reports on the physiology of plants.
- C—Physiologic chemistry in the narrower sense (constituents of the body and their derivatives).
- D—Chemistry of the tissues and organs under normal and pathologic conditions.
- E—Chemistry of digestion, secretions and excretions, metabolism and blood.
- F—Ferments and fermentations, toxins of a nonbacterial nature.
- G—Chemistry of the pathogenic microorganisms (toxins, anti-toxins), phenomena of immunity.
- H—Toxicology and pharmacology.
- I—Hygienic chemistry, disinfection, examination of water.

As this is the only international organ devoted to these scientific fields, American observers and investigators will find it to their interests to prepare abstracts of their papers which have appeared since January 1, and will appear hereafter, and send them to Heinrich Stern [Editor for United States and Canada], 56 East Seventy-sixth street, New York City.

**New York State Hospital for Crippled and Deformed Children.**—The annual report of the surgeon-in-chief and the superintendent of this institution for the year ended September 30, 1902, has been issued. When the previous annual report was made there were 19 patients under treatment in the hospital. Since then 16 new patients have been received, 10 have been discharged, and 25 were under treatment at the conclusion of the report. The superintendent states that the hospital is crowded to its utmost capacity, and applications are constantly being received for further admissions, but on account of the overcrowded condition and restrictions as to age and deformity, these patients cannot be admitted into the institution. Of those now under treatment, 15 are suffering with hip disease, 1 with congenital dislocation of the hip, 1 with Pott's disease of the spine, 2 with clubfoot, 3 with deformity from infantile paralysis, 1 with lateral curvature, and 2 with white swelling of the knee. Reference is made to the great interest which the visit of Dr. Lorenz to this country caused, and the increased demand made for admission into the hospital. The hospital is established for "the care and treatment of any indigent children who may have resided in the State of New York for a period of not less than one year, who are crippled or deformed or suffering with a disease from which they are likely to become crippled or deformed."

## PHILADELPHIA, PENNSYLVANIA, ETC.

**New Jersey State Village for Epileptics.**—The annual report of the Superintendent of the New Jersey State Village for Epileptics states there are in the village 30 patients—17 males and 13 females. The report contains a detailed account of the work accomplished, hours of labor, as well as the necessities of the village. Attention is called to the fact that the last Legislature did not appropriate sufficient funds for the extension and maintenance of the institution, and an appeal has been made for assistance in these particulars. The superintendent estimates that there is one epileptic for every 500 of population. From this he concludes that there are probably about 2,500 epileptics in the State.

**New Jersey Sanatorium for Tuberculous Diseases.**—The annual report of the Board of Managers of this institution, which has just been issued, contains much of interest regarding the prevalence of pulmonary tuberculosis in New Jersey. In order to ascertain, at least approximately, the number of persons in indigent circumstances suffering from the disease circular letters were sent to all the legalized practitioners throughout the State, numbering more than 2,000, asking for their cooperation in securing this information. From the answers received (615) it appears that the medical practitioners addressed had under their care no less than 2,148 cases of this disease and that of this number 450 persons were in indigent circumstances. From these statistics it is calculated that the total number of cases in the State is at least 5,000 and that the number of indigent patients is at least 1,000. Assuming that one-half of these cannot be benefited by sanatorium treatment there remain at least 500 to be provided for, and after allowing for those who will not apply for treatment, it was decided to recommend the erection of a sanatorium with a capacity of 250 patients. However, the cost of building such a hospital and furnishing it with all the modern appliances needful in the treatment of these patients will be at least \$300,000. As the sum provided for this work was only \$50,000 it was decided for the present only to select and purchase the site for the hospital, therefore a tract of land con-

taining about 550 acres was purchased near Glen Gardner. The land adjoins the Central Railway and the proposed site of the buildings is less than three-fourths of a mile from the station. It is easily accessible and at the same time secluded. The air is very pure, the soil is dry and porous and there is plenty of good water on the place, and altogether it is considered an ideal place for a sanatorium.

**Bill Regulating Proprietary or Patent Medicines.**—A bill has been introduced into the Pennsylvania Legislature which provides that any and all proprietary or patent medicines prepared, sold, or offered for sale in Pennsylvania shall contain upon the label a true and correct copy of the formula, ingredients or constituents of the same, together with a true and correct printed statement in English of the several and respective quantities or proportions thereof. No person shall be employed or engaged in the manufacture and the mixture, compounding or preparation of any proprietary or patent medicine who is not a regular graduate in pharmacy and so registered under the laws of this State. Persons violating this act are liable to a fine of \$1,000 and imprisonment of one year, or both, one-half the fine to go to the person furnishing the information.

**Sanatorium Treatment for Inebriety.**—A bill has been introduced into the Pennsylvania Legislature which provides for the commitment of persons addicted to the use of alcoholic or other intoxicating drinks to a hospital or asylum for restriction, care, and treatment. According to its provisions any two relatives of the alleged drunkard may apply by petition to the Quarter Sessions Court or magistrate, setting forth the facts upon oath, with an affidavit of at least two physicians based upon examination accompanying the petition, stating that in their opinion treatment in a hospital will be of benefit to him. If after a hearing the court is satisfied that the petition should be granted the person shall be committed to a hospital for treatment until the judge or magistrate shall be satisfied that further restriction is of no longer benefit, with the further provision that no commitment shall be for a longer period than one year and all commitments shall be reviewable under a writ of habeas corpus.

**The Twelfth Annual Report of the State Board of Medical Examiners of New Jersey** gives considerable space to the discussion of reciprocity in the matter of licentiates from other States. Medical reciprocity between New Jersey and other States whereby the examining board of one State endorses other licentiates in lieu of their own examination has been tried on the one hand and the individual merit of the applicant or endorsement has been tried on the other, and the latter has been found by far the most satisfactory to the present board of managers, and the mutual reciprocity system has been entirely abandoned. The report states that after wide experience and much consideration the board has adopted as a basis of endorsement the personal fitness and professional qualifications of the candidate, plus a State certificate of license, issued after examination in substantially the same medical branches and under essentially the same conditions as the law of the State and the regulations of its board require. Equally as high qualifications and as full compliance of the law are required of candidates for endorsement as of candidates for examination. This system could not prevail under the mutual reciprocity system, hence the abandonment of the latter. The five conditions of endorsement relating to the moral character of the applicant, the academic education, medical training, nature and extent of the State examination, and average attained, are fully set forth. According to the present report licentiates were endorsed who represented 26 colleges and eight State examining boards.

#### SOUTHERN STATES.

**Statistics Relative to Typhoid Fever in the District of Columbia.**—Abstracts from the Health Office records in Washington for the six months ended December 31, 1902, have been made public. During this period there were reported 1,290 cases of typhoid fever. Of these 156 terminated in death. In 25 cases no personal history of the patient was obtainable. It is believed that 154 cases were contracted outside of the District of Columbia, 93 by direct exposure to other cases, and 21 through infected milk supplies. The best endeavor of the department failed to disclose in any considerable number of the remaining 997 cases a common exposure to any ordinary source of typhoid fever other than the drinking water. Potomac river water is said to have been used exclusively by 739 of the patients included in this last class and to have been used in conjunction with other waters in 103 additional cases, making a total of 842 cases in which Potomac water was used. Well water is said to have been used exclusively by 99, spring water by 23, well and spring water by 21 and melted ice by 7.

#### WESTERN STATES.

Another edition of the "Vaccination Creed" amounting to 50,000 copies has been issued by the Chicago Health Department. Since this creed and explanatory circular were first published, one year ago, more than 1,000,000 copies have been printed and distributed by the department, by other health authorities, by railway managers, and by other large employers.

**War on Bubonic Plague.**—In view of the action of the conference of the State Boards of Health held recently in Washington, which declared that bubonic plague existed in San Francisco, the commercial organizations of San Francisco held a meeting recently and adopted resolutions urging the Governor and the Mayor and supervisors of San Francisco to take such steps as shall secure a prompt cooperation of the various boards, to the end that all danger from bubonic plague may be eradicated, that all fears of infection may be removed, that the confidence of the Boards of Health of other States and Territories may be restored, and that no injury, however remote, may result to the foreign and interstate commerce.

**Mortality of Michigan for the Year 1902.**—The total number of deaths registered during the year 1902 was 30,962, corresponding to a deathrate of 12.6 per 1,000 estimated population. For the year 1901 the number of deaths registered was 33,848, and the deathrate was 14.0. There were 2,886 fewer deaths registered for 1902 than for the preceding year. At certain important ages, deaths were returned as follows: Infants under 1 year of age, 5,754, or 18.6%; children aged 1 to 4 years, both inclusive, 2,214, or 7.2%; and elderly persons over 65 years, 9,081, or 29.3%. The diseases causing the greatest number of deaths were pneumonia, 2,907; pulmonary tuberculosis, 2,030; cancer, 1,441; diarrheal diseases in those under 2 years, 1,350. There were 1,951 deaths due to accidents and violence.

**To Combat Whoopingcough.**—The Bulletin of the Health Department of Chicago for the week ended February 7 contains the following:

The frightful mortality from whoopingcough this winter induces the department to call public attention to the claim of Dr. Cenex, of Bohemia, that the vapor of formalin is a specific and preventive of this disease. After citing a number of cases in which the cough was cut short within 24 hours, he concludes that

1. By the proper inhalation of the vapors of formalin it is possible to destroy the germs of whoopingcough—those existing on the mucous membrane of the respiratory organs and also those in the surroundings of the patients. By this means the disease is cut short and further infection inhibited.

2. In accordance with these experiences it seems advisable that schools, hospitals, churches and other localities should from time to time be thoroughly disinfected.

It is hardly necessary to add that the treatment should be directed or administered only by a physician.

**Chicago's Health.**—An eminent specialist in diseases of the throat, nose, and chest has addressed the laity of Chicago through the public press on the "Prevention and Cure of Pneumonia." In the course of his address he adduces the striking fact that the influence of dissipation on pneumonia is shown by a mortality of 79% in those given to the excessive use of alcohol. A peculiar feature of the smallpox situation in Chicago is the disproportionate number of colored persons afflicted with the disease. It is stated that according to the Census of 1900 the negro population of Chicago formed 1.6% of the total, which would give them about 30,000 out of a total of 1,885,000 at the present time. In this proportion if the whites neglected vaccination to the same extent as does the negro there would now be nearly 1,200 white patients with smallpox in the hospitals to balance the 19 colored patients, whereas there are but 14 whites. The Bulletin of the Health Department appeals to the negro leaders of intelligence and influence to do something to secure the vaccination of a class whose members come into such close personal relations with all others in the community.

#### CANADA.

**Graduates of Medicine Must Pass More Rigid Examinations.**—It is announced that a bill has been introduced in the Michigan Legislature which gives the State Board of Registration greater authority in passing upon the qualifications of physicians who seek to practise in that State. It is asserted that owing to the high standard of examination before the Ontario Medical Council, men who could not stand the test in Ontario, or who did not want to take the long course demanded in some institutions across the border have been flocking into Michigan in large numbers. In order to stop this practice the board is empowered to compel all Ontario graduates to spend at least one year at a recognized medical school in Michigan before being allowed to write on the State examination.

**Medical Missionary Work in Labrador.**—Dr. Wilfred Grenfell, the medical superintendent of the Royal National Commission to Deep Sea Fishermen, in a lecture which he recently delivered in Toronto, stated that the mission now represents about 30,000 people. The work is purely medical in character and the constant object is to reach isolated cases of sickness among fishermen in Labrador and Newfoundland. Dr. Grenfell's field of work covers about 1,500 miles of the coast, and he is assisted by two physicians and two trained nurses. There are three hospitals in connection with the mission, and two hospital ships. The hospitals contain 24 endowed cots. The growth of the work is seen from the fact that in 1892 there were about 900 patients treated, while last year there were 2,774. The expense for last year amounted to \$20,000, and of this sum \$2,000 was contributed by Canadians.

## FOREIGN NEWS AND NOTES

## GENERAL.

An epidemic of "sleeping-sickness" is reported to be spreading rapidly in British East Africa. Great fears are entertained that the disease may reach the seacoast, in which event it might be conveyed to other countries. It is reported that in one year 50,000 natives succumbed to the disease. The *British Medical Journal* announces that the committee of the Royal Society appointed to investigate this subject has received reports from the observers sent by the society to Uganda in July, 1902. The researches so far made not being considered conclusive, Lieutenant-Colonel Bruce, who is a member of the committee, will proceed at once to Uganda to superintend further investigations as to the nature, mode, spread, and means of prevention of the disease. Dr. Castellani, a member of the original expedition, is still in Uganda and claims that he has discovered the parasite which is the cause of the disease.

**Management of Cholera Epidemic.**—The Public Health Reports give the following instructive and very interesting account of the management of the cholera epidemic in Egypt. It demonstrates clearly what may be accomplished when modern scientific measures are vigorously applied. The first case of cholera was reported in the interior of Egypt July 15, 1902. The disease spread rapidly to all parts of the country. By the middle of September there were more than 1,500 new cases per day. After that period, as the sanitary measures became perfected, there was a rapid decline in the number of cases. By December 1 the disease had been entirely stamped out, with the exception of a few cases at Alexandria and at a small number of the villages. By January there was only an occasional case at Alexandria. The total number of cases reported to date for all Egypt was 39,892; total number died, 33,986; total number recovered, 5,906. The general opinion among the sanitary authorities is that water and possibly a few food products are the only means by which the diseases were spread. The principal food products suspected are those which are generally washed with water, such as dates, lettuce, etc. It is not believed that the Nile was infected, or at least only locally here and there. Experiments made here recently seem to indicate that any running stream of the size of the Nile does not become sufficiently infected to convey such a disease as cholera. The experiments consisted in placing large numbers of *Bacillus prodigiosus* in running water and attempting to recover the organism a short distance below. The results were always negative. The measures employed to combat the epidemic were isolation, disinfection, and the supplying of drinking water free from cholera germs. The wells were considered the principal source of infection. More than 10,000 of these were disinfected in Cairo alone. Taps from which free drinking water could be obtained were temporarily constructed in all the infected districts of Cairo. In districts where this was done there was an almost immediate falling off in the number of cases. In the villages artesian wells were bored and the water from them alone used. The disease in such places was checked almost immediately. Persons afflicted with cholera were immediately taken to an isolation hospital. All fabrics found in the infected houses were taken to the disinfecting station and disinfected with steam. All containers for fluids were broken and new ones issued in their stead. The floors of the houses and walls to a height of about 5 feet were sprinkled with a 1 to 1,000 mercuric chlorid solution. This was followed by whitewashing the walls with a freshly prepared solution of unslacked lime. The wells were disinfected either with potassium permanganate or lime solution, the principal object being to so discolor the water in the wells that the natives would not drink it. When these measures were not effective sulfuric acid was poured into the wells. In the neighborhood of Cairo the Nile was patrolled by guards and vessels in order to prevent people from infecting it with dejecta or otherwise. The dead were wrapped in sheets saturated with mercuric chlorid solution.

## CONTINENTAL EUROPE.

An epidemic of enteric fever which is prevalent at Prague has assumed such serious proportions that the German deputies from this district have petitioned Parliament to adopt measures for the alleviation of the sufferers and against the spread of the disease. The Governor of Bohemia has also issued orders to the same effect. The disease is attributed to the foul water of the Moldau river, which supplies the city, and to the defective drainage of the city.

**Annual Deathrate of Berlin.**—The rate of mortality in Berlin was so low during the year 1902 that the total number of deaths was less by 3,000 than during the foregoing year. In the year 1902 the total number of deaths here amounted to only a little more than 30,700, while during the year 1901 there were registered in round figures 34,100 deaths—that is to say, there was a decrease in 1902 of 13 more per 1,000 as compared with the preceding year. The decrease was most noticeable in the infant mortality, due largely to the cool summer of 1902. In the year 1901 there were registered more than 11,300 deaths among the children in their first year, while in 1902 not quite 9,000 deaths were recorded among that age class. The contrast was

most apparent in the months of July and August, during which months in the year 1901 the total number of deaths among children in their first year amounted to 3,536; in 1902 in the same months only 1,521.—[*Public Health Reports.*]

## OBITUARIES.

**Soyetsu Kumagawa**, one of the foremost physicians in Japan, died recently in Tokio, aged 64. For many years he devoted himself to the advancement of medical science in his native country. He founded an association under the auspices of which a dispensary was established where the poor were treated gratuitously. This was the germ of the Tokio Charity Hospital, which was founded ten years later. In 1874 he opened an ophthalmic hospital in Tokio. He was a member of the Committee of the Sanitary Association of Tokio, and of many other hygienic and philanthropic societies. Dr. Kumagawa was also a vice-president of the Sei-I-Kwai, or Society for the Advancement of Medical Science in Japan.

**Emma Constance Stone**, said to be the first Australian woman to adopt the profession of medicine, died recently in Melbourne, aged 46. She first studied medicine at the Woman's Medical College, Philadelphia, and afterward in London and finally in Melbourne, where she started in practice. She was instrumental in founding the Queen Victoria Hospital.

**Franklin A. Gardner**, in Washington, D. C., February 13, aged 45. He was graduated from the New York Homeopathic College in 1882, and was a member of the American Institute of Homeopathy and the American Electro-Therapeutic Society. He was physician at the White House during Harrison's administration.

**James M. G. McGuire**, in Berryville, Va., January 24, aged 70. He was graduated from the University of Pennsylvania, Philadelphia, in 1855. He served as major and surgeon in the Confederate Army.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## WOUNDS PRODUCED BY SUGGESTION.

BY

JOHN MADDEN, M.D.,

of Milwaukee, Wis.

It is questionable whether one does not owe the profession an apology for dragging forth at this time the subject of suggestion.<sup>1</sup> The uncanny things some medical men claimed they were doing with it a few years ago are now ancient medical history. Charcot, Bernheim, Liébault, Wetterstrand, Hack-Tuke, Lloyd Tuckey, Kingsbury, Sidis, and a score or more of other prominent physicians were flooding medical periodicals with startling accounts of hypnotic manifestations. The lay public became infected, and the acme of its mad interest was reached when a prominent publishing firm paid \$50,000 and a royalty to the author of "Trilby," she of the matchless feet and doubtful morals, who was dominated by the hypnotic eye of the unwashed Svengali. Happily she died; then her creator, unable to bear the weight of so much popularity, unable to sit in the focus of the public eye, and fearing that his reputation was written in the sand, turned his face to the wall and also died. He was a true prophet. Were he alive today would he not, as the author of "Trilby," be as utterly neglected as his dead heroine?

It is difficult to read the medical literature of ten years ago without concluding that a sort of "suggestion" madness had seized prominent men in the profession. Their results astonished the world. Psychic eccentricities of the most marvelous kind were daily exhibited by subjects *en rapport* (not to say *en league*) with their principals. These goings-on got into the secular magazines and newspapers and all the world stood agape.

With the psychic manifestations of suggestion, however, this paper will not attempt to deal. There is evidence enough that hypnotists have played battledoor and shuttlecock with the minds of innumerable hysteric women and not over-strong-minded men. Our purpose here is to examine the evidence which supports the assertion that wounds, generally burns, either slight vesication or of such severity as to leave permanent scars, have also been produced by suggestion with or without hypnosis.

Jendrassik and Krafft-Ebing<sup>2</sup> experimented with a subject in the Rochus Hospital in Pesth in May, 1885.

The subject, Ilma S., was an incorrigible female of 17, who bore many of the well-known marks of degeneracy. Her father was a drunkard, who committed suicide; her mother was a paralytic, as the result of a cerebral hemorrhage; her maternal grandfather, one brother, and one sister also committed suicide, and another sister was subject to hysteric convulsions.

She was a logical product of such an ancestry, a proper member of such a family. She was a thief at 14, a thief and forger at 16—a cunning but evil-minded hysteric always. She had some physical abnormalities to add to the many of the mental kind, among which were anesthesia, hyperesthesia, neuralgia, and faults in the organs of special sense; some of these probably simulated. Jendrassik noticed when examining the patient "a scar representing a pair of medium-sized scissors" on the right side of the thorax near the shoulder. This scar was made, so he was told, while the patient was in a hypnotic state by being accidentally touched with a pair of scissors, the suggestion being somehow conveyed to her that the instrument was red hot, when as a matter of fact it was cold. Jendrassik took the hint. Ilma was seen to be very susceptible to hypnosis, so she was hypnotized and touched with a metallic letter K, a key, a monogram, the rim of a graduate, and some other objects suggested to her as being red-hot but really cold, and burns were produced of the identical size and shape of the objects with which she was touched. Jendrassik is not specific on the subject, but he makes the general statement that conditions were such that "deception is entirely excluded."

She was then turned over to Professor Krafft-Ebing for further experiment. On February 21, 1888, while in a state of hypnosis, "a circle was drawn with a pencil on the outside of the dress, over the region of the left scapula" and the patient commanded to "let it appear as a red line on the skin." On

the twenty-second the circle could not be seen. Hypnotized again the subject remarked: "You did not do that well; you made it on the dress instead of on the skin." This time the circle was drawn on the skin; and on the twenty-third not only did it appear, but there also appeared an identical circle on the opposite shoulder, each exactly 4 cm. in diameter. On the twenty-fourth the subject after being hypnotized was touched with the letter K, which was cut from a piece of zinc, the suggestion at the same time being made that it was hot. She was then bandaged and the bandages sealed. On the afternoon of the twenty-fifth the bandages were removed after it was ascertained that they had not been tampered with. "On the place suggested there was an irregularly shaped (not a K shape) irritated surface 5.5 cm. long and 4 cm. wide."

The other wounds were produced in the same manner, but were not duplicated on the opposite side. A sheet of writing paper was bound on the girl's left leg, and, under the suggestion of a sinapism, a blister was produced; no burn, however, appeared on the right leg. Nevertheless the author assures us that "If anything is pressed on her left side and suggested as red-hot a burn appears symmetrically and reversed on the right side."

Liébault's<sup>1</sup> experiments in the matter of producing burns by suggestion were reported in the *Journal of Hypnotism* in 1894. With both of his subjects in the hypnotic state he had them touch a cold stove suggesting to each that it was red-hot. So soon as they were awakened, it was observed that on the hand of one there was a "lively reddening" where it came in contact with the stove, while on the hand of the other there was a burn followed by a characteristic exfoliation of the epidermis and subsequent healing.<sup>2</sup>

Forel reported that he had received two photographs from Wetterstrand showing "two beautiful burn blisters," one of which was fresh and the other dry, under which Wetterstrand had written "Two burn-blisters originating through suggestion in somnambulism, the one in the middle of the hand October 7, 1890, the other on the side of the thumb suggested October 14, and photographed October 15. Both blisters arose eight minutes after suggestion, and the subject was, during the time, under complete control and observation."

We have the testimony of Bernheim that blisters were raised by postage stamps on the shoulders of a hypnotic subject, acting under the suggestion that they were sinapisms. In this manner five blisters were produced by eight postage stamps. Bernheim also mentions cases of hemorrhagic stigmata, bleeding from the hands, feet and sides on Fridays at the points wounded in the crucifixion of the Saviour.

While we might cite more evidence of this same kind, we have enough for our purpose. Let us examine it.

It is difficult to escape the conviction that the subject of Jendrassik's and Krafft-Ebing's experiments deceived those eminent investigators. In the first place she was a hysteric degenerate, a criminal, a clever forger, and a past master in the art of deception. In his volume detailing the experiments, Professor Krafft-Ebing does not tell us what measures were taken to prevent deception. He does tell us that such measures were taken, but if he had told us just what they were and permitted us to exercise our own judgment as to their adequacy it would have been more satisfactory. We have not, of course, lost sight of the fact that the subject was bandaged on one occasion, and while there was no apparent tampering with the seal put upon the bandage, a burn appeared nevertheless, but the character of this burn furnishes us the very strongest evidence that the patient had practised deceit. It will be remembered that before the bandages were applied the "suggested" burn was exactly the size and shape of the letter K with which the part had been touched, but the burn which appeared after bandaging was irregular in shape, many times larger than the K, and bore not the slightest resemblance to it in form. The proper inference to be drawn is that failing to reach the spot after the bandaging, with the heated initial (which she must have had access to before) she was enabled to produce a burn of a diffuse character through the bandages, possibly with a heated needle or by means of a jet of steam. Certainly the appearance of this burn was enough to condemn the entire experiment. Another condemning fact which has not been referred to before is this: On the shoulder touched by the metal initial, the burn appeared just like the K, while on the

<sup>1</sup> Is not the nonsense taught by the profession regarding suggestion largely responsible for the thousand forms of present day "mental healing" quackery?

<sup>2</sup> "An Experimental Study in the Domain of Hypnotism," by Krafft-Ebing, translated by Dr. Chaddock.

<sup>1</sup> *Zeitschrift für Hypnotismus*, Bd. 3, S. 40, 1894.

<sup>2</sup> *Zeitschrift für Hypnotismus*, Bd. 7, S. 137, 1898.

opposite shoulder it was not like the metal K reversed, but more like an H. Still another fatal defect in the experiments with this subject was the length of time which elapsed between the suggestion and the wound produced by it. In no case was it less than 24 hours. Why should so long a time be necessary? Wetterstrand's subjects were blistered in eight minutes and Liébault's apparently in a few hours at most.

We can, I think, without the slightest hesitation or injustice to the distinguished investigators, throw the case of Jendrassik and Krafft-Ebing out of court upon the ground that there is no reason to believe that their subject was sufficiently controlled, and that the nature of the wound produced after bandaging justified the conclusion that neither that nor the other wounds were produced by suggestion.

We cannot, however, so easily get rid of the testimony of Liébault and Wetterstrand. In the latter's subject especially, vesication was produced in the very short period of eight minutes, and while we are not informed that the distinguished "suggestion" therapist kept the spot under his eye during the process of vesication, deception under ordinary circumstances would not have been easy. In Liébault's cases deception might have been practised, so far as the information he gives us to the contrary is concerned.

Assuming that the truth has been told us regarding these wounds, it is a peculiar circumstance that they are always burns. Why not varicosities, cuts, scratches, penetrating wounds, tumors, or ulcers? If it is possible to produce burns by suggestion, why is it not possible to produce other kinds of anatomic change? Moreover, if suggestion can produce a burn on the skin of one subject in eight minutes, why should it take three times as many hours to produce the same extent of vesication on the skin of another person by the same agency? We answer, of course, that we don't know. The length of time required to produce a burn by suggestion is, however, a matter of comparatively little importance. The burn itself is the thing which needs explanation. Let us try to understand it. The subject receives the stimulus through the special sense of hearing; it goes to the auditory center for analysis, from thence it goes to the center of judgment, and this tells him that the object touched is hot; then somehow a destructive impulse must be sent from the center of judgment to the spot touched.

Just at this point we are all at sea. In the first place we know of no impulses under any circumstances sent out from the cerebral or other brain or cord centers producing an immediate destruction of protoplasm, or a violent or even a mild form of inflammation. To make this theory of a destructive force acting from within plausible, we must assume that (1) every minutest portion of the surface of the body has a center somewhere within the cerebrospinal axis with which it is connected by an *afferent* nerve-path; (2) that this center may be stimulated to the exclusion of all other centers; (3) that it may be stimulated by way of the higher centers (the judgment); (4) that the stimulus may be so strong as to cause immediate tissue destruction. But we know that no such nervous mechanism exists in the human body. As a matter of fact, the "suggestion" wound is explainable upon no rational physiologic theory, and it is a thousand times easier to believe that the experimenters were deceived than that wounds may be thus produced.

Physicians have sought to explain these wounds as manifestations of altered nutrition. They tell us that, as the nervous system is directly concerned in the nutrition of the cell, destruction might take place through the "nerves of nutrition." While the whole subject of nutrition is but imperfectly understood we know that the vasomotor system is directly concerned in the nutritive functions chiefly by regulating the blood-supply, and hence the food supply carried with it. Let us grant, however, that there is a system of nerves which are concerned directly in the nutrition of the cell, that nutrition is much or little, depending upon the strength and number of stimuli carried to the cell by this special system. But is it not a remarkable fact that no other kind of stimuli but those of suggestion can produce vesication, and burns followed by deep severe wounds and indelible scars? Is it not a remarkable circumstance that suggestion is the only force acting from within which can destroy a definite, limited area on the surface

of the body? Moreover, if it were a manifestation of nutrition gone wrong, why do we not sometimes have "suggestion" ulcers and "suggestion" gangrene? Some professional men also have seen analogy between these wounds and blishes. They tell us that in blushing there is a local dilation of the vessels; but no one ever saw a blush in the shape of a K of such intensity that it caused a burn, followed by a severe wound and an indelible scar.

Let us now look at the matter from the standpoint of the psychologist. It is universally believed, and with reason, that the emotions have much to do with the individual's health; that pleasurable emotions, hope, love reciprocated, the esteem of one's fellows and the satisfying mental attitude it brings, the possession of material wealth and its attendant sense of security against the evil day of poverty, bring with them physical health. They cause the heart to beat stronger, stimulate the flow of the digestive fluids, promote the contraction of unstriated muscle everywhere, improve the appetite and increase the capacity for digesting and assimilating food. In other words, all cause for worry is removed, and with it such central inhibitory influences as disarrange the whole circle of the vegetative functions, and nutrition goes on undisturbed. On the other hand, the victim of an unrequited love, the one who has failed to gain the good opinion of his fellowmen, he who is in constant fear of poverty, or who has the sword of a threatening fatality of any kind hanging over him, will be a victim of malnutrition, because these emotions weaken the action of the heart, inhibit the secretion of the digestive fluids, take away the appetite and lessen, it may be very markedly, all the functions of nutrition.

But we get no help from these wellknown psychophysiological principles. Pleasurable emotions produce no local nutritional phenomena, but redound to the benefit of the entire organism. Reciprocated love, the good opinion of one's fellows, material prosperity, cannot produce a hugely efficient biceps of the right arm while the nutrition of every other muscle remains in *statu quo*; nor can the emotions of fear, despair, unrequited love, cause an atrophy of one organ or part to the exclusion of every other organ or part. Those, therefore, who seek to explain "suggestion" wounds such as we have discussed, by calling our attention to nutritive changes which may be brought about by mental states wander very far from the field of logic. Not the slightest analogy exists between them.

Still another aspect of this subject presents itself for our consideration. We are gravely informed by accredited medical men that a "deviation from a normal state of certain functions frequently lapses into actual structural disease, as the effect of the faculty of the attention being for a lengthened period concentrated on this action" (Forbes Winslow, quoted by C. Lloyd Tuckey, "Psycho-Therapeutics," Chap. 11). The same authority says: "Certain feelings of uneasiness or even pain originate in the mind a suspicion of disease existing in particular parts of the body, stomach, heart, brain, liver or kidneys. Some slight irregularities and functional disturbances in the action of these organs being noticed, are at once suggestive (to the hypochondriac) of serious and fatal disease being established in the part to which the attention is directed." Thus organic change, even a cancer of the stomach, may originate.

This is given as a sample of the argument which is not infrequently heard to show that the mind may actually bring about organic disease through a process of auto-suggestion. Is it not weak to the point of childishness? Is it not a thousand times more reasonable to conclude that the vague sense of uneasiness existing before the appearance of the disease, is really the disease in its incipency, that an organic change has already taken place which is not yet palpable, discernible?

To conclude, we believe that the evidence upon which is founded this theory of anatomic change by long-continued auto-suggestion is unworthy of serious consideration, and like that which supports "suggestion" blisters should be thrown out of court summarily.

NOTE.—Suggestion therapeutics never obtained a hold with us here in America. Whether any one among us ever witnessed any of the phenomena of tissue change, vesication, hemorrhage and the like, on our own soil, I do not know. All my efforts thus far to learn of a subject with whom I might

demonstrate them have been practically without result. Readers of *American Medicine* may recall that I offered through the medium of this journal \$200 for a subject upon whose body might be demonstrated the possibility of producing vesication by suggestion. To this proposal a number of replies were received, some of which showed that the offer was misunderstood, others showed a desire to get \$200 as easily as possible, but had nothing to offer in the way of a subject. Two physicians offered themselves, but for obvious reasons a physician for such demonstration is not a desirable subject. One man, represented as a physician, telegraphed that he would accept the proposition. He presented himself the next day, saying that he had a subject with whom he had already demonstrated the possibility of producing vesication by suggestion. He could, however, not comply with the requirements, as he could not give assurance that his patient would consent to become a subject for such experimental research. He said, indeed, that while he had repeatedly hypnotized her, she was not even aware that she had been subjected to the process, that if she were aware of it she would never come near him again.

I then proposed to go to his city and witness the experiment. To this he agreed, saying he would write me when to come, but when I definitely fixed upon a time for witnessing the operation, he found an excuse for refusing to do anything further in the matter. It was then I discovered that the man is not a physician at all, at least he is not practising legitimate medicine, but is the proprietor of a "Demonstrative Institute of Mental Therapeutics," a fact which he cunningly kept from me until I had become insistent in my desire to see him make good his claims. So out of the answers to my offer through *American Medicine* the only one promising anything to aid in settling in a practical way the question of producing wounds by suggestion is completely discredited. It may be that some physician who reads this will recall evidence of such results seen either in Europe or America, and if so he will confer a great favor by writing to me. Of course, I shall want this evidence to be first hand. I desire that the person himself was a witness of the operation under such circumstances as to make fraud absolutely impossible. Personally I believe that vesication by suggestion is a physiologic impossibility, that one can no more "think" a blister on his body than he can "think" his arm or leg off.

Since the above was written, I have received several letters from this man. They bear all the ear-marks of the genuine charlatan.

## ACCIDENTAL GUNSHOT WOUND OF CHEST.

BY

ALFRED RICHARDS, M.D.,

of Fort Hunt, Va.

Contract Surgeon, U. S. Army.

*Clinical history* of private W. S., Forty-seventh Company Coast Artillery, aged 25, single; height, 5 feet 9 inches; weight 173 pounds; chest measurement: expiration, 37 inches; inspiration, 39½ inches; expansion of right chest, 1½ inches; left chest, 1 inch.

*Present History.*—On August 25, 1902, at 5.50 p.m., the discharge of a gun was heard at the guardhouse, and instantly there was a call for help. Fortunately, being near at hand, I was able to respond immediately. On reaching the guardhouse I found S— lying upon his face on the floor in a pool of blood and the contents of his stomach which had been vomited. The hemorrhage was profuse, the blood flowing from a wound in the posterior portion of chest, and also from one in the anterior portion of chest in the cardiac region. His shirts were cut off and the first aid administered. The shock was beginning to be manifest, and to limit its degree if possible, to relieve the pain and to steady the heart action which was irregular, slow, and intermittent, a hypodermic of morphin sulfate, 16 mg. and nitroglycerin 0.65 mg., was administered. Sterilized towels were placed over the anterior and posterior wounds and a bandage applied. While administering first aid, hemoptysis was noticed. (Instructions had been given to have normal saline solution ready for use if necessary.) He was placed on a litter and carried a short distance to the hospital, arriving at 6 p.m. The patient was placed in a warm bed and 500 cc. of normal saline solution was introduced into the cellular tissue of his right chest.

*Position of Wounds.*—The wound of entrance was 2½ inches from the sternal junction of the third rib in the third interspace 2½ inches obliquely above the left nipple toward sternum, as

seen in photograph No. 1. The wound of exit was 3½ inches from the angle of the scapula, axillary line, and 1½ inches from the wound to the muscular fold of the left axilla, as seen in photograph No. 2. At 6.50 p.m. the patient had rallied to a great degree from the shock. I decided to redress the wounds. The skin around the wounds was carefully washed with sterile water and green soap, then with 1-2,000 mercuric chlorid solution, followed by alcohol. The skin around the wound of entrance for about two to three inches was powder stained. There was slight emphysema for about four or five inches around the wound of entrance. Sterilized gauze in pads, and a large quantity of sterilized absorbent cotton were placed over the wound of entrance and that of exit. A little iodoform was sprinkled over the wound of entrance. The dressings were held in place by adhesive plaster and a four-tailed bandage.

Regarding the accident the patient said that he was a supernumerary of the guard and in charge of three prisoners who were cleaning out and clearing brush from around a ditch to improve the drainage and to destroy some mosquito breeding grounds. The tools of the prisoners were a scythe, a brush-knife, and a spade. He loaded his rifle for protection and after returning the prisoners to the guardhouse forgot to unload. Before leaving for the evening he began rubbing his gun-barrel and bayonet to prevent rust from the moisture obtained at the ditch. The bayonet was difficult to remove from the rifle and in taking it off the rifle was discharged. The distance of the gun-barrel from the chest was about 1½ to 2 feet. The rifle was of the United States service variety (modified Krag-Jorgensen) .30 caliber type. The powder was of the nitroglycerin type, giving a muzzle velocity in the rifle of about 2,000 feet per second. The bullet had a core of lead and tin composition, jacketed with cupronickel, weighing 220 grains.

*Treatment.*—Liquid diet and absolute rest in bed were ordered. Owing to the oozing the wounds had to be dressed frequently. It was found necessary to add additional cotton to

A, wound of entrance. B, wound of exit.

the posterior wound on the afternoon of August 26, also at 10.40 a.m. on the twenty-seventh. The dressings were found on the twenty-eighth saturated with blood serum, making a new dressing necessary for the posterior wound. September 3 complete new dressing of the anterior and posterior wounds was done. September 8 both wounds were redressed; the posterior one was completely healed; the anterior, owing to the nearness of the gun-barrel to the chest and deposition of powder in the skin, did not heal so quickly. Hypodermics of morphin 8 mg. were given as required, to prevent further hemoptysis and coughing and for its quieting effect, since physical signs of pneumonia, complete consolidation of left lung, were found on August 26. Stimulants were given as required. There was little if any cough or pain after the first two or three days. Food was gradually increased until September 15, when he was given full diet. On the same date lung gymnastics were begun by the method of compression of the side of chest over an arm-chair, allowing greater expansion of opposite lung. Physical examination of chest was made every morning from the last mentioned date for effect of gymnastics. The lung gradually cleared up, except the lower part of the anterior portion of the left lung. On October 9 Wouffe's bottles were tried with success.

The temperature seemed to indicate a delayed traumatic pneumonia. In the last week or two the temperature varied between 98° and 100.2° F., and as the patient seemed to be in perfect health I discontinued the use of the thermometer.

The pulse varied considerably, ranging between 72 and 120. No abnormal sounds were heard in the cardiac area.

On October 20, 1902, the patient was returned to duty, having made a perfect recovery. Chest examination: Inspection shows a slight flatness of the whole of the left side of the chest. Over the sixth rib on the left side there is a slight depression, but the lung is perfectly clear, with good expansion. Auscultation and percussion are normal. Exertion causes a very rapid heart action, which declines to the normal in a few minutes.

## ORIGINAL ARTICLES

CHRONIC PANCREATITIS.<sup>1</sup>

BY

B. L. HARDIN, B.S., M.D.,  
of Washington, D. C.

Chronic pancreatitis was first described in 1896, but it is only about 18 months ago that the true significance of the disease was brought to the attention of the profession. Because it is practically a new disease to all of us, because it is not an uncommon disease, because its diagnosis is possible, because its treatment can be brought to a successful issue, and for other reasons to be described later, I feel justified in reporting the following case in some detail:

Mrs. C., aged 49, November, 1901. Family history was uninteresting; likewise her personal history, until August, 1896, when her left breast was removed by Dr. Deaver, of Philadelphia. The same surgeon removed her right breast in August, 1900. With the exception of an acute attack of indigestion, manifested by abdominal pain and vomiting, for a few hours in October, 1900, she had been a healthy woman until early in November, 1901, when, without any premonitory symptoms, she was attacked suddenly with a severe epigastric pain, lasting four hours. During the succeeding two days she complained of fullness and discomfort in the region of the stomach, accompanied by eructation of gas, and on the third day she had a second attack of severe pain, followed this time by jaundice. In about a week the jaundice disappeared, the urine cleared, and the stools resumed their normal color. She then began to have mild attacks of epigastric pain, with indigestion, soon followed by a recurrence of the jaundice, with loss of weight and a sense of great exhaustion. These symptoms continuing about a week, she was again seized suddenly with an agonizing attack of pain located in the epigastrium and radiating through to the back and interscapular region. From this time on these agonizing paroxysms recurred with remarkable regularity about every third day. In the intervals she suffered with great oppression and weight over her stomach, often temporarily relieved by eructation of gas in loud explosions. There was moderate irregular pyrexia, occasional nausea, complete anorexia, constipation, insomnia, exhaustion, and mental depression.

*Physical Examination.*—This showed a medium-sized, fairly well nourished woman, moderately jaundiced, with a facial aspect of suffering and despondency. The thoracic organs were normal. There was slight tenderness and resistance to deep pressure, localized in the epigastrium. There was no dullness on percussion and no palpable tumor. The liver was not enlarged, nor the gallbladder palpable. The urine contained bile; specific gravity was 1.026; albumin and sugar were absent. The feces were clay-colored, fairly well digested and contained no free fat.

The paroxysms of pain continued with regular intermittence, the jaundice gradually deepened, loss of flesh and strength progressed with marked rapidity, and the case took on a very serious aspect. The patient presented this history: Both breasts had been removed for cancer; there was epigastric pain, permanent jaundice and rapid loss of weight, all of which pointed to malignant disease. On the other hand, the blood showed no secondary anemia, the red count being 4,630,000, and hemoglobin 80%. There was no leukocytosis, nor was cachexia pronounced. Therefore we concluded the case was one of chronic obstruction of the common duct by a gallstone, and determined to operate. The patient was therefore operated upon for gallstone obstruction by Dr. Stone in January. On opening the abdomen the pancreas was found to be greatly enlarged, hard and nodular, especially at its head. The ducts appeared normal and contained no calculi. Our fears seemed realized, and we looked in dismay at what we thought was cancer of the head of the pancreas. The gallbladder was opened and drained to relieve jaundice, the wound closed and an unfavorable prognosis made to the family. Fortunately, during the operation, a section of the pancreas was removed and submitted to Dr. Carroll for examination. He reported chronic pancreatitis and no evidence of malignancy. We hastened to change our prognosis. The patient made an uneventful recovery and is now well.

A consultation of the modern textbooks scarcely showed a reference to chronic pancreatitis, but at the Army Medical Library we were astonished to find that just such experiences as ours had been encount-

ered in recent years by several observers, notably the English surgeon Mayo Robson, who published his first case in July, 1900. Since then he has reported 22 operated cases, with only one death, the latter patient being in extremis when operated upon. If we stop to consider the amount of literature on diseases of the bile ducts, and the amount of operating done for gallstones in the last 12 years, we must be astounded to think attention was so long in being attracted to the pancreatic duct, which, on account of its like function and similar anatomic arrangement, must be subject to the same lesions as the common duct. Of course, chronic pancreatitis is not a new disease, and the case just reported illustrates how closely the symptomatology resembles that of malignant disease, thus teaching the sad lesson that many patients suffering from chronic pancreatitis have been consigned to their graves with a certificate of malignant disease when their lives might have been saved. In truth, a review of the cases that have come to autopsy in recent years confirms this conclusion. Robson and Opie have done considerable to bring this disease to the attention of the profession, but notwithstanding their efforts we conclude they have met with poor success when we turn to modern textbooks on medicine and surgery. For instance, a prominent textbook on medicine issued this year remarks: "Chronic pancreatitis is thus far only of anatomic interest." Others give a few lines to the disease, and suggest medical treatment without so much as a reference to surgery. One of the latest books on surgery does not even mention the disease.

The first case of chronic pancreatitis was recorded by Riedel in 1896, and was encountered while operating for gallstones. Körte and Oser reported cases in 1898, Lancereaux in 1899, Ebstein and Robson in 1900, Robson stating that he met his first case in 1892. Since 1900 many surgeons have encountered the disease while operating for gallstones.

As a result of the experiences of these men the pathologists and bacteriologists took up the subject, and it is largely their experimental work that has given us a clue to the causation of the disease. Their work has secured the following evidence: The injection of bile into the pancreas causes chronic enlargement and hardening of the organ. Obstruction of the pancreatic duct and

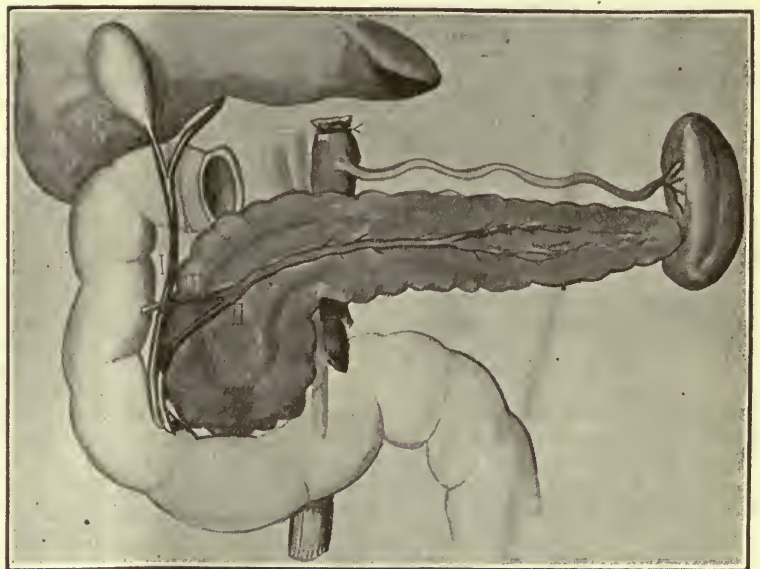

Fig. 1.—I, common bile duct. II, pancreatic duct. III, duct of Santorini.

damming back of the secretions also produce chronic inflammation and sclerosis of the gland. The injection of *Bacillus coli* or fecal matter into the duct produces the same result. Now, with these premises, let us set to

<sup>1</sup> Read before the Medical Society, District of Columbia, November 15, 1902.

work to find out for ourselves what conditions will bring about these results in our fellow creatures, beginning with a study of the anatomy.

**Anatomy.**—The pancreas is a compound racemose gland of very soft texture, and is drained by the pancreatic duct or canal of Wirsung, which passes transversely from right to left through its substance. On leaving the head of the pancreas the duct comes into relation with the common bile duct and they continue for a short distance side by side, entering the wall of the duodenum together, where they then unite to form a short cavity, called the diverticulum of Vater, discharging their contents through a common orifice into the canal of the duodenum. The common bile duct becomes constricted immediately before it unites with the pancreatic duct, and it is here that a gallstone is most likely to lodge. The lesser duct of the pancreas, or the duct of Santorini, usually opens into the main duct near the duodenum, but sometimes it enters the duodenum separately, at a distance of an inch or more from the entrance of the main duct. This is important to note, for in this fact lies the explanation that in some cases of complete obstruction of the main duct the gland secretions may find escape through the lesser duct. In 34 out of 104 cases examined by Shirmer the lesser duct did not join

Fig. 2—I, common duct. II, pancreatic duct. III, duct of Santorini. IV, diverticulum of Vater.

the larger duct or enter the duodenum, and it is only in such cases as these that a stone lodged in the terminal end of the common duct would completely obstruct the pancreatic secretion. Therefore, in only about one-third the cases of obstruction are we apt to find resulting changes in the pancreas.

**Etiology.**—Bearing in mind the similar anatomic arrangement of the two ducts we form two conclusions: First. That whatever obstructs the common duct tends to obstruct the pancreatic duct. Second. The pancreatic duct is liable to infection from the same septic organisms as the common duct.

The causes of chronic pancreatitis may then be divided into:

First. Obstruction of the pancreatic duct. This may be brought about by: (a) Calculi lodged in the pancreatic duct. (b) A gallstone lodging in the common bile duct, where it lies alongside the pancreatic duct, may

Fig. 3—I, stone in pancreatic duct. II, gallstone in common duct. III, stone in common duct. IV, stone in ampulla of Vater.

sufficiently press on the latter as to occlude it wholly or partially. Or, a gallstone lodged in the diverticulum of Vater may obstruct both the biliary and pancreatic secretions, converting the two ducts into a continuous channel through which the bile passes directly from the liver to the pancreas.

Second. Infection by microorganisms. It is well known that the duodenum and especially the bile ducts are common habitats for various septic organisms, and in cases of partial obstruction of the duct of Wirsung conditions arise that favor the entrance of these organisms into the duct. But infection and pancreatic inflammation may and do occur without any duct obstruction whatever. Robson's belief that all cases of chronic pancreatitis are due primarily to obstruction by calculi is not substantiated by the literature, for there are several cases on record in which there was no antecedent history of gallstones, and in which there was no evidence of calculi at the time of the operations.

Opie has recently reported four cases of chronic pancreatitis associated with persistent vomiting during life, and remarks that the vomiting favors ascending infection through the ducts.

Third. Toxic substances in the blood. Alcohol has been thought by many to be an important element in the production of chronic pancreatitis, but in the majority of reported cases there has been no alcoholic history. On the other hand, Opie has shown that in about one-fourth the cases of cirrhosis of the liver coming to autopsy, sclerosis of the pancreas has been found associated in greater or less degree. Hence we must conclude that the factors at work in the production of cirrhosis of the liver must also influence the pancreas. Interference with the circulation in chronic disease of the heart and lungs does not materially affect the pancreas.

A few students have written much to prove congenital

and acquired syphilis a cause of chronic pancreatitis, but this view is not supported by the literature.

Cannot brought attention to the occurrence of chronic pancreatitis in general tuberculosis. Tuberculous lesions of the pancreas have been recorded only a few times, and in these instances have not explained the pancreatitis.

*Pathology.*—Whether by obstruction from calculi or extension of inflammation from a duodenal catarrh the first step is infection of the pancreatic duct and an extension of the infective process into the head of the pancreas, resulting in inflammation of the gland. This infection if virulent may produce acute pancreatitis of hemorrhagic and suppurative varieties, but more usually a slow interstitial effusion takes place, enlargement and organization following. The enlarged organ now presses on the common duct, giving rise to enduring jaundice, thus simulating cancer of the head of the pancreas. As explained before, under these same conditions of infection the organ may escape serious changes, provided the accessory duct is so situated as to allow free drainage, and this may happen in a considerable number of cases.

#### CONCLUSIONS.

Chronic pancreatitis is caused by infection, the toxic material usually gaining entrance through the pancreatic duct, sometimes through the general circulation. Obstruction of the duct by a gallstone is the most common primary cause.

*Symptomatology.*—The patient may have suffered with long continued chronic gastric catarrh. Suddenly he is attacked with severe epigastric pain. The pain, as illustrated in the case reported, is central and not over the gallbladder. It radiates either to the back and interscapular region or toward the left. After lasting a variable time the paroxysm recurs with either regular or irregular intermittence, or there may be no paroxysmal pain, merely a deep-seated dull ache. Nausea and vomiting may accompany the paroxysms. In the interval the patient has anorexia, a sense of epigastric fulness and weight, belching or pyrosis. Sooner or later jaundice appears, the stools become putty-colored, and the urine contains bile. With each paroxysm the jaundice deepens, and finally becomes permanent. Now there is a progressive and quite rapid loss of flesh and strength until a most perfect picture of malignant disease confronts us. Some patients have complained of a curious sense of faintness almost amounting to collapse, and often there is a moderate degree of fever at intervals, again resembling cancer. Diarrhea or constipation may be present. The stools contain an excess of undigested muscle fiber and sometimes free fat. Lipuria is of rare occurrence. In advanced stages of the disease glycosuria occurs, but sugar will not make its appearance until a large portion of the gland parenchyma has been destroyed or functionally impaired, as has been experimentally proved by Opie. The pulse becomes slow when jaundice appears, and in the late stages there may be hemorrhages from various mucous membranes or into the skin. The patient finally dies of exhaustion.

*Physical Examination.*—On examination there is often a tender spot, central and about an inch above the umbilicus. There is more or less resistance to palpation over the epigastric region, and very rarely the enlarged pancreas may be felt. In a few instances when the enlarged pancreas presses on the vena cava, ascites develops.

*Diagnosis.*—This is very difficult. Thus far the best evidence of failure in pancreatic secretions is in the presence of an excess of undigested muscle fiber in the stools. Another good test is the absence of carbolic acid in the urine after the administration of salol. Unfortunately the presence of fat in the stools and sugar in the urine are of very little value as aids in diagnosis, for they are not present until a very late stage of the disease, when the pancreas is almost entirely destroyed. They should always be examined for, as their presence

would be confirmatory, but their absence would not negative the existence of the disease.

Mr. Cammidge, working under Robson, has found when urine from patients with chronic pancreatitis was boiled with an oxidizing agent and the phenyl-hydrazin test applied, there resulted a large number of delicate yellow needles, arranged in sheaves and rosettes. Normal urine, urine of various other chronic diseases, and even bilious urine, gave negative results when treated in the same way. But the cases so tested are too few thus far to allow us to conclude that it will prove useful in diagnosis.

I reported my case in detail for three especial reasons: First. To show that, while formerly, a patient suffering with epigastric pain, chronic jaundice, and loss of flesh, was thought to have either cancer or gallstone obstruction, we must now include chronic pancreatitis. Second. To show that if at operation a hard and enlarged pancreas is discovered it need not necessarily be cancer. Third. To show that the history, symptoms, and signs of the three diseases—cancer, gallstone obstruction, and chronic pancreatitis—are so similar that it is only by a thorough and painstaking refinement of symptoms that we can hope to differentiate between them.

The few points in diagnosis at our present command can best be emphasized, therefore, in an attempt to differentiate between the four diseases, namely: (1) Gallstones in the common duct; (2) cancer of the head of the pancreas; (3) cancer of the bile ducts; (4) chronic pancreatitis.

Now, these four diseases may have all the chief symptoms in common, namely, the history, the jaundice, the paroxysmal epigastric pain and tenderness, the wasting and the possible distention of the gallbladder.

We may exclude gallstone obstruction by the fact that the pain is to the right of the middle line, and radiates toward the right shoulder, and the tenderness is over the liver, which may be enlarged; whereas, in chronic pancreatitis, the pain is in the mid-epigastrium and radiates directly backward to the midscapular line, and the tenderness is in the middle line, and not over the liver. Fortunately the treatment of the two conditions is the same, and a differentiation is not so essential. However, when we come to cancer of the pancreas a differentiation is of the utmost importance. Here we must rely mainly on an examination of the blood, which shows a marked secondary anemia and leukocytosis in cancer, phenomena absent in both gallstone obstruction and chronic pancreatitis. The pronounced cachexia and painless dilation of the gallbladder are further points in diagnosis of cancer. It is true that in long-standing cases of chronic pancreatitis the gallbladder may become distended just as in cancer, but the distended gallbladder will be painful in pancreatitis and painless in cancer.

In cancer of the bile ducts, the gallbladder is much dilated. The various lymphatic glands may show involvement and a tumor is sometimes felt. Chronic catarrh of the bile ducts may be distinguished by the absence of pain, the negative physical signs, and the maintenance of the general nutrition.

The diagnosis of chronic pancreatitis must then be based on the jaundice, the paroxysmal epigastric pain, the mid-epigastric tenderness and resistance, the rapid loss of flesh and strength with the absence of marked anemia and leukocytosis, the presence of an excess of undigested muscle fiber in the stools, and the peculiar reaction of the urine to the phenyl-hydrazin test. In many cases diagnosis can be made only by exploratory operation, which should be unhesitatingly done in all doubtful cases.

*Prognosis.*—The disease may last for many months or perhaps years. Uniformly good results have been obtained in all patients properly operated upon, and, in the hands of a good surgeon, when operation is not too long deferred, the mortality should be practically nil. Of course, when sugar is found in the urine the outlook

is not favorable, for we then understand that the pancreas is almost entirely destroyed.

*Treatment.*—This is purely surgical, and is effected by clearing the ducts of obstructions so far as possible, and draining the gallbladder or both ducts, as the circumstances may demand.

## SOME FURTHER RESULTS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.<sup>1</sup>

BY

J. H. ELLIOTT, M.B. (Tor.),  
of Gravenhurst, Ont.

Physician-in-Charge, Muskoka Cottage Sanatorium.

At the meeting of this Association in Toronto three years ago I presented the results of two years' work in the sanatorium treatment of pulmonary tuberculosis. Since that time the appreciation of the merits of sanatorium treatment of this disease has rapidly increased, so that a presentation of the results of the past three years in the Muskoka Cottage Sanatorium may be of some interest to the profession. I want to assure the members of this Association of the great value of this method of treatment, and to show that not only a return to health is to be expected in a large proportion of the early cases, but that by hygienic living after returning home the gain made is permanent when the patient has remained under treatment a sufficient length of time.

The term "sanatorium treatment" includes broadly those measures now adopted by all sanatoriums devoted to the treatment of pulmonary tuberculosis: (1) Constant life in the open air; (2) general hygienic measures; (3) an abundance of nutritious food, with rest or exercise, dependent entirely upon the condition of the patient. Success will vary with the ability of the physician to plan a proper daily program for each patient, and the cooperation of the patient in following his instructions, and this will be the basis of success rather than climatic considerations or the equipment of the institution, though these play no unimportant part in the work. Each case must be a study in itself, and in absence of any specific medication for the disease the therapeutic measures must be largely symptomatic, the one object being so to improve the nutrition of the patient that he is able to resist and overcome the effects of the invasion of the tubercle bacillus and its toxins, both in the diseased area and the organism in general.

A very important factor is a cheerful mind. Everything about the patient must be planned to bring this about, and he must be impressed with the necessity of cultivating it. I have often heard patients say when advised to go to a sanatorium, "Why can I not be treated at home, I do not want to go where there are so many sick people," and very often the physician gives way to the patient, himself fearing the ill effect of such surroundings. Those who have visited a sanatorium need not be told how erroneous is this view and how little depression is present among the merry, happy people who jocularly refer to themselves as "lungers;" they know what brightness and cheer there is about the place. Though it is impossible, however much one may try, to limit the admissions to purely incipient cases, patients in the very advanced stages are not admitted, and any admissions of advanced diseases are limited to those in whom the constitution still shows some resisting power and the disease is not advancing rapidly. When the patient does reach the sanatorium he is surprised to find so many healthy looking people and soon realizes that he is at once recognized as a new patient by his pale face, which has not yet been bronzed by life in the open air. Any depression which may appear in a patient is not from seeing other patients

about him, but is always traceable to other influences, such as worries about affairs at home; for instance, a father or mother troubling about the family left behind, or the consideration of the financial burden of six months to a year away from home with no earning capacity. Everything about the sanatorium is cleanly, bright, and cheerful, and what can be more encouraging to any one afflicted with tuberculosis, which he has been taught to look upon through his life as inevitably fatal, than to see 20% or 25% of all those about him returning home apparently cured, 25% to 35% more in perfect general health, though perhaps not quite free from cough, and another 25% markedly improved, *i. e.*, of all patients treated, and many leaving before they should do so, he has a picture of 75% with marked improvement, another 15% stationary, and in only 10% any progress of the disease. When he sees this for himself he cannot but be encouraged. There is with many at first a feeling of strangeness and perhaps homesickness, but this is soon replaced by an intense interest in the new surroundings and new method of life, and immediate improvement satisfies him that he has made a wise decision in leaving home.

It is unfortunate that for the proper classification of cases there has been no uniform standard of terms adopted by those working in this department of medicine. At the meeting of the American Climatological Association in 1901 a committee was appointed to arrange a satisfactory classification and a definition of terms employed. They were, I believe, hopelessly divided among themselves, and we must go on with our own arbitrary divisions until the matter is settled. In my own work I have followed Dr. Trudeau's definitions, classifying patients as incipient, advanced, and far advanced, and after treatment apparently cured, disease arrested, much improved, stationary, or failed.

### DEFINITIONS OF TERMS EMPLOYED.

*Incipient.*—Cases in which both the physical and rational signs point to but slight local and constitutional involvement.

*Advanced.*—Cases in which the localized disease process is either extensive or in an advanced stage, or in which with a comparatively slight amount of pulmonary involvement the rational signs point to grave constitutional impairment or to some complication.

*Far Advanced.*—Cases in which both the rational and physical signs warrant the term.

*Apparently Cured.*—Patients in whom the rational signs of pulmonary tuberculosis and bacilli in the expectoration have been absent for at least three months, or who have no expectoration at all; any abnormal physical signs remaining being interpreted as indicative of a healing lesion.

*Disease Arrested.*—Cases in which cough, expectoration and bacilli are still present, but in which all constitutional disturbance has disappeared for some time, the physical signs being interpreted as indicative of a retrogressive or arrested process.

*Improved.*—Cases in which there has been some marked gain in the condition of the lungs, or in which there has been marked amelioration of the constitutional disturbances. Cases with simply a slight gain in weight are not placed under this term.

The classification is, I must admit, open to criticism, but at present I see nothing more satisfactory. The use of the term "apparently cured" in cases in which tubercle bacilli have been absent three months only, or in which there is no sputum, is open to question. It cannot certainly be used as equivalent to the term "absolute cure" used by some specialists. For this to be used there should be a probationary period of at least two years, possibly longer. Using the term in this way we would naturally expect some relapses or recurrences in the course of a few years, while in the case of those discharged with disease arrested the maintenance of the gain made will be entirely dependent upon the mode of life adopted after the return home.

Instead of presenting to you three years' statistics separately, I shall avoid confusion and save time by grouping together the results of five years' work. It will be noticed that many advanced cases have been admitted. Though our sanatorium is for the treatment of the earlier

<sup>1</sup> Presented at the annual meeting of the Canadian Medical Association, Montreal, September 16, 17, 18, 1902.

cases, we have from time to time admitted the more advanced cases rather than have our beds vacant—not hoping to cure these patients, but knowing there is no provision for them elsewhere. We have worked on the principle of the greatest good to the greatest number, and we never admit them to the exclusion of patients in whom a return to health can reasonably be expected. For the past three years we have been endeavoring to establish in or near Toronto an institution for the more advanced cases, but we have so far been constantly blocked by the property owners in the vicinity of each suitable site. So soon as the site can be arranged we are prepared to erect the home at once, and have already the promise of two cottages and \$25,000 for the erection of a suitable building. Being in or near Toronto, it will be built with the expectation of using it for clinical teaching.

Up to August 31, 1902, there have been admitted . . . 606  
 On this date there are still under treatment . . . 52

There having been discharged . . . 554  
 During this five years there remained under treatment less than one month . . . 80  
 and these are obviously not to be reported on.

Leaving to be reported on . . . 474

Condition on admission.	Number of cases.	Apparently cured.	Disease arrested.	Much improved.	Stationary.	Failed.	Died.
Incipient . . . . .	134	78	38	16	2		
Advanced . . . . .	300	17	100	48	23	10	
Far advanced . . . . .	140	1	22	45	39	27	2
Total . . . . .	474	96	160	109	64	37	8

These results show out of 474 cases, a large proportion of which were far advanced, 96 patients, or over 20% apparently cured, and 54% of apparent cures and arrested cases; of the incipient cases, 78 patients out of 134, or 58% apparently cured, and 87% of apparent cures and arrested cases. These are the actual results with patients remaining under treatment, in the majority of cases, an insufficient length of time. But every patient, whether apparently quite well, or with the disease quiescent, leaves the sanatorium knowing how to live properly, and is in a position to carry on his new method of life wherever he may go. He is taught that he may reasonably expect to retain all he has gained, but that continued progress will depend entirely upon the care he takes of himself, that if careless, reinfection or an extension of his disease may occur at any time. Knowing what is necessary to keep good health, the patient feels his own responsibility, and in the majority of cases the after results are very encouraging.

PRESENT CONDITION OF 256 PATIENTS DISCHARGED FROM AUGUST, 1897, TO AUGUST, 1902, WITH DISEASE ARRESTED OR APPARENTLY CURED.

Realizing that the value of any plan of treatment depends not only on the immediate result, but also on its permanency, and that the after history of discharged patients is of great importance, it has been my endeavor to keep in correspondence with all the patients who have left the sanatorium. I have sent letters of inquiry with question blanks to those who have left either apparently cured or with the disease arrested; their present condition I give in the following table:

96 PATIENTS "APPARENTLY CURED."

(Of these 62 had bacilli in the sputum on admission.)

In good health, August 1, 1902 . . . . .	79
Not perfectly well, but in fair health . . . . .	3
Dead . . . . .	5
Not heard from . . . . .	9
Total . . . . .	96

160 PATIENTS WITH "DISEASE ARRESTED."

(Of these 142 had bacilli in the sputum on admission.)

Apparently in perfect health, and no cough nor sputum . . . . .	26
As well as on discharge . . . . .	88
Not so well as on discharge . . . . .	2
Dead . . . . .	24
Not heard from . . . . .	20
Total . . . . .	160

That so many remain in excellent health after the elapse of from one to five years is most encouraging, and by following the rules of life learned at the sanatorium in a fair proportion of the cases classed as arrested, the patients have progressed to apparent cure.

The five deaths occurring among the "apparently cured" cases call for a short note of explanation. The first was a youth of 19, who on discharge appeared quite well. He was, however, growing very rapidly, and was not putting on weight quite in proportion to his height. He was advised to go to Calgary, or if he remained in Ontario to live on a farm. Contrary to all advice he remained about his home in a large town doing nothing and spending the greater part of his time indoors. The result which followed could scarcely be unexpected. A second patient died of tuberculous meningitis a year after discharge, having been in the meantime at work on the farm, and having at no time any return of his pulmonary symptoms. The other three patients were women, all of whom returned to their household cares and worries without allowing themselves sufficient relaxation and hours out of doors. These cases have only served to teach and impress me with the fact that the after history is almost altogether dependent upon the patient himself, and that the exercise of strict care is all that is necessary to keep well. A few patients have been sent to the West to live, but almost all have again taken up life in their former homes. They comprise tradesmen, clerks, bookkeepers, stenographers, physicians, dentists, barristers, farmers, engineers, tinsmiths, and men and women from many other walks in life. They are living in all parts of Ontario, and in the lower provinces. If a patient is cured in his home climate, there seems to be no reason why he should not remain well in it.

There is no need of sending every patient to the West or South as soon as a diagnosis of tuberculosis is made; fully as good results can be secured at home. It is not climate that cures, it is the careful supervision of the patient by his physician which is of most importance, climate being entirely secondary. Rather than have your patient go away from home among strangers, where he will not have proper attention, treat him at home if you can devote the necessary time to ground him thoroughly in the essentials of cold sponging, life out of doors, care of the sputum, the use of the clinical thermometer, regularity at his meals, in the hours of sleep, rest and exercise, and see him at frequent intervals that his daily program may be changed according to indications. I want the profession to realize fully the curability of tuberculosis and the necessity of an early diagnosis to secure the best results. For those who cannot leave home for treatment the physician must make it his duty to give them the necessary time and attention and see that his instructions are faithfully carried out. If the physician would do this conscientiously and not treat his patient as a chronic with little hopes of cure there would be more cures and the public would be less apt to take so readily to proprietary nostrums.

I hope that the success that has attended our efforts in this work and the unvarying success of sanatorium treatment in the United States and in Europe will be a stimulus to the profession and the public to urge on our governments and our philanthropists the necessity for the provision of sanatoriums throughout Canada. The National Sanitarium Association has established two at

Gravenhurst, one with 60 beds for paying patients at \$10, \$12 and \$15 per week, and a second with at present 75 beds for the indigent and those who cannot pay the full rates. Both are for the earlier cases. More sanatoriums are required, each province should have one or more. The earlier we can have them established and use them as centers of hygienic education for our people the sooner may we hope to control the ravages of this dread disease which is accountable for the yearly loss of so many of our fellow-citizens.

## DANGERS FROM THE INDISCRIMINATE USE OF MORPHIA.<sup>1</sup>

BY

T. D. CROTHERS, M.D.,

of Hartford, Conn.

Morphinism and other narcomanias are rapidly increasing in this country. Some of the more apparent causes are the nerve and brain exhaustions which are so common in all circles of life. Next are the toxic conditions, following failures of nutrition with auto-intoxications from lowered vitality and general debility. From these and other sources the brain centers lose their vigor and power of endurance and become highly sensitive to pain. The absence of proper rest to the brain centers is followed by irritation and instability which are transmitted to the next generation; this is apparent in the neurotic and hypersensitive states. The increasing number of neurotics and psychopaths in every community is an unmistakable sign of brain and nerve failure. In such persons morphinism, alcoholism and narcomania generally are symptoms of low vitality, starvation and poison states. It is these conditions that prepare the way and make ready the soil for the growth of nervous diseases, of which morphinism and other narcomanias are common instances. There are reasons for believing that physicians are responsible for many of these conditions which a larger and more accurate knowledge would have prevented. One class of physicians who are more or less responsible are the thoughtless, unreasoning ones who believe that the highest achievement of art is to relieve pain and suffering irrespective of all consequences. These physicians have never been taught that morphia therapeutically is dangerous except when used in special doses and in certain conditions. Professors of therapeutics describe at great length the value of morphin in medicine, but say little of the possible dangers from its use. In nearly all medical colleges little or no instruction and seldom any warning is given the recent graduate concerning the danger of addiction to morphia. The moral theory of vice in the wilful giving way to the impulse for relief from morphia is prominent in both medical and lay circles, and the victim who has become an habitué is regarded as one who might have done otherwise by the exercise of his will. A prominent physician recently wrote that the mania for morphin by the needle was more a moral lapse than a physical one. Another writer of eminence in this country talks at great length of the moral treatment of morphinism, conveying the same idea. Physicians believing these theories would naturally use morphia by the needle with great indifference. It is urged by some writers that in all conditions of pain it is justifiable to use morphin by the needle. Some physicians when called to an obscure case give morphia at once, before making a diagnosis, believing that after a certain narcotism of the pain centers the symptoms of the disease can be determined more easily, or they reason that the effects from cessation of pain by the needle will create confidence in the mind of the patient that will be followed by more successful after-treatment. Other physicians use morphin in the most routine way, giving

it in nearly all cases either alone or combined with other drugs, varying with the amount of pain present. In neurotic and rheumatic cases, in which the use of morphia brings rapid relief, it not infrequently happens that the physician instructs the patient in the use of the needle, trusting to his judgment when and how to use it. Instances are not uncommon in which the physician has given morphia daily for months. When it dawns on the mind of the patient that he is contracting an addiction, the physician is discharged but the drug is continued in some form or another. When the physician has concealed the drug from the patient, a change of physicians is almost sure to reveal the fact and show the inability of the patient to get along without a narcotic. Many very excellent physicians have thoughtlessly given morphia until its poison effects were marked and the patient was unable to bear its withdrawal. In that case, the patient usually drifts away from the doctor, falls into the hands of quacks and soon becomes incurable.

A second class of medical men who are very active in promoting morphinism and other narcomanias are spirit and drug-takers themselves. They are the physicians who believe in the food, tonic and stimulant qualities of alcohol and use it in so-called moderation as a stimulant, socially and at meals, or upon any occasion of strain or overwork. Morphia is used in the same way. If suffering from insomnia or overwork, morphin by the needle is used for relief. These physicians believe implicitly in the stimulant value of morphia and do not hesitate to use it on all occasions. The morphia-taking physician will combine this drug in nearly all his prescriptions whenever pain suggests its use. To them there is no possibility of an addiction, and should it follow, it is ascribed to other than the real cause. In one instance a physician of this kind was known to have made or assisted in promoting morphinism in at least six different persons.

A third class who are active in promoting narcomanias are druggists and manufacturers of proprietary medicines. The former soon discover the magic effect of prescribing doses of morphia for pain, and later teach the person how to use the needle, the druggist profiting by the sale of the drug. Many druggists change inebriates to morphinomaniacs by counter-prescribing some of the forms of opium. Physicians may start these cases, then the druggist helps on the addiction, and continues to sell the drug as long as the habitué can pay for it. The patent medicine proprietors use large quantities of opium, morphin and cocain in the pain-killers and nerve remedies. In one of these widely-advertised drugs  $\frac{1}{4}$  grain of morphia was found in every teaspoonful. Many of the brain and nerve remedies contain cocain in addition to some form of opium. The popularity of such compounds often depends largely on the narcotics they contain. After their use a few months the druggist substitutes for them similar compounds containing morphin. The patient is then a narcomaniac. Not infrequently the history of the case begins with the use of proprietary medicine. The effect of morphia is then realized, although the drug is unknown. The physician is called in and he discovers morphinism in the abstinent symptoms, when the proprietary drug is stopped. After an ineffectual struggle, he continues the morphia concealed in some other drug, and from this on the course down is rapid. The patient drifts from one physician to another, each one discovering the addiction, and, unable to check it, allows the patient to drift into other hands. Sometimes the case begins with the druggist, who prepares a mixture of morphin concealed in some flavoring substance, which is used for a time, then the patient drifts away to a physician and finally becomes confirmed in the use of morphin.

There are in every community neurotics and psychopaths who are constantly seeking relief from states of exhaustion and depression. Indigestion, excitement,

<sup>1</sup> Read before the Connecticut State Medical Society, May 20, 1902.

overwork and underwork are followed by general emotional disturbances for which drugs are taken. Such persons seek panaceas and specifics. When morphin is given, the narcotism is so perfect as to be a revelation of a new world of comfort and peace, and this is repeated with eagerness and reckless disregard of consequences. Should the drug produce nausea, and after a short period of quietness and rest be followed by still greater depression, it is not usually used again. It is one of the unmistakable signs of danger when the morphin brings complete abolition of pain with quiet, restful slumber and no after-depression. Such patients are sure to become morphinomaniacs with little temptation. In one instance a physician found two members of a neurotic family peculiarly susceptible to the narcotic action of morphia given by the needle. Fearing that this would lead to a serious addiction later, he gave large doses of apomorphia, which produced intense nausea and disgust, breaking up the mental fascination for morphia. Neurothics seeking relief from both physical and physic pain should never be given morphia by the needle except for some special purpose, and then only when concealed. In these cases there is often a needle mania or an intense desire to get instantaneous effects from the drug, to feel the prick of the skin and see the raised surface into which the fluid is forced. This needle mania is serious and persistent, requiring great skill on the part of the physician to break up. Hypersensitive men and women insist on having drugs given this way, and when nothing but hot water is used are satisfied. The danger of addiction to morphia by using it indiscriminately and on all occasions, while always a serious one, is by no means the most important. The physiologic action of morphia on the nerve centers is first a slight stimulant or irritant and then a narcotic. This narcosis falls most heavily on the sensory brain centers, and while checking pain symptoms and depressing functional activities, reacts on nutrient centers and the metabolic processes. Narcotism of these higher centers disturbs elimination and when continued increases the growth of toxins, which still further depress and derange the equilibrium of the nerve centers. The physiologic effect of morphia, first causing irritation, increasing the heart's action, then depressing nerve activity and consciousness to the degree of coma and sleep after which reaction in nausea and depression follow, are certainly very serious interferences with the normal physiologic processes of the body.

Recently several eminent surgeons have sharply condemned the custom of giving morphia after operations, asserting that the following narcotism still farther depresses the nerve centers, deepening the shock from the operation and depressing the vitality. Some English surgeons have recently protested very emphatically against the common use of morphia, giving as a reason the diminished secretions and changed metabolism which always follow. Dr. Price, of Philadelphia, believes that opium in any form increases the mortality from abdominal operations and sustains his argument with strong clinical proof. Other authorities condemn the use of morphia by the needle, reasoning that the sudden introduction into the blood of a toxic agent, lowering the nervous activity and concentrating its power on the sensory centers, is a far more dangerous and serious interference with the vital processes than if used by the stomach. There seem to be good reasons for believing that chemic interference from suddenly changing the hyperesthetic sensory centers is followed by other and more serious states. The mere cessation of pain may be prolonging the cause of which pain is a symptom. Morphia used to quiet pain is simply treating symptoms while the cause remains. Dr. Barrett has shown conclusively that water may be used in the place of morphia as a narcotic in nearly every instance when pain is to be overcome. Dr. Cowles concludes that the continued use of morphia favors the growth of intestinal toxins, absorption of which still further poisons

and deranges the vital processes. Opium, as a fluid or solid, has far more pronounced narcotic action and when given by the stomach is followed by more prolonged after effects. The alkaloids, morphia, heroin and other new combinations are more intense and brief in their action and all of them seem to fall more heavily on the higher brain.

Another source of danger is apparent in many of the common cases which come under daily observation. For example, a person taken down with all the symptoms of la grippe is given morphia in small doses for days and sometimes weeks. He recovers, but complains of symptoms which have all the appearance of derangements from morphia poisoning, such as nutrient disturbances of the stomach and bowels with periods of depression, irritability, and emotional sensitiveness. The appetite is variable and the brain is easily exhausted by the slightest over-exertion. While all these symptoms are usually attributed to the influenza, they resemble closely the withdrawal symptoms of morphinism and sustain the belief that they are in a large measure due to the poison action of morphia. More familiar examples are the neurotic persons who are affected suddenly with chills and coryza called colds, accompanied with mental fears of pneumonia, pleurisy, and other diseases, with morbid dreads concerning the symptoms and their meaning. Morphia used with syrups in these cases is a common remedy and is sometimes used for weeks. When discontinued, the same symptoms of nutrient disturbances, with mental and motor irritability seen in the withdrawal of morphia, follow. In an example of this kind the patient continued to be a nervous invalid for a year or more then found a specific in a quack medicine containing morphia. Later this patient became a morphinomaniac. The order of sequences was clear from the time of the first morphia prescription for the cold up to the development of morphinism. The patient was not aware of the nature of the drug, but only conscious of the good effects. Other equally common examples are those of rheumatism, nutrient and neurotic disturbances or states of toxemia in which morphia is given, alone or with other drugs. While the pain symptoms are checked, new sources of poison and new derangements follow evidently due to the action of morphia. Malarial affections, for which morphia may be given, are frequently followed by equally significant and almost pathognomonic symptoms. After a period of continuous use of this drug, either concealed or known to the patient, its withdrawal is followed by neuralgias, depressions and obscure psychopathic symptoms, for which the physician prescribes wines, and tonics containing alcohols, and inebriety and alcoholism are almost sure to follow. Cough mixtures containing morphia have been condemned by many authorities. There is not only the danger of the addiction, but marked nerve and nutrient disturbances which lead to very serious diseases later. Continual narcotism of the pain centers leaves a degree of susceptibility and feebleness of control that may continue a long time. States of neurasthenia, marked by obscure pains, both physical and psychic, with morbid fears of disease and irritability, credulity and skepticism, when treated with morphia are supposed to be cured. The temporary subsidence of the irritation and pain is followed by an increased debility and exhaustion. Patients so treated often become alcoholics and morphinists; and later the effects of this continued narcotism and covering up of the pain symptoms may culminate in pneumoparesis with death in a few hours, or tuberculosis ending fatally in a few days. The sudden pneumonias and tuberculosis so often noticed are frequently traceable to narcotism from either alcohol or opium. The routine treatment of our fathers, using calomel and venesection for all forms of disease, was infinitely superior and scientific when compared with the present use of morphia by the needle for all aches and pains.

The first fact I wish to make prominent is, that while morphia is a most valuable remedy and cannot be dispensed with in medicine today, it is an exceedingly dangerous one, and should be used with great caution and never continued long, except for special reason and under special conditions. In cases of carcinoma or fulminating diseases that are incurable to a large extent, it is invaluable. Even here the derangement that follows its use is apparent, but this is insignificant when compared with the comfort it brings. There are other diseases often successfully controlled and managed largely by the use of morphia, but the wise physician anticipates and provides for the dangers and lessens them. The second fact I wish to emphasize is, that morphia, given to neurotics and psychopaths, is almost certain to increase the brain and nerve degeneration, and even if it does not produce an addiction will increase the instability of control and the hypersensitiveness of the nerve centers. The possibility of narcomanias, including spirit addictions, is greatly increased, no matter for what purpose morphia is given. The third fact is, that morphia, while relieving the pain incident to the common disorders of the functional activities of the body, actually increases the disturbances of metabolism and favors the growth of toxins. The pain symptoms which it checks obscure the disease and make the treatment more difficult. By paralyzing the sensory centers, diverting nerve energies and breaking up their nutrition, this checking is always dangerous. Our knowledge of the good effects of the drug on the brain centers are obscure, but the injuries which follow its use can be clearly mapped out in any clinical study. Another fact, although well known to all physicians, cannot be emphasized too strongly, namely, that proprietary drugs given for the purpose of controlling pain always contain dangerous and uncertain narcotics, and their use should be condemned. Reckless prescriptions over the counters of drug stores for sudden symptoms of pain are equally hazardous. Physicians should be more cautious in the use of narcotic drugs, particularly opium and its alkaloids, and should remember that many obscure diseases can be traced to reckless medication, and are the direct result of poisons from morphia.

## ROUTINE EXAMINATIONS OF CHYME.

BY

A. L. BENEDICT, A.M., M.D.,

of Buffalo.

Consultant in Digestive Diseases, City Hospital for Women, Riverside Hospital, and Dansville Hospital.

*Test-Meal.*—For ordinary purposes the following test-meal is most convenient, as it can be taken on a train or in the waiting-room or obtained at any restaurant, and it does not clog the tube: Bread, 2 slices, or if weighed, 50 grams; butter enough to spread the bread, or 5 grams; water, one glassful, or 250 cc. However, in an emergency almost any simple meal that the patient may have taken may be investigated.

*Time of Extraction.*—For the test-meal given, 1½ hours; for a meal containing meat and vegetables, 1½ to 2 hours; hearty and varied meals can be used only for reaching approximate conclusions.

*Method of Extraction.*—Use a large tube, preferably No. 11 or No. 12 (referring to circumference in millimeters), with an open distal end, or with not more than two eyes, which must usually be enlarged with a wet knife and smoothed with sandpaper. To empty the stomach some patience is required, and the tube must be used at different depths, from 55 to 60 cm. from the incisors. Suction should be combined with compression of the stomach; the former applied by an aspirator bottle, a Politzer bag, or the modern vaginal syringe of similar shape, or by my roller pump, which strips the stomach tube and affords a suction equal to the resiliency

of the tube itself. Violent suction, as by the Allen pump or the direct suction of a piston pump, should not be used. Compression of the stomach is effected partly by external manual pressure, as in Credé's method, following the movement of the abdominal wall during deep respiration and using considerable force; partly by diaphragmatic respiration and straining with closed glottis by the patient.

After withdrawal, the chyme should be immediately cooled by running cold water outside the jar, in order to stop digestion.

*Amount.*—The stomach contents should be measured; the amount normally is 50 to 100 cc. Smaller quantities suggest hyperkinesis, but are usually explicable by failure to extract the total amount present in the stomach. These statements and all following apply to the standard test-meal mentioned, unless qualified. In states of supersecretion, the amount extracted may be double that ingested.

*Amount of Filtrate.*—The filtrate, obtained as described in a foregoing article, is normally about half as large as the total unfiltered chyme. Lower percentages indicate failure of secretion, and are found in gastric catarrh especially. Higher percentages usually coincide with hyperchlorhydria, often with pyloric closure, but there may be a supersecretion without excess of HCl, and if much mucus is present in the filtrate, the fluidity may be due to the secretion of mucus itself. In cases of dilation, abnormal fluidity suggests the presence of water or other beverages preceding the test-meal. Gross increase of stomach contents, with dilation or stagnation, of course leads to the suspicion that we have obtained not only the test-food, but the remains of other meals, and the patient should always be warned against drinking, lunching, or swallowing mucus and saliva within three hours of the time of taking the test-meal.

*Acidity.*—As the stomach-contents for some hours after a meal are practically always acid, and as the quantitative tests by titration are simple, the theoretic qualitative tests for acidity may be, for the most part, omitted, unless special attention is called by the results of titration to the necessity of qualitative examination. Using 10 cc. of filtrate, or less if only a small amount is available, free HCl is titrated with dimethylamidoazobenzol as an indicator (see preceding article), and the same portion may be used for the successive estimation of total acidity. The free HCl should be neutralized by 25% to 50% or degrees of decinormal NaOH, taking the reading when the red begins to change to orange. The total acidity should be just about twice that of free HCl, a higher ratio indicating fermentation acids, a ratio of less than 1:1.5 indicating lack of combination with proteids. The mistake should not be made, in successively titrating for free HCl and total acidity, of measuring the latter from the end of the former reaction, but both should be measured from the same beginning. If 10 cc. of chyme are used, each tenth cc. division in the buret is a degree or percent. If other amounts of chyme are used, the degrees are obtained by rule of three. In general, the higher the free HCl, the lower the relative total acidity, since a considerable amount of HCl prevents much fermentation, while the combining power of HCl with proteids rarely keeps pace with the increase of secretion of HCl.

Combined acidity is, by simple clinical methods, best determined by titrating a separate sample of chyme, using alizarin as an indicator, stopping when a purple or lilac color is reached. The difference between the free HCl reading and that by alizarin gives the fermentation acids and acid salts, which should not exceed 15°, and which may be only a few degrees in hyperchlorhydria. In ordinary cases of hypochlorhydria, catarrhal or otherwise, we may expect a free hydrochloric acidity of 5% to 10%, while the alizarin reading will vary up to 25% to 40%, the difference representing organic acids and

acid salts. On the other hand, the difference between the alizarin reading and the total acidity represents combined proteid—HCl which is normally about 20% to 30%, but which may vary considerably either way without explanation. As a practical matter, this test is neither accurate nor especially significant, unless corroborated by proteid analysis and the tests for ferments. If there is scarcity of available filtrate, it may be omitted.

**Qualitative Tests for Acidity.**—If the reaction with dimethylamidoazobenzol is uncertain, a drop of filtrate is heated, without charring, with a drop of the following:

Resorein .....	5
White sugar .....	3
Add water or alcohol .....	100

A vermilion ring, on drying, indicates HCl (or other mineral acid which, of course, cannot normally be present), the delicacy of the test being about 1:20,000. As explained in a previous article, this test may be used in titrating without an indicator to determine the proportion of HCl accurately after a preliminary rough test with dimethyl.

The differentiation of the various organic acids is not very important, nor is it important to know how much of the acidity is free and how much in the form of acid salts. Or, perhaps, it would be more correct to say that these points cannot be determined clinically with any degree of accuracy, so that we do not know how significant they might be. For instance, using congo-red or benzopurpurin, we may find no free acidity, and yet obtain a degree or two of free HCl, not to mention some free fermentative acidity which is undoubtedly present. Dr. Mark I. Knapp, of Brooklyn, has written in a very interesting way on these points, but his observations are not generally accepted by chemists.

An excess of butyric acid may be diagnosed from a strong, rancid odor. That of acetic acid is indicated by a reddish reaction with dilute solution of ferric chlorid and by the characteristic odor of the compound ether formed with alcohol. Lactic acid and lactates impart a yellow to greenish-yellow tint to almost colorless solutions of ferric chlorid. Or the color of the ferric chlorid may be masked with carbolic acid, 4% in water, or a single drop of liquor ferri chloridi may be mixed with a faintly colored solution of gentian violet, 1 or 2 cc. of the latter being used. Either of these solutions becomes yellowish or greenish-yellow on adding a drop of filtered chyme, if there is a considerable lactic fermentation. Even a moderate excess is demonstrated by the same color change on heating, and all stomach contents give the reaction if a considerable quantity is used or if the lactates are first extracted with pure ether. The quantitative determination of lactic acid is of no practical importance and, in my opinion, lactic fermentation is no more diagnostic of cancer than any other fermentation. Indeed, the diagnostic value is primarily of stagnation and only secondarily of cancer, in the sense that marked stagnation is more frequently due to cancer of the pylorus than to any other one condition. In this connection it may be repeated I have never been able to prepare a test-meal of oatmeal or other cereal free from lactic acid. In general, only a marked and persistent organic fermentation has any diagnostic significance.

Hydrosulfuric acid is detected by holding a piece of filter paper wet with lead acetate solution over a test-tube and volatilizing the stomach contents by heat. No other substance likely to be present will make the paper brown or black. Eructations may be similarly tested by having the patient expel the gas through a tube which passes beneath the surface of a lead acetate solution. Hydrosulfuric acid gas indicates proteid decomposition either in the stomach or in the intestine, with regurgitation or passage of intestinal gas through the pylorus. It is said that H<sub>2</sub>S is formed from proteids only by the colon bacillus.

**Tests for Carbohydrates.**—Starch and dextrins are

tested for by iodin. A watery dilution of the tincture may be used or the liquor. For laboratory purposes the following may be used instead of the liquor:

Iodin.....	1
Potassium iodid.....	10
Water.....	100 or 200

A bluish color indicates starch; a reddish tint, erythro-dextrin. A failure of reaction shows that the ptyalin digestion of cooked starch has passed at least as far as the achroodextrin stage. Usually a muddy, reddish purple color shows that both starch and erythro-dextrin are present and the achroodextrin stage is rarely found until at least 1½ hours after eating. Maltose may be detected by any of the modifications of the alkaline-copper-sulfate test for glucose. It is practically always present when cooked starch has been included in the test-meal, unless after a long interval, as three or four hours. In the absence of proper and, as yet, unachieved discriminations of dextrinization and quantitative standards of carbohydrate digestion in the stomach, these tests are practically valueless and may well be omitted. Even if their exact significance were worked out they would be essentially tests of salivary digestion which amount to very little physiologically. Starch can practically always be found in the residue after filtration, even many hours after a meal, as insalivation is rarely thorough and ptyalin is a weak ferment.

**Bile.**—It has been claimed that the greenish or yellowish tint of chyme, commonly attributed to regurgitation of bile, is really due to ingredients of hyphomycetes. In nearly every case macroscopically suggesting bile and actually tested by me bile has been found. It is certainly the true explanation of a yellow color not seen in the chyme at first extracted but appearing in the latter portions obtained after expression and suction, especially when the patient retches. Green bile always indicates the presence—*i. e.*, the oxidizing power—of free HCl and if the patient gives a distinct history of yellow or green vomitus and we can rely upon his observation we can safely conclude that HCl has been absent, or present, respectively. However, yellow bile may be found in chyme yielding free HCl in notable quantity, but it will change to green on standing. Aside from Gmelin's and the iodin ring test, the following may be employed: Equal parts of 1% aqueous solutions of sulfanilic acid and sodium nitrate, respectively, are mixed. To 1 or 2 cc. of the mixture a few drops of the suspected fluid are added. In the presence of bile a ruby red color develops, changing to amethyst, on the addition of one or two drops of strong HCl. If HCl is already present in the chyme, equal parts of the mixture and of chyme give a deep violet. It may be necessary in chyme containing but little free HCl to add a little more of the acid—a drop of the strong HCl.

**Proteids.**—In applying the ordinary copper sulfate and alkali test for sugar, the fluid to be examined—would not the term *investigandum* be convenient for general use?—should be added in a ring above the reagent and, if necessary, slightly warmed but not boiled. A lilac band indicates albumoses or peptones. It is almost always present in chyme, but its complete absence indicates achylia. The ordinary qualitative tests for proteids are practically valueless, but my method of centrifugal quantitative examination is of comparative value if used as a matter of routine. Dissolved albumin, which is apparently due to the action of acids but is not acid albumin in the technical sense, is precipitated by heat. After thorough centrifugalization this should amount to 2-4%. The decantate is treated with ammonium sulfate, throwing down albumoses amounting normally to a mere trace up to 4%. The decantate from this test, which still contains a minute amount of very light albumoses, is precipitated with phosphomolybdic acid, which throws down a very bulky precipitate of ammonium—if present—peptones and amido and other nitrogenous compounds. This

precipitate should amount to 20–30%. There is, as yet, no feasible method of separating true peptones from the other nitrogen compounds. If, however, a small amount of phosphomolybdic acid, preferably 1 cc. of 10% watery solution, be first added and the mixture centrifugalized, and then the same solution is added up to 5 cc.—the centrifuge tube then containing 15 cc. in all, if 10 cc. of filtrate be used as the *investigandum*—there will be found to be a fairly distinct demarcation in color between the two parts of the precipitate, the lower, more bulky part, representing more nearly the peptone. This usually amounts to about  $\frac{2}{3}$  of the total precipitate. As the albumose precipitate is small and quite different in color from that by phosphomolybdic acid, the latter test may be performed without decanting. Or the albumoses and peptones may be precipitated together with phosphomolybdic acid, ignoring the small amount of albumose which I have never found greater than 5% and seldom more than .5%. If the albumin precipitate is high and the peptone precipitate low, or if both or all are low, we may conclude that peptonization is impaired. This condition is found in general with diminished HCl secretion, chronic catarrh and cancer. If the first or second precipitates are high and the last low we may guess that the primary acidification is normal, but that the later, peptic, digestion is faulty, probably on account of impaired secretion of pepsin. If the final precipitate is abnormally high, the demarcation line is almost always relatively low, and we may infer an abnormal formation of ultra-peptone products, but the exact explanation and significance is not known. A final precipitate between 20% and 30% may be considered normal. Differential N-determinations of these precipitates have been essayed by several investigators, but practical results have not yet been reached and the methods are beyond the clinician's ability.

*Microscopic Examination.*—Various forms of starch, muscle fiber, plant hairs, cellulose, spiral ducts, diatoms, etc., are found, but are of no special clinical value, unless some medicolegal problem should arise, based on the food ingested.

Various microorganisms are found and high grades of fermentation are marked by an excess of long, thread-like forms, sarcinas, yeast cells, baseball bat bacilli, etc. While the last and thread-forms are especially common in lactic acid fermentation, no pathognomonic value attaches to such examinations, and differentiation of bacteria, etc., depends upon culture-methods.

It is worse than searching for a needle in a hay stack to attempt to diagnose cancer, ulcer, catarrh, etc., from the microscopic examination of the residue after a test-meal. Occasionally diagnostic material might be detected, but for any serious investigation with regard to these points the jejune stomach should be washed out. Scraps of exfoliated gastric epithelium are practically always found, as well as some leukocytes and mucous strings. Pavement epithelium and ciliated epithelium from above the stomach are of no direct diagnostic value but must be distinguished. Very minor traumatism by the stomach tube frequently cause the presence of a few red blood cells and the guaiac-turpentine test will then usually respond, although red cells may be seen when there has not been enough hemorrhage to meet the limit of delicacy of the hemoglobin test. Red cells resemble yeast cells, minute bubbles, fat drops, etc., but any considerable number may be detected by a skilled observer. In digested blood, hemin crystals may be developed by the use of a few particles of salt and a drop of acetic acid and by drying and examining under the microscope. Grumous blood has often passed the point at which hemin can be developed, but the brownish, irregular masses may be distinguished by one familiar with them. The appearance of bismuth must be learned by experiment to avoid confusion. Shreds of normal or catarrhal mucosa are quite often detached by the stomach tube and

it is sometimes difficult to distinguish these from indications of cancer or ulcer, although some authorities claim to be able to make the distinction in all instances. I freely acknowledge that the more I study these bits of tissue the less confident I am of their nature in any given specimen. Setting aside cancer and ulcer, it is extremely difficult to distinguish between the normal shedding of epithelium and indications of genuine gastritis. Indeed, I am disposed to think that every stomach is almost constantly in a state of localized catarrh. L. Kuttner,<sup>1</sup> in discussing achylia gastrica, makes the general statement that the study of particles of gastric mucosa is practically valueless. In many instances, however, shreds of mucosa, infiltrated with red and white cells, are found, which justify the belief that they emanate from the borders of an ulcer of some kind. In connection with the history we may differentiate between peptic, varicose and other forms of gastric ulceration. Cancer can never be diagnosed by the microscopic examination of gastric debris till it has reached an ulcerative stage—it ought not to be necessary to state such a truism. Occasionally considerable fragments of a cancer are brought up by vomiting or lavage, when a definite diagnosis can be made after teasing or cutting into sections. The ordinary, partially decomposed and digested debris from an ulcerating cancer is much more difficult of detection than has been stated by some authorities. I have never found any such fragment upon which I would be willing to base a diagnosis, yet the accumulation of probabilities by the appearances of a considerable number of such scraps has frequently led to a positive diagnosis, subsequently verified, and in no case has such a diagnosis been disproved in my personal experience.

## BRIEFS ON PHYSICAL TRAINING.

BY

G. FRANK LYDSTON, M.D.,

of Chicago, Ill.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's Hospital.

No. 1.

### The Physician Should Have a Practical Knowledge of Physical Training.

It has been said that the general trend of the profession is toward therapeutic nihilism. To this statement I would most respectfully demur. In my opinion, the present trend of medical thought is toward drug nihilism, not therapeutic nihilism. There is a most beneficial tendency on the part of the latter-day physician to rely less and less upon drugs, while seeking methods of health-building more in accordance with rational medical philosophy and along strictly physiologic lines. Preventive medicine is becoming richer in resources. Physical training has this advantage, that it is not only a very important department of preventive medicine, but it can enter largely into curative therapeutics. When it is understood by the profession generally that the physiologic training of muscles invariably results in an improvement of circulation and visceral conditions, general nutrition and all the bodily functions permanently profiting by proper exercise, the importance of the subject will be much better understood. Physical training as a distinct department of therapeutics has been neglected. Nowhere has the profession exhibited more inattention and absolute ignorance than in this particular field, unless perhaps it be in the field of dietetics. It seems to be quite the fashion for the physician to prescribe exercise in an offhand manner for his patients.

The grim humor of the situation is illustrated by the occasional prescription of the walking habit to a sick postman, and of plenty of outdoor air to a gripman on a

<sup>1</sup> *Zeitschrift für klinische Medizin.*

cable car. These incongruities, however, do not disturb the doctor. He goes right on prescribing a remedy of which he knows nothing.

The routine prescription of an abundance of walking is perhaps rarely ill-timed, but as a system of physical training, when such is indicated, it is rank fallacy. A department of physical training should be an adjunct to the chair of general therapeutics in every modern medical school. The instruction ought to be practical, not theoretic, and the various forms of physical training, which should, of course, be based upon rational physiologic principles, should be practically studied, not only upon the persons of their classmates, but upon themselves, by all students. I would suggest that practical experience in dietetics, hydrotherapeutics and electrotherapeutics should be conjoined with the practical study of physical development. This department of physical culture should also include massage and Swedish movements; these valuable therapeutic resources should no longer be relegated to irregulars and quacks. If the medical profession had done its duty in this respect, osteopathy would not have been possible.

The layman not infrequently has a valuable lesson to convey to the profession. I remember once taking an interest in an intelligent young mulatto who chanced to be working in a gymnasium which I frequented. Noticing that he had a special predilection for exercises tending to chest development, I asked him what his special object was in training.

He said that he was suffering from his third attack of incipient tuberculosis. In the two previous attacks he found that medical men could do nothing for him so he determined to take exercises to develop the chest, thinking this would help him. He improved and got apparently well both times, but had been compelled to discontinue training because of lack of time and to this fact he attributed the attack from which he was then suffering. Upon being asked if he had confidence in getting over his present trouble by training, he replied that he was sure he would get well, as he was getting better every day.

At last accounts, some years later, this man was perfectly well and taking systematic exercise as a matter of precaution against recurrence of his pulmonary trouble.

It has been my fortune to observe many persons in training in whom incipient tuberculosis, or a distinct tendency to pulmonary disease, with the usual contracted chest and weak lungs, with or without hereditary predisposition, existed, and I have accumulated ample evidence of the value of physical exercise in the prevention and cure of pulmonary tuberculosis.

So far as the value of general muscle training is concerned, there is much more to be said than it would be wise for me to attempt in the series of short papers which I purpose writing upon the subject. The individual who has systematically trained his muscles within physiologic limits is better capacitated thereby for the battle of life. In addition to the advantages of symmetric muscle development I would mention the increased activity of tissue metamorphosis and stimulation of the excretories of the body which is always beneficial when kept within reasonable bounds, but which, contrary to the ordinary belief, may become injurious. Like all other remedies which are potent for good, physical training has within it the capacity for evil.

The physician, of all men, should endeavor to attain physiologic muscular development. The impression made by the springy step and vigorous breezy manner of the physician whose muscles are well trained and under perfect control upon the *morale* of his patient is decidedly tonic.

It is a common experience that, while the phenomenal athlete and the ideal scholar are rarely, if ever, combined in the same individual, the best mental effort and the most abundant intellectual products are likely to emanate from the man whose muscular system is in

a physiologic condition—*mens sana in corpore sano*. Exceptions to this rule are abundant, but the fact remains that it is not from the Fitzsimmons and Sandow types, nor from physical degenerates, that the highest intellectual capacity is expected. It must be remembered that in such individuals intellectual development can never be, in the ordinary acceptance of the term, of a high order.

The value of a knowledge of physical training in such special departments of medicine as neurology and surgery, more particularly of orthopedic surgery, is at once obvious.

In the consideration of physical training and its methods, the end and aim of the latter should be understood to be, to express it briefly, the utilization of such physical capital as is inherent to the particular individual and to bring it up to its normal physiologic standard. The object of physical training should not be to bring the individual up to any standard save that which is determined by his natural capacity.

The character of work should be selected with this end in view, the object being to develop the muscular and visceral capacity of a given individual to the full normal standard. A small muscle under proper control, and the nutrition of which is normal, may be ideal in its development, while on the other hand a large, bulgy, illy controlled and stiff muscle is merely pathologic, and is the direct antithesis of the standard at which we should aim. Not to put an abnormal amount of muscle upon an individual whose natural capacity for muscular development is small, from the standpoint of bulk, but to develop thoroughly and make ready to his command the muscular tissue to which he is naturally entitled, should be the ultimate aim of physical training. The round, smooth, supple, "intelligent," cat-like muscle is the ideal standard.

It must be admitted that anything which tends to the physical improvement of the race within strictly physiologic limits must be of inestimable value to humanity. It needs not the testimony of artists to demonstrate that humanity has drifted widely from the ancient ideals. It is a wellknown fact that the ideal human form is very rare, that depicted by the modern artist being usually a composite, and often a very poor one. He is compelled to use one model for the torso, another for the lower limbs, another for the upper, another for the neck, another for the head, and the feet and hands must usually be taken from separate models.

It is not my intention to endorse the ideal proportion standards of the average artist, as idealism and normal anatomy and physiology do not usually harmonize in his hands. There is still, however, a lesson to be learned from the difficulties which beset him in his endeavor to secure suitable models of the human form. As illustrative of the infrequency with which figures approximating the ideal are to be found in the male, I will state that, in a series of two thousand examinations for military service, I noted but one subject who, from a casual study, would conform to my ideal of perfection of physical proportions. This individual was physically untrained, and had never performed much muscular labor. He was as ignorant as possible, and had no idea that there was anything out of the ordinary in his physical proportions.

The tendency on the part of human nature is to glorify the extremes of intellectual and physical development. The standard of intellectuality, on the one hand, is the degenerate genius, and, on the other, the physical freak. The advantages to the race, of harmonious physical and intellectual development are not appreciated as they should be. It is not well to lay physical perfection as a burnt offering on the altar of genius, nor to sacrifice intellectual culture to physical development. Neither the extraordinary genius nor the physical phenomenon are such potent factors in our social system as hero-worshippers would have us believe. It is the well-balanced

man and woman who furnish the power that moves the world. The crank genius is, after all, but an incident in the machinery. He may develop certain things in literature, science, and the arts, which constitute a long step in advance of his day and generation, but oftentimes the same things would eventually be accomplished in a normally progressive manner by the average intelligence which constitutes the mainstay of the body social. It is true there are exceptions to this rule.

The happy medium between physical and intellectual development, if acquired by the human race, would stamp out degeneracy, and, far more than this, the transitory flight of geniuses across life's horizon would raise the average of intellectual capacity of the human race. The attempt to attain either the physical or intellectual ideal, as ordinarily measured, can bring only disaster—intellectual death on the one hand, and physical death upon the other—to man, the most precious fruit of the tree of life. Both the physical and intellectual average of the human race might be raised to the physiologic ideal if man applied the same common sense rules to the breeding of human beings as he does to that of the lower animals. Under present conditions there must be a large proportion of weaklings, both intellectual and physical. A more intelligent treatment of these weaklings will, however, do much toward the prevention of disease, pauperism and crime. More attention should be paid to the bodies of the weaklings in our social system, as a direct prophylactic against evils, in the correction of which vast sums are yearly expended. When our social system expends at least as much in giving clean and healthy bodies to the individuals composing it, and especially to the young and growing children, as it does to correctionary and curative institutions, the expense of the complicated machinery of our legal and penal systems will be enormously reduced. The experience of the Elmira Reformatory in the matter of physical training of young culprits has proved the truth of the foregoing assertion beyond dispute.

## GONORRHEA IN CHILDREN.

BY

H. LOWENBURG, A.M., M.D.,  
of Philadelphia.

Lecturer on Pediatrics at the Medico-Chirurgical College, Pediatricist to St. Joseph's Hospital Dispensary.

The occurrence of extragenital infection by the gonococcus of Neisser among infants and young children is by no means uncommon. The usual seats of attack are most often found upon the conjunctivas and the mucous outlets of the body, as the mouth and anus. So great, indeed, is the frequency and so destructive are the effects of ocular infection that many States have upon their statute books laws which are mandatory in compelling the physician and accoucheur to exercise the most careful and approved methods of prevention. Gonorrheal ophthalmia neonatorum is most often encountered among the poverty-stricken and illiterate. Its origin can, in the majority of instances, be traced to those cases in which the physician is handicapped by ignorant parents or his own carelessness.

The textbooks of medicine and surgery are fully descriptive of these various forms of gonorrheal infection, and contain full accounts of the latest methods of prevention and cure. But upon gonorrhea of the urogenital tract, especially in males, they are generally silent; and apart from the mere statement that such infection can occur they leave the student uninformed as to the more important points in symptomatology and therapeutics. Gonorrheal vulvovaginitis between the ages of 2 and 5 is frequently seen, especially in dispensary practice, and is traceable to gonorrhea in the mother or nurse, unclean rags and towels and the use of infected syringes. Many apparently innocent cases of vulvovag-

initis, diagnosed as secondary to oxyuris, ascarides, filth, and other local irritants, very often may be proved to be gonorrheal by microscopic examination of the discharge.

The literature upon gonorrheal infection of the urethra in boys is very scant. Holt mentions the case reported by Poynter, of a boy of 5 who required treatment for urethral stricture secondary to an attack of gonorrhea at the age of 3. Reese records a case of specific urethritis occurring in a boy of 7, the subject of rape. That the disease is rare is unquestioned, since it has been met but twice within the past two years in a total number of dispensary patients exceeding 1,500. This fact alone is sufficient cause, however, why we should be on the alert and view with suspicion all instances of urethral discharge in young children.

One case which came under my observation was that of a colored boy, aged 8, who was the victim of rape. The second case is of sufficient interest, as to the manner of infection and complications, to warrant a full report:

**CASE.**—R. S., white male, aged 4, was brought to the dispensary of the Medico-Chirurgical Hospital with the following history: Both parents are living and well, as are two brothers, one younger than the patient.

**Previous History.**—The patient's birth was normal, and he was breast-fed for one year. Dentition was normal. He had measles at 2 years, chickenpox at 3. Otherwise he has been well.

**Present History.**—February 14, 1902. The patient complains of burning and painful urination and intense itching about the penis. When seen, he had not been able to micturate for 16 hours. There is severe pain and a feeling of weight in the hypogastric region. He cannot walk erect, but leans forward with legs separated. Examination of the penis reveals an intensely inflamed and adherent prepuce, which is in the position of phimosis with a small preputial orifice from which exudes a thick, creamy, yellowish discharge. The foreskin is edematous, and the bladder is easily palpable for 1½ inches below the umbilicus. The child is fretful and his expression is anxious. Pulse is 100, temperature 101° F.

Some smears were made and examined immediately by Drs. L. N. Boston and P. J. Craney, who reported the presence of gonococci in large numbers. The mother was questioned and denied any vaginal disease. She lived in a disreputable neighborhood, and stated that the lad was wayward and was in the habit of picking rags and cloths from refuse boxes. At night he slept with his 8-year-old brother and during the day was left in charge of a female friend. This woman also denied any vaginal discharge, and subsequent examination of the vaginal secretions of both women failed to discover the micrococcus of Neisser.

The presence of gonococci was not considered a contraindication to circumcision, the necessity for which seemed urgent to relieve the symptoms and to provide for better drainage. The operation was done under chloroform anesthesia, and within a short time a large quantity of urine was eliminated. The parts were kept moist with a wet mercuric chlorid dressing, and the cotton which received the discharge was changed frequently. Irrigation was tried, but had to be discontinued on account of the pain and fear. Within ten days the circumcision wound had healed, but the infected urethra still continued to emit its purulent discharge. Restricted diet, broken doses of calomel at times, plenty of water and alkaline drinks, together with a modified Lafayette mixture, completed the treatment, and within two months the discharge had ceased. The boy was ordered not to handle his penis nor to carry his hands to his eyes, which fortunately escaped infection.

This boy probably received the gonorrheal pus upon his hands and by this means transferred the infection to the parts involved. The lesson which this case teaches may be embodied in the following conclusions:

1. All urethral discharges in young boys should be viewed with suspicion.
2. All such discharges should be submitted to a microscopic examination.
3. Should the gonococcus be found the possibility of the case assuming a medicolegal nature should be remembered.
4. The question of rape should be carefully eliminated or conclusively proved.
5. Treatment consists in securing local cleanliness and a free action of the emunctories in conjunction with the administration of urinary antiseptics and alkalies.
6. Gonorrhea is no contraindication to circumcision.
7. Vulvovaginitis in little girls is very often due to gonorrhea.

## SPECIAL ARTICLES

## VITAL STATISTICS: A PLEA FOR ACTUARIAL ADMINISTRATION AND CONTROL OF THE GREAT RESOURCES OF PREVENTIVE MEDICINE.

BY

JOHN S. FULTON, M.D.,  
of Baltimore, Md.*[Concluded from page 289.]*

## SOME OLD USES AND NEW COMPLICATIONS OF STATISTICS.

The laboratory has of late filled so large a place in the prosecution of scientific research that other and older methods of inquiry do not attract enthusiastic and patient workers as they formerly did. The practice of numerical statement has, with the development of laboratory methods, grown to a degree of tediousness far exceeding that of vital statistics and holds hundreds of workers to tasks of mere enumeration. The statistics of hematology, for instance, although involving minute and protracted labor, are studied with marvelous patience and have become indispensable to the practice of medicine and surgery.

Numerical statement is more extensively demanded and more generously supplied at present than ever before in the history of medicine, though some of the older and no less profitable uses of the statistical method have fallen somewhat into disuse.

For the purpose of showing that studies in vital statistics may and often do point to true conclusions well in advance of the studies of minute phenomena, I venture to produce here a statement of Longstaff made in 1880 which has come to the final proof in this year of grace, about a quarter of a century after it was written. At the end of an interesting statistical study on "The Causation of Summer Diarrhea" Longstaff says: "There exists . . . a specific form of diarrhea which makes its appearance in the summer months, disappearing again with the advent of cold weather; this disease kills persons at all periods of life, but in much larger numbers at the extremes, and in by far the greatest proportion during the first two years after birth." This is a remarkably definite statement, which, if it be affirmed by the results of other and more conclusive methods of investigation, will be entitled to admiration as a feat of logical analysis.

Many of us remember the long battle of the unicists and dualists concerning croup and diphtheria. The first proclaimed unicast, Bard, appeared forty years before the word diphtheria was coined. From Bretonneau (1828) to the sixties the unicists grew numerous, and from then to the nineties the dispute was hot. It is of more than curious interest to note that the medical statisticians were unicists. When presented in graphic form the statistics of croup, diphtheria, cyanche maligna, and quinsy from 1850 to 1880 seem as suggestive as those from 1880 to the present are confirmatory of the demonstrated truths of the later period. The records display the medical mind in process of discovering its own common sense.

Another vague perception almost as ancient concerns the relation of puerperal fever to erysipelas. In 1874 Minor wrote a paper on "Erysipelas and Childbed Fever," based upon the returns of the Ninth Census and upon an epidemic of puerperal fever in Cincinnati. This paper attracted wide attention.

It happened that 1874 was a memorable year for English obstetricians, and the soul of Matthews Duncan was vexed that the unprecedented ravages of puerperal infection should be connected with the unusual prevalence of erysipelas. He published a paper in 1876 in which, by pointing out the no less striking parallelism of the rheumatic curve to that of erysipelas, he sought to prove that neither puerperal fever nor erysipelas is an epidemic disease, and that the two diseases are not etiologically related. Two years later a trained medical statistician, Longstaff, attacked by the graphic method some 89 of the causes of death found in the Registrar-General's reports, and when he had completed 1,425 of the 3,916 operations undertaken, he found himself strongly impressed with the apparent kinship of puerperal fever, erysipelas and rheumatism. He says with

regard to the former two, "I find it difficult to avoid the conclusion that they are both due to one poison" (1880). And again in 1890, on the same subject, "A relationship which holds good in the several parts of the country as well as throughout the entire area cannot be fortuitous." With respect to erysipelas he says in 1880, disregarding the settled notions of the time: "We may infer some close relationship to rheumatic fever—a point that I must reserve for further investigation." Again in 1890, having in the meantime read Duncan's paper, he expresses surprise that Duncan should have selected rheumatism as a typical nonepidemic disease, and says with admirable caution, "The term rheumatism is too vague for our purpose, and another ten years must pass before we can draw a conclusion." "Another ten years" brought Döderlein, and with respect to rheumatism, in so far as the vagueness of the term has diminished, Longstaff's opinion of 1880 might now be stated more boldly.

Not only have statistical studies pointed in this way to true relations, but they have also definitely distinguished diseases which bore superficial evidences of kinship, as, for instance, scarlatina and diphtheria, variola and varicella.

I cannot leave the subject without considering for a moment one or two comparatively new points in the practical application of the statistical method to the problems of hygiene. Some well recognized sources of error have, through the growing complexity of modern life, grown more serious and more puzzling. The classification of population according to age has always been difficult on account of false statements by young women, by old people of both sexes, and by parents with respect to the ages of children. This tendency to falsification has become more important of late years, through the influence of the laws on child labor, by the increasing difficulty experienced by men above 40 in getting employment, and by the spread of industrial insurance. Great corporations will no longer engage men who appear to be, or who admit they are beyond a certain age. Many of them also retire their employes at a certain age. Altogether the man of today is as hard beset as ever woman was by the temptation to conceal and misrepresent his age.

It is possible that a similar stress of circumstances may have operated to alter the relations of causes of death. For instance, a notable decline of the pulmonary tuberculosis rate has of late been a cause of congratulation among hygienists, while a steady and strong rise of the pneumonia rate has given them some concern. The two diseases have, in some large cities, exchanged rank.

Almost every experienced hospital physician may recall his sensations on the occasion when he first learned that his certificate of death from tuberculosis annulled the insurance claim of an impoverished family. The dispensary records of the case may have covered a period of years with occasional intervals when the patient appeared to be well. During one of these intervals he may have obtained insurance, acting in good faith, never having been informed of his disability. But no matter what may have been the moral aspects of the original contract, its outcome is in all cases distressing. The stiff uprightness that is always equal to such an occasion is a trifle beyond envy. Few attain and none aspire to moral ankylosis. One may admit that men of any and every calling can withstand the pressure of these circumstances as well, almost, as physicians, but this proposition has two cutting edges. It offers advantages to the dishonorable, and it takes advantage of the honorable. The results are possibly discoverable in the decline of the tuberculosis curve.

Mr. Frederick Hoffman has furnished conspicuously fine statistical studies of the tuberculosis mortality experienced by the Prudential among the industrial classes. Prudential does not void its contracts on account of the history of tuberculosis, and it would be of great interest to compare the tuberculosis experience of Prudential with that of companies pursuing the opposite policy. But statistics for this use are, so far as I know, not published.

If the decline of the tuberculosis rate should be in part explained by the medical perversion of the death certificate, one could face the proof without blushing for his profession, for this phase of medical certification is perfectly familiar with

regard to alcoholism, syphilis, gonorrhoea, abortion, and suicide.

The prevarication of medical men is about as unsophisticated as "peek-a-boo," and the missing data are not usually very far to seek. Since the pneumonia rate has risen with the fall of tuberculosis and with the spread of industrial insurance, one would examine first the pneumonia returns. A study of the general mortality from pneumonia alone would not suffice, but it would furnish some indications. If the age incidence of the pneumonia mortality has been markedly altered during the period of its rise, and particularly if an excessive mortality appears to have fallen upon the middle periods of life; if the occupation distribution of the pneumonia mortality has changed so as to fall disproportionately upon the wage earners; and if a similar analysis of the tuberculosis mortality shows that the gains are credited to corresponding ages and occupations, then an indictment of the death certificate will surely be found. Next, if by appeal to the figures of the companies it is found that the mortality accounts of those companies whose contracts are contestable for tuberculosis, when compared with the general mortality account, are somewhat long in pneumonia and short in tuberculosis, while the accounts of those companies whose contracts are incontestable for tuberculosis are, as compared with the general mortality, long on tuberculosis and short on pneumonia, a conviction of the death certificate must follow. That such an investigation would result in a correction of the tuberculosis rate is more likely than that the pneumonia rate would be reduced in a corresponding degree.

The doubt which is here expressed concerning both of these rates is based upon something more than suspicion, for proposals to amend medical certificates of death have several times come within my experience, and attempts on the part of claimants in insurance to suppress the facts concerning tuberculosis are often referred to in medical gossip. Observe, also, that this suspicion of error concerns the largest single problem of the day in public hygiene.

#### SUMMARY.

The natural sciences have contributed to the welfare of mankind no gifts more beneficent than those which are appropriated to medical uses. Preventive medicine, in particular, has been vastly enriched, insomuch that we seem in danger of forgetting that resources so great need to be economically administered. But even unlimited means cannot, by mere distribution, either reach the greatest number of beneficiaries or confer the greatest benefit so far as they reach.

The profits of public hygiene are realized no more in individual safety and comfort than in improved business and social conditions. It is in the latter aspect that the benefits of public hygiene are most striking and have greatest influence upon appropriations of public money to sanitary work. Moreover, the agencies themselves, whose employment leads to such results, need both the highest form of certification for their present performances and the surest actuarial basis for their future enterprises.

As certainly as the problems of transportation wait at present upon the perfection of roadmaking rather than upon improvement of rolling stock or motive power, so certainly do the "giants of the hour," the natural sciences tributary to preventive medicine, wait upon a correct and economical administration of the resources of public hygiene.

The urgent need of the moment is a thorough and comprehensive plan of accounting for vital memoranda. The sources of essential information are, speaking broadly, two, viz.:

The federal census, which, being now maintained as a permanent part of the national government, should (a) be, at the approach of another census year, better than ever prepared rapidly and accurately to count the people, making notes of all the data needed for statistical purposes; (b) should make such *ad interim* studies of the births and deaths occurring in nonregistration areas as will serve for the better correction of the enumerators' returns for the census year; (c) should commit all vital returns to the hands of a trained medical statistician who understands the moods and tenses of vital mathematics.

Local registration under State laws, embracing in their operation all the people, rural as well as urban; with substantial agreement among the States as to the essential data of

record; respecting fully the rights of registration cities to the custody of their own records; but securing absolute unity of method in statistical treatment, with an open display of both gross and net mortality and of the means of arriving at population estimates.

Local registration must cover: (a) Records of death made at the time and place of their occurrence, by the most competent persons acquainted with the facts, including a medical certification of the cause of death, the making and filing of such a record being in every instance an indispensable preliminary to the disposal of the dead body; (b) records of birth, secured by the payment of fees, by every appeal to private interest and public necessity, including, if possible, conditioning of certain privileges of citizenship upon recorded evidence of attained age; (c) records of marriage and divorce, with all such items of information as have statistical importance; (d) records of sickness, including all cases of those infectious diseases which fall within the provisions of the notification laws, all cases of sickness which come under study in the public health laboratories, all sickness which is relieved at public cost, all sickness falling under the observation of inspectors of schools, tenements and factories, and all sickness occurring in the public services, e. g., Army, Navy, police, and fire departments.

Finally, the data of vital statistics should be systematically utilized, not only for the broader purposes which have grown into common use, but for the minuter inquiries which such records may answer.

## THE IMPORTANCE OF MECHANICAL MANUAL TRAINING TO THE SURGICAL STUDENT.

BY

S. D. VAN METER, M.D.,

of Denver, Colo.

Visiting Surgeon Arapahoe County Hospital.

It is deplorable that the most superficial investigation and observation of the methods of the majority of surgeons today reveals that there are a great number sadly deficient in speed, dexterity, and ability to apply readily mechanical principles so important in the simplest surgical procedure. In making this statement it is not intended to give ground for inference that I think there is any retrograde tendency in surgical science, because it must be conceded that we have more brilliant surgical operators today than ever before, and that they are doing work creditable to the utmost degree. Let us, however, not be led into the unenviable position of believing the profession "can do no wrong." Better be honest with ourselves and admit deficiencies exist not only in the rank and file, but that all err at times.

We must admit that were we brought face to face with the proposition of having to be operated upon ourselves for some major or even minor trouble, we would quickly decline to have many surgeons of our acquaintance, who possess great reputations, perform the operation because we know they are lacking in the points mentioned.

With such conditions existing we are confronted with the question, Why is it? It certainly is not the result of any one cause, but like most evils is due to a combination of influences, chief of which, in my opinion, is the little attention that is paid in our medical schools to manual training and the practical teaching of mechanical principles. Were curriculums more thorough in that respect it would work a twofold good. A long and thorough course of such teaching would develop and train the future surgeon in manual dexterity as nothing else will; secondly, when we remember that the dream of 9 out of every 10 medical students, prompted as they are by the tangibility of operative work seen from the much haunted first row of the amphitheater, is that they will some day be sur-

geons, it would, in many cases, be dispelled by the early recognition of their own natural deficiency in mechanical aptitude, manifested by their awkwardness and inability to handle the simplest tool. We need as many good medical men as we do surgeons, and the former should receive equally as good incomes as the latter. Better let those who have and those who have no natural aptitude for surgery learn early in their course of study that they may, so far as is possible, choose wisely the branch upon which they should spend their greatest energy, time, and money. There are many graduates in medicine and surgery who, by studious application, have mastered the principles of surgery and surgical anatomy to a degree of perfection which enables them to give, theoretically, the technic of operations in the most masterly manner. Call on these same men to perform such operations, and how disappointed we may be to observe awkwardness in the very way a knife is picked up, much less handled in dissection. The number that will take hold of the handle of a hammer at the proper point, and not short up as if it were really too long, is surprisingly few. Those who attempt to sever a bone speedily by "jiggering" a saw are more numerous. Many could well learn a valuable lesson from our distastefully compared competitor, the butcher, as he divides the femur of a beef with the graceful strokes of a saw in cutting a round steak with far less muscular mutilation than is seen in the majority of amputations.

Admitting that these deficiencies in most instances are due to a lack of actual experience in the manual use of tools, or instruments, and that nothing but repeated practice in anything brings perfection in those blessed with natural aptitude, and that it is especially essential to the great majority not so gifted, it is reasonable to claim that opportunity for such experience should be open to all students of surgery whose one great accomplishment should be dexterity in the use of instruments.

How is such practice to be obtained? Not by insisting upon adding to the already long curriculum an apprenticeship at a mechanic's bench, although many practical lessons to the future surgeon can be learned by spoiling a few drills or other tools in an occasional attempt at such work. However, it cannot be too strongly recommended that all of the operative courses now given to surgical students should be lengthened, and not limited in the senior year to one or two hours of ligation and amputation work upon cadavers unfit for dissection, this being the extent of such courses in many of our medical schools. True, some have a more extensive course, but more have less or none. In every large hospital there should be a workshop for the manufacture and repair of orthopedic and other surgical appliances, and no college has a right to confer the degree of Doctor of Medicine unless its students have the clinical and other advantages only to be had in a modern hospital. Therefore I would suggest making it a requirement that all students aspiring to a surgical practice devote a certain number of hours each year in such hospital workshop making some of the simple appliances used in every-day surgical practice. If it were no more than the making of a fracture box, or a Bond splint, they will have gained a mechanical knowledge, a practical use of tools and a manual dexterity that in their future work as operating surgeons will be of the greatest value.

Since the advent of anesthetics the profession has lost the great stimulus to perform rapid and dexterous operations, viz., that of the patient's physical and mental suffering during the operation. Many patients die of "shock" who would be discharged as "cured" were the surgeons in charge able to operate more rapidly. At the same time, while speed is so desirable, haste should not be advocated at the sacrifice of accuracy. What we need most today to hold up the good name of the surgical profession and achieve the greatest good for suffering humanity is an increase in the number of good operators, competent to perform skilfully and rapidly those operations required most often. It is commendable in any surgeon to devote time and energy in devising new means or operations for the relief of conditions that at present are classed as incurable or inoperable; but the tendency on the part of some of our profession to be constantly on the alert to attempt that which no one else has ever done, or as the laity often expresses it, "see how near they can come to taking out the heart without

causing death," for the simple sake of notoriety, should be heartily condemned. It would be better for their patients, as well as their own good, did they devote their time and energy in perfecting their technic of herniotomy and appendectomy. They may think they are past masters at both, but they who feel they can improve with each successive operation as a rule do the best work, and those who devote time in mastering the mechanical principles and manual technic, so important in surgery, are more likely to be skilful, dexterous, and successful operators. We often laugh at the country boy for his lack of knowledge of customs urban, but the brilliant success of more than one of our American surgeons has been in a great part due to the store of common sense and self-reliance acquired by a youth spent in close touch with nature and her numerous practical lessons; with daily opportunity and constant necessity of application of mechanical principles so important in the development of manual dexterity, notwithstanding, in many instances, a jack-knife served as the only working tool.

### Boston Medical and Surgical Journal.

February 12, 1903. [Vol. CXLVIII, No. 7.]

1. Irrigation in Acute Urethritis. ARTHUR L. CHUTE.
2. A Report of a Case of Multiple Neuritis of Questionable Origin. ARTHUR W. MARSH; remarks by GEORGE C. SMITH.
3. Subdural Cervical Carcinoma, Secondary to Carcinoma of the Breast. E. W. TAYLOR and G. A. WATERMAN.

1.—Irrigations in Acute Urethritis.—Chute says this is not done with the idea of aborting the disease, as any antiseptic solution capable of killing the germs buried in the tissues would seriously injure the tissues themselves. The irrigation acts mechanically by washing away the products of the disease. Rather than increasing he thinks it lessens the tendency to posterior urethritis. Some of its advantages are: A great increase in comfort; speedier recovery; lessened liability to complications peculiar to the acute stage, and probably a decreased liability to late complications. The amount of discharge is much lessened, ardor is reduced, and chordee is absent. Irrigation should be instituted so early as diagnosis is made. Potassium permanganate 1:8,000 gradually increased to 1:2,000; or protargol 1:2,000 to 1:1,000 gives the best results in the early stage. In the subacute or chronic stage, silver nitrate 1:15,000, gradually increased to 1:3,000 gives the best chance of cure. For internal medication he prefers oil of sandalwood in capsules of 10 drops. The technic of irrigation is fully given. [A.B.C.]

2.—Multiple Neuritis.—Marsh and Smith report at great length a case beginning with a slight attack of pharyngitis, followed by two weeks of general weakness with freedom from pain, but great nervousness; then seven weeks of pain, swelling, and tenderness in all four extremities, with hallucinations, followed by a month of freedom from pain, but increasing mental cloudiness, and finally four or five days of high fever, terminating in death. They discuss sewer gas poisoning, rheumatism or gout, a general nervous breakdown, and tuberculosis as the etiologic factors. [H.M.]

**3.—Subdural Cervical Carcinoma, Secondary to Carcinoma of the Breast.**—Taylor and Waterman report the case. A woman of 48 began to complain two years before her death of sensory and motor disturbances in the left arm, which in 21 months went on to complete paralysis. There was later disturbance of the left leg and less involvement of the right arm and leg. One year after the beginning of these symptoms a tumor of the left breast was first noticed, which proved to be cancer. There was kyphosis in the region of the fourth and fifth thoracic vertebrae, with erosion of one vertebra. At autopsy the membranes of the cord were found thickened in dorsal and cervical region. These thickenings when seen by the microscope were typically carcinomatous. The authors believe cancer of the breast had existed a long time before it was recognized and the malignant process spread to the membranes by metastasis. Important points in connection with the case are: A growth of long standing in the immediate neighborhood, but with slight involvement of the cord. Limitation of the new growth essentially to the subdural space. Extensive motor and sensory paralyzes from involvement of nerve-roots alone. Absence of pain attributable to invasion of sensory roots. [A.B.C.]

3. The Radical Cure of Inguinal Hernia with Local Anesthesia. J. A. BODINE.

**1.—Cytolysis and Immunity.**—Prudden traces the development of present theories from the early years of the new bacteriologic era. He explains the side-chain hypothesis of Ehrlich by which he strove to account for the phenomena of antitoxic immunity in diphtheria and tetanus. He illustrates his conception by the use of graphic figures, and shows the further application of the hypothesis in explaining cytolysis and bacteriolysis. He discusses the resulting modification of the doctrine of phagocytosis and the investigations leading to the discovery of agglutinative and precipitating substances with their diagnostic and forensic bearings, and briefly reviews Welch's hypothesis as to the cause of the greater potency of infectious organisms developed in the body over cultures of the same. He gives a table showing various forms of adaptation products, with their relationships and synonyms. He dwells on the problem of securing suitable complements to act with immune substances and on the importance of maintaining sufficient of these complements in the human body as protectives against infection, noting the reduction of them by alcohol, thus explaining predisposition. He touches on the outlook for the preparation of sera which will limit or destroy malignant or other tumors. Further development of present theories may help us to understand internal secretion and those disturbances of chemical adjustment which give rise to auto-intoxication. [H.M.]

**2.—The Problem of Epilepsy.**—Clark and Prout submit the results of histopathologic examination of the cortex in 21 cases and conclude that epilepsy is a disease resulting in diffuse and profound cortical degeneration; a highly complex sensory motor phenomenon, primarily sensory with a motor expression. The lesions are a swollen nucleus, destruction of the nuclear membrane and intranuclear network; easy extraction of the nucleolus by the knife, as it becomes a loose body in the nucleus; diffuse chromatolysis and other protoplasmic changes. These lesions result in disappearance of the cell as a biologic unit and its replacement by a gliosis. The lesions are induced by a toxic or autotoxic agent operating upon an organic anomaly of the cerebral cortex, which forms the predisposition. They urge special accommodations for the reception and study of each new case admitted to the colonies, arranged on similar lines to the psychopathic hospitals abroad, and they suggest that some central scientific advisory committee be appointed to formulate a correlated plan for future research. [H.M.]

**3.—Radical Cure of Inguinal Hernia with Local Anesthesia.**—Bodine has operated on 48 cases, using local cocaine

anesthesia in all cases, and in no case was more than one-half grain used. After getting through the skin and external oblique muscle, his aim is to find the iliohypogastric, the ilioinguinal and genitocrural nerves and cocaineize them by injection into the nerve substance. This abolishes all pain. The iliohypogastric is the most constant, was found in all his cases, and is the most important. All were inguinal hernias, in patients from 16 to 76 years. Five were strangulated, and these were slightly more painful than the nonstrangulated. Of the 43 nonstrangulated cases, 6 had thick, adherent sacs, requiring scissors and gauze rubbing to separate the cord. In 5 the omentum was ligated and excised. In 1 the amputated omentum weighed 16 ounces, and was ligated in 16 sections. There was no pain in this manipulation. The appendix was adherent to the sac in one case, and was painlessly amputated without additional cocaineization. Three cases were of the congenital type. In 18 cases there was entire absence of pain; in 28 the pain was moderate, and in 2 it was acute when ligating the neck of the sac. In 3 cases of double hernia, which are classed above as moderate in pain, the second side was done with local anesthesia at the patient's request. [A.B.C.]

2. Immigration a Factor in the Spread of Tuberculosis in New York City. HENRY L. SHIVELY.
3. Tuberculous Laryngitis. J. CLARENCE SHARP.
4. The Modern Aspect of Common "Colds." JOHN ZAHORSKY.
5. Some Unusual Cases of Appendicitis from Private Practice. HOWARD LILIENTHAL.

**1.—Astigmatism cured by operation** is reported by Bull. The left eye had an inverse astigmatism of 1.75 D., due in large part to the corneal curvature being greatest in the horizontal meridian. There was also an exophoria of 6° or 8°. He made a complete (subconjunctival) tenotomy of the left external rectus, being careful not to cut the capsule much beyond the upper and lower borders of the tendon. Three days later the ophthalmometer showed that the corneal astigmatism of the left eye had disappeared. The curvature of the vertical meridian had not changed; that of the horizontal meridian had diminished. An astigmatism of 1.75 D. had disappeared and the vision had changed from  $\frac{1}{16}$  to  $\frac{1}{8}$ . Bull says that such an operation for the cure of astigmatism should be undertaken only in exceptional cases. If a tenotomy of one of the straight muscles of the eye can have the effect observed in this case, it is obvious that the tension of the external muscles has an important bearing on intraocular tension. He suggests that the cause of inverse astigmatism, sometimes progressive, in many cases of glaucoma, may be found in the position and relative tension of the ocular muscles. [C.A.O.]

**2.—Immigration and Tuberculosis.**—Shively takes up the subject of immigration and shows that it is a very important factor in the spread of tuberculosis in New York City. Of 497,791 steerage passengers inspected upon arrival at Ellis Island last year there were certified on account of dangerous contagious or loathsome diseases or of other physical causes 2,833 persons. The increase of alien immigration over the previous year was not quite one-third, yet the comparative increase of diseased immigrants for the same period was more than two to one of the entire number of diseased persons reported; only 29 were certified for pulmonary tuberculosis, one for chronic phthisis, and eight for chronic pleurisy. Shively believes that many cases of unrecognized tuberculosis were passed, as the staff of examiners is too small to permit of any but the most hasty and superficial examination. If the proportion of tuberculosis were the same for the entire number of immigrants coming to this country as for applicants for aid of the same class to the United Hebrew Charities, 4.8%, it would make the total number of the tuberculosis admitted 23,893 for the year 1902. Illiteracy renders futile the propaganda of education against tuberculosis among immigrants. [C.A.O.]

**3.—Tuberculous Laryngitis.**—Sharp divides these cases into two main classes: Cases in which the ulceration is confined to the true cords, ventricular bands and interarytenoid commissure, without infiltration of the surrounding structures;

and cases with ulceration of the arytenoids, aryepiglottic fold, true cords, and ventricular bands with infiltration, or infiltration without ulceration. He believes that this condition is always secondary to pulmonary tuberculosis. In patients with ulceration without infiltration, and with pulmonary involvement not far advanced, particularly if little digestive disturbance has occurred and the patient can well tolerate large doses of creosote, the chance of recovery is good. But if infiltration of the aryepiglottic fold and arytenoids has occurred, no matter how slightly, the patient will certainly die unless he can at once be removed to a high altitude and dry climate. If to the infiltration is added an ulceration of the aryepiglottic fold and arytenoid the patient will die in from three to six months. He should receive morphin enough to keep him comfortable and to quiet his cough. Creosote should not be given in these cases, as it irritates the mucous membrane. Cases in which the tuberculous deposit has not broken down the author prefers to send to the Adirondack Mountains. Cases in which there is ulceration of the interarytenoid commissure, ventricular band, and true cord, but in which infiltration is absent, will do well on large doses of creosote; and if the drug is well borne a large percentage of the patients will recover if they lead an outdoor life. Sharp insists upon these patients bathing every morning in as cold water as possible and sleeping in a well-ventilated room. He does not advise any spraying of the larynx. [C.A.O.]

4.—Common "Colds."—Zahorsky maintains that colds are contagious and that a relative immunity follows an attack. The immunity conferred is fleeting. The disease is prone to occur in the winter because of imperfect ventilation. Repeated colds may be explained on the ground that different germs produce disease at different times. The digestive apparatus and general nutrition should receive attention. A change of diet is often advantageous. The chronic deformities and affections of the upper air passages must be corrected. [C.A.O.]

5.—Appendicitis.—Some unusual cases are reported by Lilienthal. The first case was that of a girl aged 16, who apparently suffered from an acute attack of recurrent appendicitis. An almost solidly obliterated appendix was removed that showed no evidence of acute infection. It was noted that the ileum was thickened and injected, and that the mesentery was filled with swollen lymph nodes. The diagnosis of typhoid fever was made. Death occurred after several days. The second case was appendicitis accompanied by a severe hemorrhage from the bowel. Partial recovery followed, but some months later the symptoms again became acute, and there was a profuse discharge of dark blood from the rectum. On incision, an axial twist of the appendix with its mesentery was found. There was a distinct hemorrhagic appendicitis with clots within the organ. Prompt recovery followed. The third case was severe septic nephritis following an operation for an apparently mild appendicitis. In another case the gangrenous appendix, already perforated and containing a large concretion, was found between the walls of the mesocolon, which was itself extremely edematous. Perfect drainage was established, but death occurred three days later. A case is reported of a man of 33, who three years before and again one year before had been operated upon for suppurative appendicitis. A third attack following, the appendix, a nodular tumor, and the cutaneous cicatrix were removed. Complete recovery followed. A case is also reported in which syphilis caused delayed union in the abdominal wound which healed readily following the administration of potassium iodid and mercurial inunctions. There was no signs of syphilis, except the progress of the wound and a mealy eruption one month before operation. [C.A.O.]

5. Laboratory Aids in the Diagnosis of Typhoid Fever. E. E. SMITH.

6. The Influence of Sodium Chlorid Upon Gastric Secretion. L. B. STOOKEY.

1.—**Bacillus from a Case of Fatal Diarrhea.**—This organism described by Hiss agglutinates in high dilutions with the serum from dysentery patients and animals immunized with Shiga bacilli. Formerly this bacillus "Y" could not have been differentiated by valid culture tests from the bacillus of Shiga, and the mannite test being unknown might easily have been confounded with Shiga's organism, unless its agglutinating reactions had been carefully studied in such a serum as that from typhoid immune animals, or from the normal beef, in neither of which the true Shiga bacillus, according to the tests, agglutinates in appreciable dilutions. The bacillus described is closely related to *B. typhosus* in agglutinating and cultural characters, but can be separated by absence of motility and its reactions in the maltose and dextrin media employed. It differs from all hitherto described dysentery-like bacilli in its agglutination in high dilutions of dysentery serum. Its etiologic significance has not been yet determined. Its description seemed important to prevent its being confounded with Shiga's bacillus and its subsequent use for serum diagnosis. [H.M.]

2.—**Postdiphtheric Ocular Paralysis.**—Schwenk notes that the ciliary muscles are more frequently involved than any other portion of the muscular system except the velum palati. Diphtheric paralysis is generally bilateral, and the total hypermetropia after this exceeds all that can be rendered manifest by any cycloplegic after the patient has recovered from the paralysis. The paralysis manifests itself in two to six weeks after the attack of diphtheria, and generally passes off in about the same time. When the external muscles are affected the duration is generally short, except when the internal recti are involved. The external rectus is peculiarly liable to be affected. The seat of the lesion is still under discussion. It is impossible to account for the active pupil, the frequency of paresis rather than paralysis, and the bilateral character of the lesions on any other theory than the peripheral one. [H.M.]

3.—**Postdiphtheric Paralysis Affecting the General Nervous System.**—Peter believes the frequency of paralysis is in direct proportion to the severity of the general infection, although a severe palsy may follow mild intoxication. Diphtheria of the nares especially predisposes to both local and general paralysis. The generally accepted view is that the entire neuron, either motor or sensory, may be the seat of pathologic changes, the peripheral neuritis usually predominating, and often existing without demonstrable change in the cord. All degrees of severity are met with, from a mild, general paresis with slight emaciation to complete palsy of all the body muscles associated with cardiac and respiratory paralysis. The prognosis is good, except when the heart and respiratory muscles are involved. That extensive use of serum has lowered the mortality without diminishing the proportion of cases followed by paralysis, is explained by the hypothesis that many of the present paralytic patients are those that would have died without the serum, the palsy being due to the severity of the infection. In animal experimentation early injection of the serum is absolute protection against paralysis. Second to serum as a prophylactic Peter places absolute rest, not only during the acute stage of diphtheria, but for some days after the external evidences of the disease have disappeared. It is also the best curative agent, aided by massage, galvanism, iron and strychnin. [H.M.]

4.—**Postdiphtheric Paralysis Affecting the Ear and Throat.**—The most frequent site of paralysis is the throat. The muscles of mastication are rarely implicated. Felt has been able to find but two recorded cases of deafness. The location of the membrane has little to do with determining the subsequent distribution of nerve or muscle degeneration. Antitoxin prevents, never causes paralysis. If the injection is delayed the toxin attacks the cells of the organism and only that part is neutralized which is free in the system. Streptococcal infection, so frequently found with diphtheria, may cause paralysis, which would not be prevented by even the early injection of diphtheria antitoxin. The author recommends rest combined with the usual remedies. [H.M.]

**5.—Laboratory Aids in the Diagnosis of Typhoid.**—While the New York Health Department finds the diazo reaction present in over 90% of cases, Smith has found it distinctly less frequent. Various conclusions as to the value of Ehrlich's test are explained somewhat by the different standards as to what constitutes a positive reaction. Isolation of the infecting organism is of clinical value only when it can be expeditiously accomplished. By the use of special media the typhoid organism in many cases can be identified in 48 to 72 hours. It is difficult to get specimens in private practice except from the urine and feces, but this should be done more frequently than it is at present. A positive Widal test must be given great weight in diagnosis. Absence of reaction with typhoidal symptoms may point to paratyphoid infection, and the clinical pathologist has two additional agglutination tests to distinguish the paratyphoid species. [H.M.]

**6.—Influence of Sodium Chlorid on Gastric Secretion.**—As a result of autoexperimentation Stookey concludes that excessive quantities of NaCl apparently exert an inhibitory influence on HCl secretion, and thereby may impede gastric digestion. The ingested NaCl is apparently not directly converted into HCl in the stomach to the extent—if at all—which one might theoretically expect, assuming the theories of Koeppel and Brasch to be tenable. [H.M.]

1. Tropical Diseases: Fourth Lecture in a Course on Tropical Diseases. CHARLES F. KIEFFER.
2. A Physician's Holiday in Vichy. JAMES TYSON.
3. Remarks on the Treatment of Pneumonia. FREDERICK P. HENRY.
4. The Röntgen Treatment of Malignant Disease. CHARLES LESTER LEONARD.
5. Acute Urethritis. D. A. SINCLAIR.
6. A Contribution to the Therapeutics of Children. N. G. PRICE.

**1.—Tropical Diseases.**—Kieffer discusses epidemic gangrenous rectitis, chronic diarrhea, hill diarrhea, and sprue, psilosis or atrophic enteritis. The first is treated by antiseptics of the rectum with creolin or hydrogen peroxid, adding opium to the local treatment for the relief of pain. If prolapse of the rectum occurs it should be covered with an antiseptic powder, or with freshly ignited charcoal. This disease is very fatal, but patients may recover after the comatose stage and even after the prolapse and sloughing of the rectum. Chronic rectitis is very stubborn and resists every plan of local treatment. The only procedure of service is a wide divulsion of the sphincter and the insertion of a tube, wrapped with iodoform gauze, sufficiently large to include all the inflamed rectum. The tube is retained three days. The treatment of hill diarrhea is directed to the restitution of intestinal digestion and the maintenance of a relative degree of rest to the alimentary tract by liquid or milk diet. Small doses of calomel are of value. Clinically, sprue presents three cardinal symptoms: sore mouth, flatulency, and diarrhea. The treatment of the latter disease consists in putting the patient upon an absolute milk diet, gradually increasing it until a gallon a day is being taken and assimilated. [F.C.H.]

**2.—The Vichy Waters.**—Tyson describes a trip to Vichy. There are many minor conditions which are well treated at Carlsbad and at Vichy, cases in which a change of scene, diversion and a restful life are needed. Pure gastric derangements, such as deranged secretion and fermentation processes, renal lithiasis of the uric and oxalic kinds, should be sent to Vichy; while cases requiring depletion of the upper alimentary canal, hepatic torpor, biliary lithiasis and gout should be treated at Carlsbad. [F.C.H.]

**3.—The Treatment of Pneumonia.**—Henry confines his remarks to primary pneumonia dependent upon the diplococcus of Fränkel. The general state of the system at the time of the attack is of great prognostic significance. The tendency of acute lobar pneumonia, in uncomplicated cases, in children and in young, healthy, and temperate adults, is undoubtedly toward recovery. Pregnancy is a serious complication, the gravity of which depends upon the degree to which it is advanced. The best prophylaxis for pneumonia consists in protecting the body against cold and dampness with woolen underclothing, and the avoidance of prolonged exposure

during the inclement seasons of the year. In accordance with the fact that pneumonia is an infectious disease, the sputum should be carefully disinfected. Into the spit-cup is poured a solution containing 3% each of caustic potash and borax, which is colored red by a trace of phenolphthalein. The sputum is completely dissolved in this alkaline solution. Enough of a solution of hydrochloric acid and mercuric chlorid is added to decolorize the red alkaline solution, and when this has taken place the cup is emptied. Pain, when it interferes with pulmonary function, is injurious and demands relief. This may be obtained in the majority of cases by external applications or leeches. Occasionally these will fail, and a small dose of morphin should be given hypodermically. If the temperature remains persistently at a high level, and is associated with other marked signs of nervous disturbance, measures must be taken to reduce it. For this purpose hypodermic injections of quinin are of the greatest value. For the cough and to promote expectoration kermes mineral, 1/32 grain every two hours, is strongly advocated. Strychnia may be used to decided advantage. No drug relieves venous congestion more effectively than nitroglycerin. In the writer's opinion the most valuable of the recent contributions to the therapeutics of pneumonia is the subcutaneous use of quinin. Henry prefers the hydrochlorosulfate of quinin for hypodermic purposes, because it is the most soluble of the quinin salts. [F.C.H.]

**4.—The Röntgen Treatment of Malignant Disease.**—Leonard believes that even if recurrence does take place, the results of the treatment of malignant disease by the Röntgen ray demonstrate the efficiency of this method and that renewed treatment will free the patient from the disease. The best method of treatment seems to be the combination of early radical surgical operations and the Röntgen treatment. The best results, in the average case, are achieved through the replacing, as the result of a retrograde metamorphosis of the malignant tissue, by fibrous or adipose tissue. More rapid results, but possibly more dangerous, can be produced by the sloughing and necrosis of the pathologic tissue. [F.C.H.]

**5.—Acute Urethritis.**—Sinclair emphasizes the following: That the malaise, and to a certain degree, the pain and burning in acute urethritis are due to the gonotoxin, a subject hardly considered in former years, but of late receiving much attention from competent observers; that protargol as a hand injection, while powerful and, compared to silver nitrate, a very unirritating preparation, is useful only as an adjuvant in the treatment of urethritis and does not prevent the infection of the posterior urethra. The patient after all must seek the constant care of the surgeon and receive irrigation treatment. This applies to all other hand injections. [F.C.H.]

**6.—A Contribution to the Therapeutics of Children.**—Price concludes that heroin is a nonirritating remedy, and its dose to a child 1 year old should be  $\frac{2}{10}$  gr.; it possesses antispasmodic properties more potent than the bromids and the belladonna groups; it is a sedative to all mucous membranes, especially the mucous membrane of the respiratory tract; it diminishes peristaltic hyperactivity and hypersecretion of the intestine; this drug is completely oxidized in the symptom and produces no cumulative symptoms; heroin hydrochlorid is preferable to the alkaloid, because it is readily soluble in all vehicles; heroin hydrochlorid is compatible with the expectorants and with the other antispasmodic analgesic and sedative remedies. [F.C.H.]

#### CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

#### EDITORIAL COMMENT

**Tuberculosis in Cleveland.**—An energetic committee, with Professor William T. Howard, Jr., at its head, has undertaken the study of tuberculosis in Cleveland. The subject has been distributed among several subcommittees, and some of these have just issued their reports.<sup>1</sup> Drs. John C. Darby and Henry P. Parker have examined 658 autopsy records for

<sup>1</sup> Cleveland Medical Journal, February, 1903.

the frequency, site, and course of tuberculosis, and have found definite tuberculosis in 296%. The adding of 5.75% of cases with apical adhesions or puckering, gives a total of 35.3%; *i. e.*, more than one-third of all autopsies showed tuberculous change. This they consider (and we are sure that it is) a very conservative estimate. Active tuberculous processes were found in practically half of all cases showing definite tuberculosis. The relative frequency of tuberculosis in a few of the principal organs was in the following order: lungs, bronchial glands, spleen, intestines, kidneys, liver, and nervous system. The primary focus seems to have been almost invariably in the lungs, and occasionally in the bronchial glands. Dr. Cullen F. Welty took up the subject of the nativity of those that had died of tuberculosis during the period from 1895 to 1901, and compared the figures with those given by Köhler in his report of the tuberculosis mortality in the several countries of Europe. It would seem that the mortality for Germany and England is 1.6 times that for persons of German and English birth in Cleveland, while in the case of Ireland the mortality is almost the same. The Hungarian seems to have profited greatly by his change of residence, Hungary giving 2.5 times the mortality shown by persons of Hungarian birth in Cleveland. The mortality from tuberculosis in Cleveland, according to Dr. George Wilton Moorehouse, constitutes 8.7% of the total deaths; 55.6% of all deaths were in males; 44.4% in females. Some attention was paid to the influence of the conjugal condition upon the deathrate from tuberculosis, but no definite results were obtained, and it could not be inferred that marriage increases the liability to death from tuberculosis. Regarding the distribution of tuberculosis in Cleveland, Drs. William O. Osborn and Frederick C. Herrick found that certain districts of the city show a mortality from that disease much above that of other districts. These districts are (1) old portions of the city; (2) the part within one and one-half miles from the Square, excepting a single ward (the Twenty-fourth); (3) the parts in or near manufacturing or railroad districts; and (4) those occupied by the laboring classes. House infections were not discovered in any considerable number. In the same symposium Dr. Martin Friedrich discusses municipal prophylaxis. He advocates reporting tuberculosis cases to the Health Office, at present for the sake of the records alone. The Health Department should prepare printed instructions for tuberculous persons, which should be handed to the physicians for distribution to their patients. The physicians should see that the necessary precautions are taken, and should call in the Health Department when it is thought necessary. Dr. Friedrich also advocates a municipal hospital in Cleveland for incurable consumptives who are too poor to support themselves and need the aid of the city.

#### REVIEW OF LITERATURE

**Nutrition of the Newborn.**—To control Schlesinger's statement that undiluted cow's milk is the most rational artificial diet for nurslings, Rissmann and Pritzsche<sup>1</sup> have tried this method of feeding for 19 newborn children, using exactly the same precautions which Schlesinger advises. But few of these children gained in weight at all and only one seemed to be in a thriving condition; they conclude that it would be unwise to start with undiluted milk immediately at birth. They do not agree with investigators who advise considerable dilution, but instead propose the use of a dilution at birth of one-half, gradually diminishing this so that the child is getting full milk by the time it reaches the age of 3½ months. To support this advice a number of chemie and physiologic calculations and observations are given. [E.L.]

**Infantile Diabetes Mellitus.**—Lomax<sup>2</sup> writes a very readable article on infantile diabetes mellitus and reports two

cases, one in a male aged 3, terminating by death during coma, the other in a female of 2 years and 9 months, terminating in recovery. In the latter, fasting for 24 hours followed by absolute milk diet for two weeks produced immediate improvement. Lomax states that the most rational dietetic treatment of adult diabetics is to allow them as much carbohydrates as they can assimilate. In children, in whom the disease is more acute, it is of paramount importance to enforce the most rigid diet, a sudden transition to this giving good results while old people often rapidly fail when carbohydrates are suddenly eliminated from their diet. Arsenic and iron give better results in infantile cases than do drugs of the opium group. [A.G.E.]

**Inoculation Metastases in Carcinoma.**—Olshausen<sup>1</sup> reports the case of a woman, who 21 years ago had both ovaries removed for papillary cysts. He is of the opinion that all such tumors are carcinomas. She remained well until six months ago, when a mass began to show itself in the abdominal wall. At operation this was found to be a malignant tumor, which extended to and along one side of the previous scar, but not across it. He believes it a metastatic mass inoculated during the first operation. He believes benign ovarian cysts are also capable of producing such metastases in the connective tissue. [E.L.]

**The So-called Hardening of Children.**—Hecker<sup>2</sup> opposes the "hardening" of infants and children as it is usually conducted. To use cold water in the bathing of infants, to douche them after a warm bath with cold water, to make them sleep in cold rooms, or take them out in all kinds of weather, he considers deleterious to their general health. It does not diminish their tendency to cold, but rather increases it; it is also conducive to inducing other diseases of the respiratory tract (bronchitis, rhinitis, adenoids, etc.). He reports a number of cases where grave anuria, pneumonia, general nervousness, intestinal catarrhs, and various psychic disturbances have been traced to such a manner of hardening. He approves of a system of hardening, but it should be arranged for every individual case by the physician in attendance and no kind of hardening should ever be attempted with nurslings; they must always be kept warm. All hardening should be done gradually and almost imperceptibly in the manner of getting accustomed to a strong electric current. The idea of the hardening process should not be the lessening of parents' work and worry but rather the strengthening of the child's forces, so as to permit it to overcome inclement influences of any kind. He describes a number of methods capable of gradually producing this seasoned condition.

**Congenital and Infantile Myxedema.**—Pathologically sporadic cretinism, or infantile myxedema, may be separated, according to Pineles,<sup>3</sup> into two or more distinct diseases. The first of these, congenital myxedema, is dependent upon congenital absence of the thyroid gland. He bases this classification upon 20 autopsies made in cases of so-called sporadic cretinism, and states that he is of opinion that the greater number of cases of sporadic cretinism are really congenital myxedema. Another division is infantile myxedema; this condition arises as the result of a diseased state of the thyroid gland, the affection beginning some time after birth, usually about the sixth year. A very small number of cases of sporadic cretinism does not fit in with either of these, and they should be the only ones to retain the name "sporadic cretinism." Clinically, congenital myxedema, infantile myxedema, and endemic cretinism are easily differentiated. [E.L.]

**Pleural Effusions in Heart Disease.**—Esser<sup>4</sup> reviews the opinions of various authors concerning the cause of increased right pleural effusions over left in chronic heart disease. He reports three cases of his own, in each of which the autopsy showed very much enlarged, indurated, pigmented, and calcareous lymph glands at the right hilus, while those of the left were but little changed. The right mediastinal glands were affected. This proves the pleural effusion to be due to mechanical obstruction and not to inflammation; but ordinarily such an obstruction is of little importance, on account of the venous

<sup>1</sup> Deutsche medicinische Wochenschrift, October 16, 1902.

<sup>2</sup> Münchener medicinische Wochenschrift, November 18, 1902.

<sup>3</sup> Wiener klinische Wochenschrift, October 23, 1902.

<sup>4</sup> Münchener medicinische Wochenschrift, November 4, 1902.

<sup>1</sup> Archiv für Kinderheilkunde, 1902, xxxiv, 249.

<sup>2</sup> Albany Medical Annals, February, 1903.

anastomosis; is more frequent in myocardial disease than in valvular, because of the greater weakness of the heart muscle in the former. From the right pleural cavity the lymph is collected by the right lymph duct; this terminates in the right subclavian vein. Ordinarily, if there is an obstruction along the lymph paths, the veins will directly absorb the lymph, but when associated with cardiac weakness this is impossible, because of the increased pressure in the veins. The combination also explains the persistence of such effusions in spite of all treatment. The longer such an effusion exists the higher is its specific gravity. [E.L.]

**The Best Means to Control Tuberculosis.**—Le Cavalier<sup>1</sup> concludes that the majority of the tuberculous die because we are not given the means with which to treat them and holds that provincial governments are bound by humanitarian laws to provide for each city of more than 60,000 people a sanatorium for the indigent tuberculous. With suburban sanatoriums should be combined urban antituberculous dispensaries having a threefold object: (1) to aid there as many people as possible to prevent overcrowding of the sanatoriums; (2) to give gratuitous advice, hygienic and medical, to persons suspected of tuberculosis; (3) to visit the homes of the tuberculous, disinfect and prevent spread of the contagion. High tribute is paid the women of France and Canada for their part in providing funds for this cause and for their work, moral and humanitarian, in the homes. [A.G.E.]

**The Value of Leukocytosis in the Diagnosis and Prognosis of Diseases.**—Marcel Labbe<sup>2</sup> discusses the relation of leukocytosis to the infectious diseases, the intoxications, diseases of the skin, parasitic affections, cancer and leukemia. He believes that (1) hypoleukocytosis coincident with a grave general condition is a serious indication in which the prognosis is usually fatal. It indicates that the organism can not react nor defend itself; (2) a hyperleukocytosis of moderate degree indicates a disease of moderate gravity; (3) but hyperleukocytosis and excessive polynucleosis are indications of grave importance in which, however, the diagnosis is not necessarily fatal. They show a profound infection and also an extraordinary degree of resistance. It must not be forgotten that each individual has a characteristic leukocytosis, so that leukocytosis has no absolute diagnostic or prognostic value, and to be properly interpreted it is necessary to take into consideration all the clinical signs in each particular case. [J.H.W.R.]

**The Course and Etiology of a Hospital Epidemic of Diphtheria.**—Sixteen light cases of diphtheria were observed in different parts of one of the hospitals at Frankfort during a period of 15 weeks. To find the source of infection Cuno<sup>3</sup> examined the throats of every one who came in contact with the patient. From the throat of two of the nurses diphtheria bacilli were isolated; one of these presented the picture of chronic pharyngitis; the other had a subacute laryngitis, and cultures from her had been found negative at several examinations. The former's routine of service corresponded to the onset of the individual cases, all of them taking place while she was on duty in the respective rooms. She was isolated and no more cases occurred. Cuno is of the opinion that the one Sister carried the infection to the children, while the other was herself infected by the children. [E.L.]

**Effects of Acid Fermentation Upon the Curd of Milk.**—W. G. Murphy<sup>4</sup> believes a precipitation of the curd of milk by a fixed quantity of acid is not a fair criterion to the precipitation of the curd during digestion. When acid is added slowly precipitation is not as rapid and the curd not as heavy and solid as when it is added quickly. Certain experiments described indicate that the purer and fresher the milk the more loosely organized and easier of digestion the curd. The acid coming in contact with an alkaline milk has to transform this to an acid medium before the precipitate can be thrown down and the resulting curd is more gradually formed. In inflammatory conditions in which there is hyperacidity, the curd is large and tough. Babies can digest a stronger milk in winter, when there are fewer bacteria and less acidity, than in summer;

babies in the country where milk is obtained fresh twice daily, are less liable to digestive disturbances than city children fed on milk 24 hours old. A breast-fed child gets its nourishment more gradually than bottle-fed babies and slower precipitation occurs. [H.M.]

**Stenocardial Pain in the Epigastrium.**—Kaufmann and Pauli<sup>1</sup> report eight cases, in all of which there was stenocardial pain; the pain was violent and cramp-like, lasted anywhere from a few seconds to five hours, and usually followed bodily exertion, horizontal position, or a hasty meal, associated with abdominal distention. The quality of the food seemed in no way connected with the attacks. In some cases the pain preceded a typical attack of angina pectoris, in others there was no connection at all, but there was always anguish and a sense of oppression. The pain was situated in the epigastrium, or around the umbilicus. The patients were all middle aged men with some degree of arteriosclerosis, and often other pathologic conditions of the circulatory system. There is, during the attacks, marked tenderness over the abdominal aorta. It exists to some extent also between the attacks. [E.L.]

**Mercurial Injections in the Treatment of Syphills.**—Renault<sup>2</sup> gives his experience with this method when a hospital interne in 1868 and also details later cases. Results have been contradictory, though asepsis now avoids the occurrence of abscesses which formerly followed injections. The question is still open, both as to the method itself and the best solution to use when injection is employed. Renault is not able to satisfy himself regarding it. The question is an important one and can only be settled by comparative study of all the methods employed. [A.G.E.]

**A New Sign of Pleuritic Effusion in Children.**—S. W. Kelley<sup>3</sup> has observed that with the advent of effusion the child who has previously been lying on the affected side in order to relieve the pain due to adhesions, now instinctively turns and prefers to lie on the back or be propped up high, and avoids bending toward that side or pressing upon it. After emptying the pleura by aspiration, the patient will again turn to the affected side until the fluid reaccumulates, when he will roll over on the back. It is only when a large effusion has existed so long as to create tolerance that the patient prefers to lie on the side. When on the back there is the least pressure on lung, heart, and vessels, allowing freer breathing and circulation. The child with pneumonic consolidation may lie on the back, but does not make the marked change from the lateral to the dorsal position, and it does not refuse the lateral position. [H.M.]

**The Treatment of Barlow's Disease.**—Bolle<sup>4</sup> reports a typical case of Barlow's disease in a child of 2½ years. It had been suffering for 1½ years with diarrhea, which persisted in spite of treatment. Different varieties of milk and food preparations had been tried without avail. The child could not walk, was fretful, sleepless, and had swollen feet and legs. There was bleeding from the gums. He gave the child uncooked pasteurized milk, warm oatmeal, carrot juice and liquid yeast. Improvement was at once noticeable; later he added uncooked, diluted beef juice. Within 10 days the child was taking uncooked milk, and by the seventeenth day recovery was complete. Barlow's disease, in Bolle's opinion, is brought on by the prolonged use of sterilized milk, and its cure is dependent upon a return to uncooked milk. If cooked, seven minutes should be considered the limit of heating. [E.L.]

**Care of the Tuberculous.**—Bracken<sup>5</sup> considers three classes of cases, the uninfected, the mildly infected or incipient cases, and the advanced or probably fatal cases. He condemns the rejection by State institutions of advanced cases. These demand the same care as acutely ill and surgical patients. Municipal sanatoriums are believed to have an advantage over a single State sanatorium. It is an imperative duty to protect the nontuberculous by removing all tuberculous individuals from the homes in which they are a menace. The work of the Free Hospital for Poor Consumptives in Philadelphia is highly

<sup>5</sup> *St. Paul Medical Journal*, February, 1903.

commended. Every tuberculous patient should be told that he has that disease. These patients are hopeful, and the physician must have their cooperation. Notification is advisable. [A.G.E.]

**Morphin Poisoning in Early Childhood.**—Katzenstein<sup>1</sup> reports the case of a child, 24 days old, which was given a powder containing 0.007 gram ( $\frac{1}{3}$  grain) morphin. The symptoms of poisoning consisted chiefly of tonic contraction, with recurring eclamptic convulsions, and cramp asphyxia, marked lowering of temperature, cyanosis, irregular heart, pin-point pupils; no vomiting occurred. The child recovered, chiefly due to long continued artificial respiration, heat constantly applied locally, hot rectal enemata, and subdermal saline infusions. It was 26 hours before the child was considered safe. Albuminuria persisted for six weeks. [E.L.]

**Antistreptococcic Serum in Scarlet Fever.**—Baginsky<sup>2</sup> examined the throats of 701 children and found streptococci in 696. Streptococci were found at autopsy in the organs of 100 bodies of scarlet fever patients. Hence he concluded that scarlet fever is caused by the streptococcus. Four cases are reported in which the patients were treated with the new Aronson antistreptococcic serum. The patients improved and finally recovered. Baginsky employed 20 cc. injections two or three times during the course of the disease. He considers this new serum a success, and although its action is slow, yet its effect is of long duration. [W.E.R.]

**Angiosclerosis of the Intestinal Arteries.**—Ortner<sup>3</sup> reports the case of a man of 55 who, two to three hours after every large meal, was seized with violent burning pain around the umbilicus and over the ileocecal region. The ascending and transverse colon became plainly visible, the sigmoid flexure contracted, and he complained of abdominal distention, dyspnea, oppression, belching, etc. There was no visible peristalsis. These symptoms always lasted several hours. Constipation was marked in spite of all treatment. He died of septic peritonitis several days after an exploratory laparotomy. The autopsy showed chronic endarteritis of the thoracic and abdominal aorta and all its branches. The case is evidently analogous to Charcot's intermittent claudication of the lower extremities. As the result of the sclerosis of the vessels, there is produced during the activity of the bowel an ischemia in the area supplied by the mesenteric vessels; this induces a secondary spasm and the symptom-complex above described. [E.L.]

**Concerning the Detection of Lactic Acid in the Gastric Juice.**—Bönninger<sup>4</sup> has made a large number of tests in all sorts of patients to settle the dispute concerning the detection of lactic acid in gastric contents. He says if a distinct ferric chlorid reaction is obtained after the use of Ewald's test-breakfast, lactic acid is present; in cases of motor insufficiency the presence of lactic acid is proved if a strong reaction is obtained from the lavage material after a night's fast. Riegel's test-meal is of no value. Should motility be good, should there be suspicion of lactic acid fermentation, and a test-breakfast give a reaction not absolutely positive, a liter of gruel should be given and removed after 2 to 2½ hours. A positive result always indicates the presence of lactic acid. [E.L.]

**A case of chronic empyema of the frontal, ethmoidal and both sphenoidal sinuses,** with extensive necrosis, complicated with adenoma of the posterior, ethmoidal and sphenoidal regions (and a review of the literature) is reported by Bryan.<sup>5</sup> [A.O.J.K.]

**Leukemia and Miliary Tuberculosis.**—Quinke<sup>6</sup> reports two cases of leukemia and one of splenic pseudoleukemia, in each of which the development of miliary tuberculosis caused a remarkable diminution in the size of the spleen, and in the leukemic cases caused a pronounced reduction in the number of leukocytes. Since other infectious diseases influence leukemia in the same manner, it may be assumed that the infectious processes produce substances which act destructively on the leukocytes. According to Lazarus, it is probable that in the ordinary course of leukemia a somewhat rapid cell destruction

is going on, and that this destruction is offset by a corresponding cell production. But under the influence of miliary tuberculosis the new formation of leukocytes is reduced to a minimum. This influence has suggested to Quinke the idea that the administration of the tuberculosis toxins, as contained in tuberculin, may be of therapeutic value. He tried tuberculin injections in six cases of leukemia. In three incipient tuberculosis had been suspected, and a febrile reaction was produced. In the other three cases there occurred a marked reduction in the number of leukocytes and size of the spleen, and a decided improvement in the general symptoms. [B.K.]

**Scarlatiniform Serum Eruptions During the Course of Diphtheria.**—Leiner<sup>1</sup> reports a number of these cases, all of which turned out to be true scarlet fever. Of 297 diphtheria patients, 22 showed this exanthem. They all occurred within five days of the serum injection, were followed by typical desquamation; a number of them had glomerulonephritis as a sequel. The eruption was contagious to other children; the tenacity of the contagium was great, and was not destroyed in every case by formalin disinfection. When transferred to the scarlet fever department such children never developed scarlet fever. All these points make the author certain that he did not have to do with scarlatiniform eruptions, the result of a serum injection, but with true scarlet fever. [E.L.]

**Diphtheria With and Without Antitoxin; 159 Cases.**—C. G. Kerley,<sup>2</sup> in calling attention to the immunity of the very young, records that in an epidemic covering three years in an institution where there were constantly from 75 to 100 infants from three weeks to six months of age, but one took the disease. In suspicious cases he uses antitoxin without waiting for a culture, giving 2,000 units to children under one year, and 3,000 to those over one year. If after 12 hours no improvement has taken place, he reinjects. If there has been a fall in temperature and the membrane has taken on a ragged, granular appearance, he waits 12 hours more. If then the membrane remains unchanged or shows fresh deposit, with increased temperature and prostration, the antitoxin is repeated, and so on until the membrane disappears. When in doubt, intubate; so when in doubt, inject. About 20% develop urticaria, which is annoying for a few days. He has seen no other unpleasant symptoms. [H.M.]

**Diagnosis of Pulmonary Cavities.**—Cybulski<sup>3</sup> says if the ear is held close to the widely-opened mouth of the patient, and he is told to take a deep breath, sonorous and metallic rales are heard which are identical with those heard while auscultating the cavity in the ordinary manner. This sign is of importance in case the cavernous rales are obscured by other noises originating in the surrounding tissues. [E.L.]

**Prophylaxis of Tuberculosis.**—Roberts<sup>4</sup> considers first how the healthy individual may avoid contracting the disease, and second, how the tuberculous individual may avoid giving the disease to others. The control of the spitting habit receives a large share of attention. Chicago has an antisputting law, etc., but an impression is not yet made on the people. The American habit of spitting can nowhere be entirely stopped, and authorities should be made to place receptacles in all public places or conveyances. Dry sweeping of the city streets is criminal. Compulsory registration of cases will come later, but the time for enforcing it has not yet arrived. [A.G.E.]

**The Relations of the Enlarged Thymus Gland to Sudden Death.**—After reviewing the cases reported in literature concerning "sudden death as the result of hypertrophy of the thymus," and discussing the reasons given by different authors for and against the possibility of an enlarged thymus producing death, Penkert<sup>5</sup> reports two cases in support of the theory. In both of them no other cause for sudden death was found except the enlarged thymus gland. He concludes that an enlarged thymus without anything more is capable of producing difficulties in respiration; it may even completely compress the trachea, and through this indirectly produce air hunger and death. [E.L.]

**The Pancreas in Cirrhosis of the Liver.**—Steinhaus<sup>1</sup> reviews the literature on the subject of the relation of diabetes to diseases of the liver and pancreas, and details the autopsy findings in 12 cases of cirrhosis of the liver. Eleven of these cases showed a chronic interstitial inflammation of the pancreas, similar in each case to the condition found in the liver of the same subject. In only one case were the islands of Langerhans affected. The diminished tolerance for sugar frequently observed in cirrhosis of the liver is therefore probably due to the implication of the pancreas and not to the liver condition. It is not necessary to classify separately the glycosurias accompanying cirrhosis of the liver, arteriosclerosis, pancreatic disease, etc. Rather is it to be inferred from all recent investigations that every case of glycosuria is probably due to some disturbance in the function of the pancreas, and that this organ alone controls the carbohydrate metabolism of the organism. [B.K.]

**Congenital Diabetes Insipidus Associated with Epilepsy Arising After Insolation.**—Lichtwitz<sup>2</sup> reports the case of a young man, who from birth had an insatiable thirst, so much so that he drank of the water he was bathed in. He had polyuria. As he grew older his deficient intellect was marked. He was always weak, but no convulsions occurred. At the age of 23, after an afternoon of hard work in the sun, symptoms of heatstroke appeared, and two weeks later he had his first epileptic seizure. They have been frequent since. The author believes the cause of the diabetes, deficient intellect, and microcephaly, to be a congenital brain anomaly, and that the epilepsy was induced by the sunstroke. [E.L.]

**Arizona as a Resort for the Tuberculous.**—Stroud<sup>3</sup> writes from a personal experience of 20 years in Colorado, California, and Arizona, and considers Phoenix as having the fewest disadvantages and most advantages of any place in the United States. He speaks of three winter resorts, Yuma, Phoenix, and Tucson, these having altitudes of 90, 1,080 and 2,500 feet respectively, and two summer resorts, Prescott, 5,500 feet, and Flagstaff, 7,000 feet. Roughing it will never do for the tuberculous, and fresh air and sunshine, with unexceptionable food, must be secured without this element. Rest and exercise must be adapted to the individual case. Stroud protests against the action of physicians regarding these points, most patients sent to Arizona coming with instructions to ride, drive, play baseball, football, etc. Rest is harder to enforce than any other measure, and patients who indiscriminately follow the above advice of their home physicians bring on injurious and often fatal results. [A.G.E.]

**The Results of Sanatorium Treatment of Tuberculosis.**—C. J. Macalaster<sup>4</sup> believes that if we are guided only by the registers of institutions we shall get wrong impressions concerning the real results of treatment, a considerable proportion of the "cures," "arrested cases," and "greatly benefited cases" subsequently breaking down again. The Germans have taken great pains to establish data concerning permanence of cures in connection with certain insurance institutions. Their statistics do not give great encouragement as to absolute permanence. From six months onward after dismissal from the sanatorium there is a rather rapid decline in the capability of the patients to work, and by the end of four years only 20% are wholly or in part capable, the remaining 80% being either dead or incapacitated. Lasting benefit can be obtained only by suitable surroundings after treatment, or by emigration to favorable climates. It is difficult to select cases suitable for sanatorium treatment. Some of the earliest ultimately break down and some in which there are cavitation become to all appearances quite well, and the latter should be given a chance. The sanatorium does much good in prolonging life and in educating the public in preventive medicine. [H.M.]

**Palpation of the Pylorus.**—Normally the pylorus is covered by the left lobe of the liver and cannot be felt. If the liver is displaced upward, or the stomach downward, it can be palpated. The transverse colon can be felt distinctly some dis-

tance below it. Obrastzow<sup>1</sup> was able to palpate it in but nine instances in 900 cases, but he thinks if all patients were regularly examined for this organ it could be felt oftener. He relates briefly the nine cases. [E.L.]

**Sanatoriums and Hospitals for the Tuberculous.**—Klebs<sup>2</sup> states that to accomplish the desired ends of sanatoriums, and to insure the adoption of their rules by patients after they return to their homes, the arrangements must be of the simplest type. Too often their complication is a hindrance. Covered walks connecting cottages are better than ordinary galleries. Day rooms, except those for meals, are but little needed, and to make them too attractive is a mistake. The kitchen should be so placed that patients will not be annoyed by its smell, this important point being often neglected in the building of sanatoriums. The statement is made that nearly all the German sanatoriums are founded for economic rather than humanitarian reasons, organs of legal insurance being the prime movers in the effort to return people to work. Tuberculous children in all countries are too much neglected. [A.G.E.]

**Lobar Pneumonia with Consecutive Acute Pemphigus in a Child.**—Moos<sup>3</sup> reports a case of acute croupous pneumonia in a child of 2½ years. On the ninth day of the disease numerous vesicles containing a clear fluid appeared on the chest. They grew rapidly in size, appearing at the same time over other parts of the body. The child's condition became critical. Desquamation followed several days later, and about the same time the pneumonia terminated by lysis. The author considers it a case of mild infection, the acute pemphigus being engrafted upon the pneumonia. [E.L.]

**Importance of the Sanatorium in the Crusade Against Tuberculosis.**—Elliott<sup>2</sup> speaks from the experience gained as physician-in-charge of Muskoka Cottage Sanatorium. Attention is called to the difference in meaning of *Sanatorium* and *Sanitarium*, and their wrong synonymous use. The proper location and arrangement of sanatoriums are considered, followed by the means of treatment, including aërotherapy, diet, dress, disposal of sputa, constant supervision of patient, and medicinal. The results are shown by the fifth annual report of Muskoka. During the year 102 patients were treated, of whom 28 were discharged apparently cured, and 45 with disease arrested. Of 84 with bacilli in the sputum, 31 became free under treatment. The average length of stay was 169 days. Sanatorium patients learn hygiene and the rules of health, and are missionaries among their friends when they return. [A.G.E.]

**The Blood in Ulcerous and Gummatous Forms of Syphilis.**—Löwenbach<sup>4</sup> and Oppenheim add to their previous investigations in the early stages of syphilis the results of their present investigations in the later stages. They detail the symptoms and blood-counts in 36 cases, and draw these conclusions: In tertiary syphilis the hemoglobin and iron content of the blood are considerably diminished. Neither factor is influenced by the usual therapy. The iron and hemoglobin determinations correspond fully with each other. The number of red and white blood-corpuses varies within normal limits. [B.K.]

**The Intestinal Action of Atropin with Reference to Its Use in Obstruction.**—Pal's<sup>5</sup> experiments justify the following conclusions: Atropin injures the nerve endings of the pneumogastric and splanchnics, sometimes paralyzing them completely. The muscular coil of the intestines and the ganglia governing peristalsis are not injured. The intestinal tone is considerably diminished for a time, but as the intestines are made less susceptible to inhibitory influence, the conditions for intestinal motion are made more favorable. To produce these, doses of morphin and opiates produce similar results. Atropin is therefore useful in dynamic and paralytic obstruction in cases in which the obstruction is a symptom and not the disease. Atropin should be rigidly excluded when true stenoses are suspected, or when the nature of the condition is in doubt. It may, beside doing harm, obscure the clinical picture and prevent an operation at the proper time. [E.L.]

**A Case of Intestinal Obstruction Treated With Atropin.**—Gebauer<sup>1</sup> reports a case of intestinal obstruction due most likely to adhesions which, as operation was refused, was treated with hypodermic injections of atropin. The dose varied from 1/65 to 1/10 grain daily, and was followed at first by relief of some of the symptoms, but neither bowel movement nor flatus resulted. All symptoms returned with greater violence, the patient dying on the seventh day. In mechanical obstructions atropin is valueless, and in all cases in which such an obstruction cannot with absoluteness be excluded, no time should be wasted trying atropin. [E.L.]

**Tuberculosis of Lungs in Early Infancy.**—Hohlfeld<sup>2</sup> reports two cases of pulmonary tuberculosis in infants 7 and 10 months old. The mother of the first child had died of tuberculosis a short time after its birth. The symptoms and signs in both pointed clearly to lung affection with its principal seat in the right upper lobe. Cavities were diagnosed in both of them during life, and sputum collected directly from the pharynx was found loaded with tubercle bacilli. The autopsy of the first case showed a large cavity in the right upper lobe, with miliary tubercles scattered through the rest of the lungs. In the second patient the cavity signs were traced to several bronchiectatic dilations, which were surrounded by tuberculous infiltration. Almost all the organs showed tuberculous nodules. [E.L.]

## GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### REVIEW OF LITERATURE

**Geographic Distribution of Stone and Calculus Disorders.**—Reginald Harrison<sup>3</sup> asks the question, has the study of the geographic distribution of calculi added to our knowledge of their causes, and if so, to what extent? He says that no one disputes that calculus disorders prevail more largely in some sections of the country than in others. The prevalence of calculi in some portions of India is well known. They are likewise plentiful in the eastern counties of the British Isles, whereas urinary calculi in Ireland are remarkably rare. His idea is that when we recognize fully and understand accurately the formation of urinary calculi we will be better able to institute some means not purely empirical which will prevent their formation. This could probably be accomplished if Rainey's views on molecular coalescence relative to the causes and formation of stone are accepted. Stone outside the human body can be formed artificially if Rainey's directions are carefully followed. The element of coalescence must be present as well as the necessary salts. Presence of urinary salts cannot possibly lead to the formation of stone unless the element of coalescence, whatever it may be, is present. Geographic considerations would seem to indicate the presence in certain districts of conditions necessary to effect a concretion of the normal or abnormal supply of concretible material, though these conditions are poorly understood. Our object should be to introduce some means to combat these conditions which lead to the concretion and preserve the salt in soluble form until excretion takes place. The author refers to a former paper in which he analyzed 110 cases on which he had operated for stone by various methods with a mortality of only six. This seemed promising, but when he realized that in the 110 persons 23 were known to have had recurrences of stone to some degree the result seemed serious. The author then began the study of some means to prevent concretion of the urinary salts within the viscous, and his later statistics as to recurrence are much more promising. These means are not detailed to great length, but change of climate, hygiene, certain waters, certain drugs, are mentioned as the agents with which the tendency to recurrence are combated. [A.B.C.]

**Operative Treatment of Pulmonary Tuberculosis.**—Landerer<sup>2</sup> advises operation in stationary or slowly advancing cases in which cavities are present. If they are situated in the

lower lobes operation is almost imperative, as such cases rarely do well with medical treatment. Moderate fever is no contra-indication. Acute cases are not suitable for operation. Tuberculous individuals take the anesthetic (chloroform) well as a rule. The operation should be performed rapidly and hemorrhage avoided. Landerer makes vertical L-shaped, T-shaped, or folding-door-shaped incisions of considerable length, resects the ribs quickly, going beyond the boundaries of the cavity in his resection; drains the base of the incision and closes the skin wound, his idea being to remove the rigid chest-wall, thus permitting the cavity walls to collapse; he rarely opens the cavity. He has operated on seven patients, all of whom were in advanced stages of the disease and hopeless; 2 were temporarily cured, 3 improved, 1 undecided, and the other 3 were certainly not injured by the operation. His conclusions are: The avoidance of operations in pulmonary tuberculosis is unjustified; such patients stand thoracoplasty well. Only in very rare cases do large cavities remain stationary. Thoracoplasty produces considerable improvement, even temporary cures. Operative interference should be especially undertaken in cavities of lower lobes. [E.L.]

**A Case of Congenital Lateral Ventral Hernia.**—Steinhardt<sup>1</sup> reports the case of a child three weeks old, which since its birth presented on the right side of the abdomen a soft mass the size of its fist; it presented all the characteristics of a hernia. At autopsy two weeks later this diagnosis was confirmed. The hernia was produced through the deficiency of all the muscles in this region, the external and internal oblique, as well as the transversalis abdominis, being absent at this point. The abdominal wall at this point consisted of only the skin, subcutaneous tissue and peritoneum. No other malformation existed. [E.L.]

**Bullet Wound of the Bladder and Both Hips.**—Goodman,<sup>2</sup> lately civil surgeon in South Africa, reports the case of a private who was shot, the ball entering 2 cm. above the right trochanter and emerging immediately behind the left sacrosciotic notch. The exit wound was large, ragged, and suppurating from a urinary discharge eight days after its infliction, when the patient came under the author's observation. It was evident that the bladder had been punctured by the ball. The author instituted perineal drainage at once by Cock's external urethrotomy method, and a drainage tube was placed in the wound. The entrance wound had healed, the exit wound was scraped and a drainage tube inserted. Later, this wound refusing to heal, a counter opening was made behind the left great trochanter. Recovery was uneventful. The following points are noteworthy: In all bladder wounds in which urine is escaping it is not enough to empty the bladder by a catheter, but it is advisable to drain the bladder by a catheter through the perineum at once, and to keep this drainage up continuously until the bladder wound is healed. The perineal catheter completely drained the bladder, the wound in which healed within 14 days after perineal drainage was established. The perineal wound healed without trouble in about 10 days; indeed, a fistula very seldom results after a Cock's perineal urethrotomy. [A.B.C.]

**The Hartley-Krause Flap in Hemorrhage from the Middle Meningeal Artery.**—The value of this flap as a means of access to the middle meningeal artery is highly extolled by Plummer.<sup>3</sup> He is not in accord with Krönlein's statement that this flap will not expose a hematoma posticum of the latter's classification. Such a hematoma has of course no definite limit but if it is of fairly large size its anterior edge will be exposed at the posterior superior border of the flap. If not exposed the opening can be easily enlarged. In 60% of Plummer's cases the artery ran in a bony canal and was ruptured in turning down the flap, but it is in full view and easily secured. Two cases of meningeal hemorrhage are reported, one resulting fatally from fracture of the base and hemorrhage into the ventricle. The rectal temperature in that case was 107° before death and 109.5° postmortem. [A.G.E.]

**Treatment of Empyema.**—Isreal<sup>4</sup> removed two inches of

<sup>1</sup> Deutsche medicinische Wochenschrift, November 20, 1902.

<sup>4</sup> Deutsche medicinische Wochenschrift, November 20, 1903.

the eighth rib, external to the costal angle, from an empyema patient and opened the abscess in a horizontal direction. After four weeks, during which the abscess did not get smaller, he resected the ninth rib for 1½ inches, and continued the incision downward in a vertical manner. Drainage now was perfect and the patient was discharged cured after 10 days. He has adopted this method of incision and opening in all cases since, extending the vertical limb to tenth rib in many cases. The advantages are the complete evacuation, the natural drainage, irrigation is made unnecessary, the cavity closes rapidly, hemorrhage is easily controlled, and cough is almost unknown. [E.L.]

**Total Extirpation of the Prostate by Freyer's Method.**—Elsworth<sup>1</sup> reports the case. The patient was aged 67. He had lived a catheter life for the last 12 months, but recently had required the assistance of a physician for his relief. The prostate was much enlarged, especially the right lobe—was smooth, firm and elastic. The patient was exceedingly frail but insisted upon an operation for his relief. Under anesthesia a coudee was passed and the bladder irrigated with hot boric solution. The bladder was then opened by the suprapubic route. The mucous membrane over the prostate was snipped through with scissors and the front finger of the left hand insinuated into the opening thus made. The finger was carried over the surface of the prostate, and the fibrous bands connecting it with the surrounding tissues were broken down. The only difficulty occurred in separating the apex of the prostate from its capsule. The whole prostate was enucleated, raised into the bladder and delivered with a volsellum. The hemorrhage was free for a short time, but rapidly ceased under the application of a hot boric solution. Suprapubic drainage was left in and the bladder was irrigated with hot boric solutions daily. Seven weeks after the operation the patient was comfortable and was able to retain the urine from two to three hours at a time. Later the length of time was much extended and the patient made a complete recovery. The tumor removed weighed 3½ ounces. The repair of the torn ureter did not seem to produce any untoward effect except increase of hemorrhage. [A.B.C.]

**Diagnosis of Acute Glanders in Man.**—Based upon a clinical observation and autopsy of a personal case, and a consideration of all cases thus far reported, Koch<sup>2</sup> discusses the diagnosis of acute glanders, which he considers a difficult diagnosis to make. Ordinarily the period of incubation is three to five days, during which the patient complains of the symptoms of malaise. His patient, a veterinary surgeon, had been complaining for three days, when he was taken with high fever, and a small pleural effusion appeared; he soon became very ill. A large mass developed over the lower left chest-wall, which required incision. Two days later the characteristic eruption appeared, and only then could the diagnosis of glanders be made. Hundreds of red spots, similar to flea-bites, came out all over the body, which quickly grew to pea-sized pustules with serohemorrhagic contents; they were surrounded by a red halo; they ruptured, producing ulcers. Pustules are an expression of general infection and are a bad sign. Boils, abscesses, lymphadenitis and lymphangitis are usually a very prominent sign. His nose became erysipelatous, and the nasal mucous membrane became diseased. The discharge, bloody mucus, contained the characteristic organisms. He died on the twelfth day. In spite of the gravity of his illness he never once considered his life in danger. The lungs and spleen presented characteristic lesions; the other organs showed cloudy swelling. In this case the disease was acquired through the respiratory tract, as shown by the large lesions in the apices of both lungs. Organisms were cultivated from the pus, the nasal secretions, and the urine. [E.L.]

**Internal Urethrotomy.**—Lockewood<sup>1</sup> finds fault with the various urethrotomes, and says that the ideal one should be small enough to pass a stricture of very narrow caliber, and that it should cut accurately from behind forward. To meet these requirements Teevan's instrument and that of Thompson are unsatisfactory. The author then calls attention to the

instrument devised by himself, which possesses all the advantages and none of the disadvantages of the two instruments above named. Illustrations are given and the instrument described in detail. [A.B.C.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Hysterectomy for puerperal sepsis** as discussed by the Fourth International Congress of Obstetricians and Gynecologists in Rome, September, 1902.—Vineberg<sup>1</sup> quotes Fehling's dictum that the attempt to divide the various forms of puerperal infection bacteriologically cannot be considered thus far as successful. Fehling is not an advocate of hysterectomy for puerperal sepsis, though it might be justifiable in those cases in which the sepsis is of uterine origin, due to retained placenta which could not be removed by the ordinary methods. He does not consider the results obtained by ligating the thrombic pelvic veins encouraging. Leopold divided the cases of severe puerperal sepsis into six groups: 1. Cases in which the pyogenic germs have penetrated the uterus and set up a general peritonitis. Hysterectomy in these cases would be useless; for the infection is now in the peritoneum and there should be an attempt to treat the peritonitis surgically. 2. Cases in which the pyogenic germs attack particularly the venous system and lead to a septic thrombosis. In some of these removal of the uterus is sufficient, in others the affected veins should also be removed. 3. Cases in which the infection principally affects the endometrium and extends and becomes localized in one or other of the adnexa, in which case the proper procedure is the removal of the affected ovary. 4. Cases in which all the symptoms point to multiple abscesses of the uterine muscularis and pelvic peritonitis. In some of these drainage of the pus foci may be sufficient, but if the uterus is thickly studded with small abscesses its removal is necessary. 5. Cases in which during labor severe bruising is inflicted upon pelvic tumors, causing gangrene and subsequent peritonitis and often requiring hysterectomy. 6. Cases in which putrefaction of the uterus occurs in consequence of retained placenta which cannot be removed by the vagina and hysterectomy becomes necessary. Vineberg agrees with Leopold's conclusions. [w.k.]

**The Neighboring Lymph Glands in Uterine Carcinoma.**—In a Vienna hospital a histologic and pathologic study was made of the lymph glands removed in 141 cases of uterine carcinoma. Wertheim<sup>2</sup> states that in 35% of these cases the glands had been attacked by the cancer. In nearly all of these they were more or less enlarged; but the long, spindleformed, very thin glands which lie between and near the large vessels showed no signs of carcinoma. About 30% of the cases showed enlarged glands, although no evidences of carcinoma could be detected, the enlargement being due to hyperplasia and infiltration. The region most frequently affected was that between the external and internal iliac arteries and the inguinal region, toward the obturator foramen. In the other third of the cases there was not the polymorphic, alveolar formation of the others, but tubular, cylindrical, often cystic cells with mucous filled spaces. Wertheim describes in detail the formation of these glands; and in order to answer the question whether there was any causal connection between their formation and the presence of uterine cancer, he had two of his pupils examine the lymph glands taken from 80 corpses without any cancer, and in none of these was there a like condition found. Hence he concludes that where the peculiar cell structure described occurs in the lymph glands we have to do, not with anything caused by disturbance of development, but with metastases of uterine cancer. [w.k.]

**Anuria in a Case of Ovarian Tumor and Pregnancy.**—Anuria from the pressure of a nonmalignant tumor is exceedingly rare, and those recorded have been pelvic tumors which pressed upon the ureters. Bernard Pitts<sup>3</sup> reports a case which

<sup>1</sup> British Medical Journal, January 17, 1903.

<sup>2</sup> Archiv für klinische Chirurgie, Vol. lxxv, p. 37, 1902.

<sup>1</sup> American Gynecology, January, 1903.

<sup>2</sup> Zentralblatt für Gynäkologie, January 24, 1903.

<sup>3</sup> Lancet, January 31, 1903.

is exceptional in that the pressure appears to have been upon the kidneys and their vessels. The patient, a woman of 44, was in the sixth month of pregnancy, complicated by the presence of a large ovarian tumor. After admission to the hospital, the urine became very scant and albuminous in spite of the treatment until only one ounce in 24 hours was passed. Symptoms of uremia set in, the temperature began to rise, and life was seriously menaced. Hence immediate operation was deemed necessary. The opening of the abdomen showed a large multilocular tumor, partly solid, and the fluid so thick and tenacious that repeated tapplings failed to reduce its size. The tumor had no proper pedicle, and was so attached to the ureters that the latter had to be sacrificed, and both were removed as rapidly as possible. No careful examination of the ureters was possible, but it was clear that the pressure was in the upper part of the abdomen, and upon the kidneys themselves. After operation anuria ceased and the patient ultimately recovered. [w.k.]

**Atypical Cases of Ectopic Gestation Illustrating the Difficulty of Diagnosis.**—Grandin<sup>1</sup> asserts that the classic symptomatology of ectopic gestation is the exception, and he believes that scores of women have died and many still die from unrecognized ectopic gestation. He states three axioms which the wise physician should ever bear in mind: 1. Any woman whatever, married or single, during her period of sexual activity, may be subject to this malignant disease, and the man who suspects every woman of having the condition is less liable to err in diagnosis. 2. Hemorrhage from the genitals of a woman who has subjected herself to the possibility of conception, means that if she be pregnant it is not after the normal fashion. 3. We should endeavor to forget the symptomatology of ectopic gestation copied from one textbook to another, and reconstruct a symptomatology which eliminates amenorrhea and enlargement of the uterus as symptoms, but which lays stress on the fact that colicky pain is diagnostic of impending or actual rupture. Any woman who complains of deviation from the normal as regards menstruation may be carrying an ectopic gestation. These points he emphasizes by the recital of eight cases seen or operated upon by him in recent years. He advises in each and every suspicious case in which diagnosis is uncertain to make it certain by means of a posterior vaginal section. [w.k.]

**Operation for Fibromyoma of the Uterus.**—Hegar<sup>2</sup> traces the operations for fibroids through the different stages from the beginning to the modern abdominal and vaginal hysterectomy. At first only fibroid polyps were removed, usually by strangulation; later fibroids visible through the uterine os were enucleated, and after ovariectomy became popular they were removed through an abdominal incision. Morcellement, the technic of which was very much improved by Hegar, was the next operation. Intraperitoneal and extraperitoneal methods of treating the stump were tried, but none proved very successful. Necrosis of the stump, general infection or suppuration of long duration often resulted. Castration and enucleation through an abdominal incision were the next operations; the former was suggested by Hegar. Both are suitable operations still in specially selected cases. The best and most modern operations are hysterectomy, if possible through the vagina; if not, through the abdomen. In some cases the two may be combined. [E.L.]

**Instrumental Dilation of the Cervix.**—Zangemeister,<sup>3</sup> after reviewing the history of several series of cases in which Bossi's or some other metallic dilator was used, is convinced that a serious objection to such instruments is the frequency of cervical and vaginal lacerations, and he warns against any dilator which is worked by a screw. When the cervix cannot be dilated with sufficient rapidity by means of intrauterine balloons or a colpeurynter, he thinks deep cervical incisions should be made, as they are less liable to septic infection than the bruised tissues of the lacerations due to the use of metallic dilators. If necessary a long sagittal incision through the anterior cervical wall is a more certain and less dangerous procedure than the use of any metallic dilator controlled by screws. [w.k.]

**Early Diagnosis and Treatment in Fibromyomatous Tumors of the Uterus.**—Bowers<sup>1</sup> insists that when a woman has had unusual hemorrhage for a few menstrual periods without apparent cause we should prepare to curet; she can be thoroughly examined while under an anesthetic and if a polypus exists it can be removed and the uterine cavity cureted and packed with gauze. The relations of any growths to the cervix or body may best be determined by examination through the vagina. Early in these cases he believes that animal extracts deserve a trial, especially the thyroid extracts. Hydrastin also has given him very good results, materially reducing the menstrual flow. It should be taken three times a day. We are justified in early operation before severe hemorrhage and other urgent symptoms exist, especially in a patient under 35, for the following reasons: It may save her a future cesarean section; it may save her from a more radical operation and greater mutilation; the operation can be done when the resistance of the patient is at the best; there will be no danger from degenerative changes; if excision is delayed until tumors become large there may be rupture of the uterus should pregnancy occur. [w.k.]

**TREATMENT**

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPELMAN

**REVIEW OF LITERATURE**

**Thiocol in the Treatment of Tuberculosis.**—Thiocol or potassium sulfonoguaicolate is indicated in all forms of tuberculosis, and may be administered in the presence of hemoptysis.<sup>2</sup> It is odorless, nontoxic, very soluble in water, and may be given in large doses either by the mouth or hypodermically. By the mouth it may be given in doses of 0.5 gram (7 grains) every 3 hours, or in the following solution:

Thiocol . . . . .	10 grams	(2½ drams)
Syrup of bitter orange-peel . . . . .	100 cc.	(3½ ounces)
Boiled water . . . . .	150 cc.	(5 ounces)

One tablespoonful every 4 hours.

In laryngeal tuberculosis, Fasano recommends the following insufflation:

Thiocol . . . . .	0.15 gram	(2½ grains)
Cocain chlorid . . . . .	104	grams (3½ ounces)
Boric acid . . . . .	1	gram (15 grains)

Thiocol should be continued internally in the dose of 1 to 2 grams (15 to 30 grains) daily. Under the influence of this drug weight increases, cough and fever decrease, the arterial pressure is raised, the quantity of urine is increased, and the elimination of uric acid is diminished. [L.F.A.]

**Treatment of Inoperable Cancer.**—Morris<sup>3</sup> concludes, after an exhaustive survey of the subject: 1. That the bacterial treatment of malignant disease is not of the slightest use in carcinoma; that not one-half of the cases of spindle-celled sarcoma disappear under treatment with Coley's fluid; that in cases of sarcoma, other than the spindle-celled, Coley's fluid is not of value; that the treatment by Coley's fluid has many dangers, and should never be employed except in absolutely inoperable cases. 2. That Beatson's treatment (oophorectomy) is limited to cases of mammary carcinoma, and the local and glandular recurrences after mammary carcinoma; and even in these only a small proportion are influenced by the treatment. 3. That rodent ulcer has in Finsen's light and in the Röntgen rays its most successful treatment, so far as we at present know. There are cases of rodent ulcer, however, which resist these means, and some are successfully treated by excision and caustics. 4. That sarcoma, epithelioma, and the other forms of carcinoma are best treated, whenever possible, by early excision. 5. That the boundary line between what are considered operable and inoperable cases needs revision from time to time; the tendency to extend the limits of operable cases needs in some instances to be restricted, and in others there may prove room for further extension. 6. That it is open to question whether some of the operations performed for relief or prolongation of life in inoperable cases of malignant disease

<sup>1</sup> American Gynecology, January, 1903.  
<sup>2</sup> Münchener medicinische Wochenschrift, November 25, 1902.  
<sup>3</sup> Zentralblatt für Gynäkologie, January 24, 1903.

<sup>1</sup> American Gynecology, January, 1903.  
<sup>2</sup> Bulletin Général de Thérapeutique, Vol. cxliv, No. 24, p. 968, 1902.  
<sup>3</sup> British Medical Journal, October 25, 1902.

should not be abandoned. 7. That investigations into both the cause and nature of cancer are of the first importance, as being more likely to lead ultimately to cure than any treatment at present known. 8. That, with few exceptions, the attempts to cure cancer by means other than early and free operations have been hitherto almost invariably futile. [A.B.C.]

**Home Treatment for the Morphin Habit.**—Moody<sup>1</sup> points out that contrary to the general teaching it is possible in a very large proportion of cases to cure the morphin habit without sending the patients to a sanatorium. It is essential that the patient be earnest in his desire for cure and that there shall be a nurse or friend sensible enough to carry out the physician's orders without attempting to exercise his own judgment as to their wisdom. It is also necessary that the physician understand completely the pathologic condition and have the unflinching confidence of the patient. On account of the deleterious effect of accumulated effete material, the result of the habit, the treatment should commence with a thorough cleansing of the system. Many of these patients have frequent bowel movements but are nevertheless always constipated, the discharge being the result of irritation of the mucous membrane from hardened feces. The first prescription should be a purgative such as the following:

Extract of colocynth compound . . .	ʒ ss	(2.0 gm.)
Calomel . . . . .	gr. xx	(1.3 gm.)
Strychnin hydrochlorate . . . . .	gr. ʒ	(0.016 gm.)
Extract hyoscyamus . . . . .	gr. x	(0.065 gm.)

Make 10 capsules.  
One every 4 hours until directed to stop.

This should be followed the next morning by a Seidlitz powder. The patient should be told that this prescription will purge him freely and that he will feel relieved afterward; the fulfilment of this prophecy will tend to increase his confidence in the physician. The other part of the treatment is a combination of suggestion and the use of nerve sedatives. At the preliminary examination of the patient the physician should make use of all possible instruments of precision such as the stethoscope, microscope, etc., as much for the purpose of making an impression on the patient as for determining the physical condition. After the purgation the patient should be told that he will receive a substitute for morphin for a few days after which he will no longer have a desire for it. This substitute should be a combination of sodium bromid and dionin, so arranged that each single dose contains half the number of grains of dionin that has been the daily dose of morphin. If the patient has been using 12 grains a day, the following prescription may be used:

Sodium bromid . . . . .	ʒ iv	(15.0 gm.)
Dionin . . . . .	gr. lxxij	(4.6 gm.)
Distilled water, to make . . . . .	ʒ vj	(185.0 gm.)

Tablespoonful as directed.

This is given every two hours until the patient becomes sleepy, after which it may be given every four hours. As each dose is taken from the bottle an equal quantity of pure water should be poured into the bottle, the patient seeing this done; he should be told that by the time the mixture is weak he will not need it. He should be thoroughly impressed with the idea that he is going to get well and that he will remain permanently cured. The belief of the patient that he is hopelessly dependent upon morphin is often one of the most difficult features to combat. If the patient is restless or complains of discomfort the most potent agency at our command is hyoscin hydrobromate, which produces a quiescence, somewhat like that of hypnotism, during which the patient's mind is freely open to suggestion. Spartein sulfate may be given simultaneously with the hyoscin if the heart is weak. The hyoscin should be given hypodermically in doses varying from 0.3 mg. to 1 mg. ( $\frac{1}{30}$  to  $\frac{1}{15}$  grain) according to the susceptibility of the patient. During its use the physician should constantly reiterate that the desire for morphin is disappearing. [H.C.W.]

**Sodium Cacodylate in Chorea.**—Lannois<sup>2</sup> employs sodium cacodylate hypodermically in the treatment of chorea in the dose of from 2 to 4 cg. ( $\frac{1}{10}$  to  $\frac{1}{5}$  grain) daily for 15 days. At the end of this time its administration is stopped 4 or 5 days,

then continued in the same dose. It may also be given in pills in double these doses for 3 days a week. Good results have followed this treatment. [L.F.A.] [Sodium cacodylate at times irritates the alimentary tract. Caution is therefore necessary. S.S.C.]

**The Treatment of Typhoid Fever.**—According to Hare,<sup>1</sup> of all diseases, typhoid fever is the one in which it is most important to avoid harmful interference. The motto in typhoid fever should be "Let the patient get well." Great attention should be paid to the kidneys, as it is through them that the toxins must be eliminated. For maintaining the function of the kidneys he advises the frequent use of water, if need be, aided by mild refrigerant diuretics, intestinal antiseptics are useless so far as the typhoid infection is concerned and are likely to add a burden to the kidneys; they may, however, prove of value by diminishing tympanites. Antipyretics are in no way beneficial, and if used in conjunction with the cold bath are capable of harm. Reduction of the temperature is the least important result of the cold bath; its dominant influences are the equalization of the capillary circulation, the redistribution of the stagnant blood, and the general stimulating effect upon the metabolism. The indiscriminate use of the cold plunge in all cases of typhoid fever is to be deprecated, equally good results can be obtained by the use of the cold rub. When there is a failure of reaction after the rub, it is owing to faulty technic. In some cases the temperature may be lowered more by the tepid (80° to 90°) than by the cold bath. This is explained by the initial contraction of the bloodvessels of the skin interfering with the peripheral circulation and the shivering following the cold bath which increases the production of heat. Turpentine is useful to combat tympanites, while alcohol is the most valuable remedy for overcoming heart failure; strychnin he believes is used too frequently, it is only a temporary stimulant and may add distinctly to the nervous irritation. As to diet, he believes the addition of easily digested starchy foods, digestion being aided by takadiastase or pancreatin, and one or two eggs to the milk diet is advantageous. In the treatment of hemorrhage the majority of substances advised are irrational. Calcium chlorid and gelatin are logical remedies, but in Hare's experience have not given good results. In this case he has found the best drug to be pill of Monsell's salt. [H.C.W.]

**Aristochin.**—Aristochin is a white, tasteless powder, freely soluble in dilute hydrochloric acid; it contains 96% quinin and is excreted as such by the kidneys in large quantities. On account of these virtues Stursberg<sup>2</sup> considers it an excellent substitute for quinin in children's diseases. He has used it in 18 cases of whoopingcough with partially satisfactory results. Its dose for children under 1 year is 0.05–0.1 gram ( $\frac{1}{20}$ – $\frac{1}{10}$  grains); for older children 0.3 grams ( $\frac{1}{2}$  grains) three times daily. [E.L.]

**Treatment of Tuberculosis by Gualacol Cacodylate.**—Gonzalve-Menusier<sup>3</sup> has obtained excellent results with gualacol cacodylate in the treatment of tuberculosis. This drug acts not only as an antiseptic to the respiratory passages by the gualacol which it contains, but it is an excellent reconstituent, due to the cacodylic acid. The modification of the tissues produced by the drug renders them unfavorable to the growth of the bacillus of tuberculosis. [L.F.A.]

**On the Use of Sulfur in Typhoid Fever.**—Woroschilsky,<sup>4</sup> led by the favorable results obtained in dysentery from the use of sulfur, has employed it in typhoid fever with good results. He gives it in doses of 1.25 grams every two hours (20 grains) so that the patient receives as high as 10 grams a day. The cases in which it was employed seem to run a milder course than might otherwise have been expected. He believes the beneficial action of the drug to be a direct one upon the mucous membrane of the intestines. It does not cause diarrhea; on the contrary, in cases presenting this symptom it seems to act beneficially. He believes that it is altered in the intestine into an alkaline sulfid, and that the portion of the sulfur undissolved acts as a protective antiphlogistic and antiseptic. [H.C.W.]

<sup>1</sup> Therapeutic Gazette, 1902, Vol. xxvi, p. 793.

<sup>2</sup> Münchener medicinische Wochenschrift, November 11, 1902.

<sup>3</sup> Bulletin Général de Thérapeutique, Vol. cxliv, No. 24, p. 939, 1902.

<sup>4</sup> Therapeutische Monatshefte, Vol. xvi, p. 563, 1902.

<sup>1</sup> Merck's Archives, December, 1902, Vol. iv, p. 470.

<sup>2</sup> Bulletin Général de Thérapeutique, Vol. cxliv, No. 22, 1902, p. 879.

**Ozone in the Treatment of Whoopingcough.**—Delherm<sup>1</sup> states that although ozone is not a specific against whoopingcough, it has a marked antispasmodic power which justifies its employment in this affection. It is without action in the catarrhal stage at the beginning and at the end of the disease; it should be used only during the period of coughing in the average dose of 3 or 4 inhalations (of mildly ozonized air or oxygen) for 10 minutes in 24 hours. By this treatment the attacks of coughing become less frequent, and at the end of 10 or 12 days the patient is often entirely relieved or has not more than 2 or 3 attacks during 24 hours. [L.F.A.]

**On the Open Air Cure for Pulmonary Tuberculosis.**—Volland<sup>2</sup> believes that the open air cure for pulmonary tuberculosis is being greatly overdone in certain institutions, especially in his own town, Davos. He is persuaded that the results obtained in these sanatoriums are less favorable than they were a few years ago, and that the open air cure is becoming an immoderate fad. He quotes with approval the statistics of Hammer, who has found that in Heidelberg better results are obtained in the ordinary clinic than in the Heidelberg Sanitarium, and also the statement of Holdheim that even in Berlin, as good results follow intelligent individualizing treatment as are reached in Davos. Two or three decades ago the majority of physicians kept tuberculous patients indoors, in order to prevent their taking cold. In many of the institutions patients are today made to live constantly, no matter what the weather is, in what is practically the open air, under conditions which would make even a healthy person sick. He has seen patients come to Davos with comparatively little cough and no fever, who when placed under the routine open air treatment developed severe bronchitis, with great increase in cough and expectoration and the production of considerable fever. The reason that good results are obtained in Davos is owing to the excellent climatic advantages of this resort, and is rather in spite of, than on account of, the treatment. If the care and the same individualizing were employed in Davos as in the Berlin clinics, the conjunction of the climate and the treatment would bring about excellent results. The exposing of patients with lowered vitality to climatic conditions which even the healthy are unable to withstand, is certainly an irrational procedure. While not denying the advantage of the open air treatment when employed with moderation, Volland believes there is great danger if it is overdone. The development of bronchitis in these patients must of necessity be harmful. [H.C.W.] [Having preached "fresh air" to deaf ears for many years, I now gladly add my protest to Volland's against the irrational extreme to which this most useful method seems in danger of being pushed with the reactionary pendulum-swing. Sheep and bell-wethers alike are going over the fence too fast. Individualization of the most careful kind is necessary in the treatment of pulmonary tuberculosis. Air, too, must be mixed with brains. s.s.c.]

**On the Value of Cinnamic Acid in the Treatment of Tuberculosis.**—Robinson,<sup>3</sup> after a thorough review of the literature on the use of sodium cinnamate in tuberculosis, comes to the following conclusions: 1. To regard sodium cinnamate as a specific in tuberculosis is absurd. 2. The drug is probably useful as an adjuvant, especially in the first stages. 3. The commencing dose must be small and gradually increased. 4. It is contraindicated in cases of hemorrhage or when the temperature is above 101°. 5. Rise of temperature following its use is evidence that the dose is too large. 6. Its action is that of a symptomatic rather than a curative agent. It is probably less useful than creasote. The dose of sodium cinnamate is 0.13 or 0.19 gram (2 or 3 grains) by the mouth, or 16 mg. (¼ grain) hypodermically. [H.C.W.]

**Ovarian Organotherapy.**—Bestion<sup>4</sup> has obtained very good results from the administration of ovarian extract in amenorrhœa due to chlorosis and anemia. In 15 cases in which this was used he had only one failure. In many cases of simple anemia menstruation returned after the administration of from 40 to 50 grams (1 to 1½ ounces) of ovarian extract daily for one or

two months. Bestion has also successfully employed ovarian extract in the systemic disturbances at the time of the menopause. He states that organotherapy should be tried in all functional disturbances of the ovaries at least, before any surgical intervention is considered. [L.F.A.]

**The Efficacy of Enquinin.**—Audry<sup>1</sup> reports the use of this drug in a case of typical intermittent fever in a boy of 13, the result being eminently satisfactory. The daily amount given was 1.5 gm. (22 grains) for four days, 1 gm. (15 grains) for three days, 0.5 gm. (7 grains) the eighth day, and as a precaution 0.5 gm. (7 grains) the tenth and fourteenth days. Audry believes the drug is to be commended, even though its cost is greater than the other preparations of quinin. [A.G.E.]

**The Medicinal Treatment of Gallstones.**—Richardson<sup>2</sup> says that gallstones are formed through the precipitation of cholesterol or coloring matters upon a nucleus of bacteria. Since the substances are held in solution by the glycocholate and taurocholate of the bile, the obvious therapeutics is the administration of sodium glycocholate. This treatment prevents the enlargement of the stones by further precipitation of the cholesterol, and is even capable of dissolving stones already formed. He gives it in doses of 0.32 gram (5 grains) three times a day. We have already called attention in a recent editorial to the fallacy of this treatment. [H.C.W.]

**Treatment of Infectious Dermatitis and Lymphangitis with Carbolized Poultrices.**—Jean Camescasse<sup>3</sup> reports a case of dermatitis with lymphangitis following a severe bruise and excoriation of the leg. The patient suffered from fever, chills and great weakness. The leg was red, swollen and very painful; there was also marked polyadenitis. Treatment consisted in the application of a poultice made by mixing about four ounces of flour with sufficient boiling water to which one tablespoonful of carbolized glycerin had been added. This was alternated with lavage of hydrogen dioxid, water and sodium bicarbonate dressings. Following the application of the first poultice, the fever decreased and the patient fell into a quiet sleep. The following day the local symptoms had greatly improved. The poultices were renewed every three or four hours, but the quantity of carbolic acid in them was decreased. Camescasse considers this treatment very valuable in such cases. [L.F.A.]

**Treatment of Tuberculous Disease with Sodium Cinnamate.**—Riegner<sup>4</sup> reports 21 cases of pulmonary tuberculosis treated with intravenous injections of hetol (sodium cinnamate). The results were sufficiently favorable to induce the author to recommend it to the profession for more general use. He states, however, that only intravenous injections will give these results. [E.L.]

**Theocin, a Synthetic Alkaloid.**—Schweitzer<sup>5</sup> writes interestingly of theocin, which is the first vegetable alkaloid to be manufactured on a large scale by simple synthesis. In 1888 Kossel isolated from tea leaves a new alkaloid isomeric with theobromin to which he gave the name theophyllin. It occurs in such small quantities that its manufacture from natural sources was impracticable. Chemic skill, however, has succeeded in preparing the same substance synthetically at a cost of \$2.30 an ounce, as compared with \$93 for the natural product. In order that the artificial alkaloid might not be confounded with the natural one, the name theocin has been given to this material. It has been clinically and experimentally investigated by Minkowski and by Dreser, who have shown that it is more nearly allied in its physiologic effect to theobromin than to caffeine. Minkowski found that in various forms of cardiac dropsy the remedy exercised a remarkable diuretic influence. In one instance the amount of urine excreted was raised from 1,300 cc. a day to 7,600 cc., and Dreser found that the solid constituents as well as the quantity of fluid were increased. Although not freely soluble in water, it is much more so than theobromin, dissolving in the proportion of 1 part in 79. It is without effect on the heart or circulation. [H.C.W.]

<sup>5</sup> American Journal of Pharmacy, lxxv, p. 27, 1903.

**Treatment of Bronchial Hemorrhages by Gelatinized Serum.**—Demange<sup>1</sup> reports that he has obtained excellent results from the injection of gelatinized serum in the treatment of three patients suffering from bronchiectasis with frequent hemorrhages. One of these patients who, on account of the frequent hemorrhages was in a state of profound cachexia, was enabled to resume his occupation. He had not had any return of the hemoptysis since the beginning of the treatment. Demange injects 45 cc. (1½ drams) of a 5% solution of gelatin every two days. This dose is perfectly well borne. The action of the gelatin is favored by rest in bed and a very light diet, preferably of milk. [L.F.A.]

**FORMULAS, ORIGINAL AND SELECTED.**

**In Early Pulmonary Tuberculosis.—**

Iodoform . . . . .	.03 to .2 or .3 gm.	( $\frac{1}{10}$ to 3 or 5 gr.)
Arsenic iodid . . . . .	.005 gm.	( $\frac{1}{20}$ gr.)
Strychnin arsenate . . . . .	.0005 gm.	( $\frac{1}{200}$ gr.)
Reduced iron . . . . .	.06 to .2 gm.	(1 to 3 grs.)
Balsam of Peru . . . . .	.3 gm.	(5 gr.)

Mix and encapsulate. Begin with the minimum dose and increase the iodoform and the iron at each (weekly) renewal of the prescription.

Dose: One capsule thrice daily after food. [s.s.c.]

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 14, 1903:

**SMALLPOX—UNITED STATES.**

		Cases	Deaths
Alabama:	Mobile . . . . . Feb. 6 . . . . .	2	
California:	Los Angeles . . . . . Jan. 17-24 . . . . .	4	
	Sacramento . . . . . Jan. 24-31 . . . . .	4

**Changes in the Medical Corps of the U. S. Army for the week ended February 14, 1903:**

The following assignments of officers are made: Colonel Alfred C. Girard, assistant surgeon-general, will report to the commanding general, department of Luzon, for assignment to duty as chief surgeon of that department, relieving Major Louis Brechemin, surgeon, who will report to the commanding general of that department for assignment to duty; Lieutenant-Colonel John D. Hall, deputy surgeon-general, now in Manila, P. I., will proceed to Iloilo, Island of Panay, reporting to the commanding general, department of the Visayas, for assignment to duty as chief surgeon of that department, relieving Major John M. Banister, surgeon, who will proceed to Manila, P. I., reporting to the commanding officer, First Reserve Hospital, for duty as chief operating surgeon at that hospital. Major George H. Torney, surgeon, is assigned to the command of the First Reserve Hospital, Manila, P. I., relieving Major Edward R. Morris, surgeon, who will proceed to Iloilo, Island of Panay, reporting to the commanding general, department of the Visayas, for assignment to duty. Captain Edward L. Munson, assistant surgeon, is, in addition to his other duties, assigned to duty as sanitary inspector, headquarters division of the Philippines, vice Captain Frank Du Bois, assistant surgeon, U. S. Volunteers, relieved. First Lieutenant Robert Smart, assistant surgeon, is, in addition to his other duties, assigned to duty as sanitary inspector, headquarters division of the Philippines.

MORROW, First Lieutenant CHARLES E., assistant surgeon, is granted leave for one month.

O'NEILL, JOSEPH A., contract surgeon, will report at Chicago, Ill., not later than February 13, for assignment to duty with the Fourteenth Infantry, and to accompany that regiment to the Philippine Islands, for assignment to duty.

YATES, WILLIS S., hospital steward, Military Hospital, Jolo, P. I., is relieved from further duty in the division of the Philippines, and will be sent to San Francisco, Cal., and will report to the commanding general, department of California.

DESHON, Captain GEORGE D., assistant surgeon, having reported his arrival at San Francisco, Cal., will proceed to Boston, Mass., and assume the duties of attending surgeon and examiner of recruits in that city.

WINN, First Lieutenant ROBERT N., assistant surgeon, is relieved from further duty at Fort Riley and will proceed to Fort Grant for duty.

MCCALLUM, FRANCIS M., contract surgeon, in addition to his present duties at Indianapolis Arsenal, is assigned to duty as examiner of recruits at Indianapolis, Ind., and will report accordingly to Major James E. Macklin, Eleventh Infantry, recruiting officer at that place.

AGRAMONTE, ARISTIDES, contract surgeon, now at Havana, Cuba, will report at Cabana Barracks, for temporary duty.

DAVIS, Major WILLIAM B., surgeon, leave granted is extended ten days.

**Changes in the Medical Corps of the U. S. Navy for the week ended February 14, 1903:**

GROW, H. C., passed assistant surgeon, detached from the Marblehead and directed to wait orders—February 7.

BELL, W. L., passed assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., and ordered to the Marblehead—February 7.

PLUMMER, R. W., passed assistant surgeon, commissioned passed assistant surgeon, with rank of lieutenant, junior grade, from June 17, 1902—February 10.

BRIGGS, R. E., assistant surgeon, appointed assistant surgeon, with rank of lieutenant, junior grade, from January 19, 1903—February 10.

SUTTON, R. L., assistant surgeon, F. W. S. Dean, appointed assistant surgeon, with rank of lieutenant, junior grade, from January 26, 1903—February 10.

BLOCK, W. H., acting assistant surgeon, ordered to the Naval Recruiting Office, Chicago, Ill.—February 10.

**Changes in the Public Health and Marine-Hospital Service for the week ended February 12, 1903:**

MAGRUDER, G. M., surgeon, granted leave of absence for one day—February 6, 1903.

DECKER, C. E., assistant surgeon, granted leave of absence, on account of sickness, for ten days—February 10, 1903.

PARKER, H. B., assistant surgeon, to proceed to New Orleans, La., for special temporary duty—February 6, 1903.

HAMILTON, H. J., acting assistant surgeon, granted leave of absence, on account of sickness, for thirty days from December 27, 1902—February 3, 1903. Granted fifteen days' extension of leave of absence, on account of sickness, from January 27—February 7, 1903.

SIBREE, H. C., acting assistant surgeon, granted leave of absence for six days from February 7—February 6, 1903.

ULBICH, C. F., acting assistant surgeon, granted leave of absence for twenty-five days from February 15—February 11, 1903.

GAHN, HENRY, pharmacist, granted leave of absence for five days from February 6, 1903, under provisions of paragraph 210 of the regulations.

*Resignation.*

MALARET, PEDRO, acting assistant surgeon, resigned, to take effect January 31, 1903.

PUBLISHED WEEKLY AT 1521 WALNUT STREET, PHILADELPHIA, BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. V, No. 9.

FEBRUARY 28, 1903.

\$5.00 YEARLY.

"Race suicide" is the phrase coined by President Roosevelt to indicate the lessened natality or birthrate of the more educated classes. President Eliot has published the statistics of the number of children of certain properly-selected graduates of Harvard College, and finds the suggestion that in all probability the intellectual and educated classes of the community are not reproducing themselves. The growth of the fashion of intentional childlessness is rightly and righteously condemned by President Roosevelt; those guilty of it are in truth "criminals against the race." But this is the crime that increases in all old, rich, and hence increasingly selfish and corrupt nations. The difficulty lies in getting the remedy, any remedy proposed, into effective action. All the statistics and arguments in the world will not make the individual parents have more children when the debasing influences of luxury and selfishness become active in over-urbanized civilized life. There are three causes, however, that if not fundamental are at least powerful in influencing the birthrate. The first is the postponement of marriage until so late in life that numerous children are impossible; the second is the murder of children before birth, and the third the license allowed the unfit to marry. It therefore behooves society and especially the lawmakers to learn and to discourage the causes of delayed marriages; to prevent the awful waste of life at present so great due to abortions and stillbirths; and more important still, to refuse the right of marriage to the hopelessly diseased and unfit, the insane, paupers, criminals, drunkards, idiots, etc. The rights of the unborn are superior to the pleasure of the living, and the rights of all the living are higher than those of a few.

The annual subsidization scramble in Pennsylvania has begun. It will be remembered that over one-half of all the money appropriated by all the United States to private charitable institutions is given by the Pennsylvania State politicians. On the boards of trustees and directors of these institutions are most of the influential men of the State. What more certain method could be devised to stifle criticism and independence in the face of corrupt political bosses than this of the threat to cut off the appropriations to the charitable institutions if a word is uttered? It is surely effective! And the millions are thrown into the trough

with the wink that the most corrupt will get the most. "You must make your cost of inpatients higher; charge up to this all the expenses of the outpatient department," said one of the dispensers of patronage to an applicant. It is said that some hospitals—according to their figures—now have twice as many bed-days as patients; that is, they could accommodate the reported patients each night only by means of putting two or more in a bed. Some of the best and noblest private charitable institutions in the State do not ask for help from the public treasury. Only when absolutely under State control should the State aid institutions. Any other plan leads to infamous abuses and injustice. There has been much discussion of late in the lay magazines and newspapers as to "tainted gifts." Should an institution, university, church, medical college, hospital, etc., accept the gifts of money obtained by corrupt methods from evil men? It would have been more instructive to find out if any such gifts were ever refused. More illuminating still would be the perfectly selfevident and historically proved truth that if they do accept the gifts of the wicked, it is to their great peril and certain injury. The character, whether giver or getter, which thinks that it can really profit by fraud and dishonor has still much to learn, even in worldly wisdom.

**The Plans of the Rockefeller Institute.**—According to Dr. Holt, the secretary, Mr. Rockefeller, who has already given \$1,200,000, will carry to full establishment the scheme for an institute for medical and pathologic research in New York City which will be without an equal in the world. The plans are for the immediate erection of a laboratory in which will be conducted investigations in all departments of medical research by a large resident staff and a coordinate staff of nonresident Fellows.

For the building of a hospital in which special groups of patients will be treated in order to develop new methods in the treatment of disease.

The establishment of a journal in which are to be published the results of the institute's investigations and which will serve as a medium for discussion of kindred topics.

The ultimate plans are:

The establishment of popular lectures by which to spread information on hygienic matters.

The institution of a hygienic museum and the dissemination of literature bearing on the problems investigated. Professor Simon Flexner has been appointed director of the laboratory, and will begin his work at the institute in July next. Full text of the official announcement of the institute is given elsewhere.

**The Importance of Teaching the Art as Well as the Science of Medicine.**—At a recent meeting of the New York Academy of Medicine special consideration was given to the necessity of radical reform in the teaching of medicine to senior students. The fact was emphasized that the scientific laboratory work of the first two years must be supplemented for at least an equal period by opportunities for acquiring the art of diagnosis and treatment through actual observation at the bedside and in the dispensary. The training of "the eye to see, the ear to hear, and the finger to feel," means to medical students training in the physician's art, in which skill is attainable only by oft-repeated and long-continued practice. Detailed knowledge of the human mechanism may be acquired in the laboratory and dissecting-room, but control of the mechanism in action can only be attained by continued dealing with the living organism. It is said that graduates of the foremost technologic institutes of the world flock to the shops of the General Electric Company at Schenectady to gain the practical skill and facility in applying scientific knowledge which can be secured by actually doing the tasks of regular workmen in the various departments. Here we have an adaptation of the old apprenticeship system as a postgraduate course in electric technology. So the modern medical school may with advantage combine the science and theory of the lecture-room and laboratory, with such practical opportunities for acquiring skill of eye and ear and hand which the old-time student secured by accompanying his preceptor on his daily round of visits or by assisting him in his office practice. How to utilize hospitals and allied institutions to the best advantage, in combination with the training of physicians, is one of the most difficult problems of medical education. Let us hope that hospital advantages which have heretofore largely gone by favor may soon become the privilege of every student.

**Deserted Cities.**—In historic times there are few instances of the complete desertion of cities, and these are of small ones, and the causes are well understood, as in the cases of Pompeii, Martinique, etc. But there exist the ruins of many large cities which in wealth and magnificence must have rivaled ours but which for some reason unknown must have been suddenly left by the inhabitants. The mystery of such a wholesale desertion is not to be accounted for by the reasons ordinarily surmised—the whim of a tyrant ruler, the failure of food or water, or the misfortune of military defeat. Possibly the reason we are about to suggest may have been offered before, but we are not aware of it, but no other than epidemic disease would seem able to account for such strange dying out or flight of enormous numbers of people. Prior to historic times the visitation of plague or of some other violently infectious disease would not

be understood and men would be able to avoid death only by flying from the pest which was really caused by their own ignorance and filth. Even in our time and in the very center of civilization the students of a great University are rushing pellmell away from it instead of going to the trouble of boiling their drinking water.

**Queensland More Progressive Than the United States as to the Adulteration of Foods.**—While we wait in vain for our political bosses to do something for the health of the people, Queensland has perfected a system to protect her citizens from the scoundrels who seek to cheat them by the most vicious criminality in the manufacture of impure and poisonous foods. Strict laws are enforced in Queensland as to the substances that may and may not be used as ingredients, coloring matters, preservatives, etc., of beer, alcoholic liquors, mineral waters, fruit essences, foods, milk, tea, vinegar, butter, cream of tartar, etc. There are detailed laws also as to the carrying on of the businesses pertaining to the manufacture and sale of all such things, and a fine not exceeding \$250 is provided for infringement of any parts of the law. Were it not for the hope that the careless and corrupt and ignorant among our people and their lawmakers will at last renounce their ways and become interested in the health and welfare of the nation, the outlook for republicanism in government would not be hopeful.

**The "Cry of the Children" Being Answered.**—It is gratifying to know that one of the greatest and long neglected needs of preventive medicine is being met. Almost every method of relieving defectives and curing disease has found support by legislators, but the children have been allowed to go crippled and diseased until cure was impossible. Leaving out of view their suffering, the pity of it all, it is incomprehensible that the benevolent should have so neglected this method of avoiding the rooted and chronic morbidity and the permanent expense of the incurable. The visit of Dr. Lorenz brought from their hiding places thousands of crippled children whose existence was unsuspected. No institution was supported by the State for their benefit. Even now it is difficult to catch the attention of the lawmakers. Private charity is seeking to bring some relief to the little sufferers. One church in New York has established a day hospital for them and is caring for more than its funds will warrant. There is also Dr. Shaffer's noble attempt to solve the problem, and the special work of "Daisy Fields" at Englewood, N. J., has now gone on for ten years, its special task being that of taking half-cured cripples to the country for convalescence. We hope the Widener School for Crippled Children will soon be in operation, and widely imitated elsewhere. As to the general care of children a number of worthy institutions exist and should be supported more generously by the public. Noteworthy among these is the perfect Children's Seaside Home at Atlantic City under the general charge of Mr. K. M. Blakiston. Most encouraging also is the lately-opened Babies' Hospital in New York, which seems from the accounts to be ideally-constructed and equipped. If the women

of the land could have their attention turned to this splendid opportunity instead of to the fashions and fads of antiscience and selfish charities!

**Yellow Fever in Vera Cruz.**—The commissioners appointed by the government of Vera Cruz to investigate and report upon the existence of yellow fever in Cordoba and Orizaba find that yellow fever actually exists in an epidemic form in two wards of the city of Orizaba; that the disease was primarily imported; that it is possible to prevent the extension and spread of the same by stringent and rigorous measures; that it is possible to eradicate the infection centers by the isolation of the patients, the destruction of the mosquitos, and the observance of sanitary rules. One physician was of the opinion that the disease was transplanted by mosquitos carried in railway trains from Vera Cruz. In Cordoba wire screens had been provided for one entire hospital, but these were ineffective because the size of the mesh of the wire cloth was too large. The commission recommended that the screens should be painted with a thick coat of white lead to reduce the size of the meshes. In Orizaba much of the water used for domestic purposes was stored in barrels and other vessels, thus creating breeding places for the stegomyia; the floors of the tenements being of earth, much of the waste water and filth was absorbed by the same; garbage and all waste matter were simply thrown into the streets. Every discovery in medicine and every step taken in sanitary science discloses the fact that the hidden meaning of the seemingly selfish and illogical rage for imperialism and colonization on the part of modern nations consists in the extension of our knowledge of the prevention and cure of disease to the barbaric and semicivilized peoples of the globe. It is our duty to see to it that the "aim of history" is realized.

**A union of scamps, medical, editorial, and manufacturing,** is planned, and, according to the circular before us, is in existence. Over 25,000 physicians, we are told, are copartners in the scheme, and they get in free of charge. The nostrum-maker is charged \$10.00, but he gets his reprints of articles lauding his preparation written by the 25,000 physicians at 50% discount from the usual rates for such literature. All, absolutely "ALL," pharmaceutical products are to have practical tests by the 25,000, and all those are to be "weeded out" which have no merit, according to the 25,000. We suspect the weeder-out will have no work to do. All that have merit, according to any one of the 25,000, are to be "pushed to the front," etc., because "this is an age of enterprise and progress," and physician or manufacturer who does not "push" in this way "gets left in the rear." This "pushing to the front" of the "meritorious pharmaceutical preparations" praised by the 25,000 is to be done, we are assured, "in an entirely ethical manner, and wholly devoid of any sign of commercialism whatsoever." We are sorely puzzled to learn how the 25,000 are to be benefited, but that will evidently be attended to by the manufacturers who pay \$10.00 for the privileges of the "Association." The most interesting detail of the plan lies in the relation of

the "Association" to the medical journals of the country. "Almost every medical journal of the United States worthy of notice" is said to be in the game; the slight limit to all-comprehensiveness is encouraging to the few professional ones. The Association can get articles in "almost any one" when this is impossible "through the regular channels." "In all cases we guarantee the publication of the article at a merely nominal figure, and oftentimes utterly free of charge, especially if the preparation concerning which the article is written is advertised in the publication applied to." Could scoundrelism be more nauseating? Here are opportunities galore for all the pathologic pathologists in the country. And yet journals are blamed for refusing papers in praise of proprietary preparations! It is long past the date when honest manufacturers should also band themselves together.

**Vaccination by "Variolinum."**—In a "Catalogue of Morbific Products, Nosodes, and Other Remedies in High Potencies," issued by a drug store, and now lying before us, we find listed and for sale two articles, *Variolinum*, and *Variolinum ovillum*, both evidently intended for internal administration. In a recent epidemic of smallpox in Philadelphia, it was gravely contended, and by physicians, too, that vaccination "by the mouth," or "by the stomach" was a real and a legally valid form of inoculation. The prompt coming down with smallpox of some of the contenders put a quietus upon their missionary zeal, at least in public. But the superstition seems by no means to be dead, and the matter has a distinct legal aspect. At the recent meeting of the State and Provincial Boards of Health, Dr. Kennedy, of Des Moines, Iowa, asked the conference to formulate a definition of vaccination. He said:

There is a school of practice in our State administering internally a preparation called "variolinum." They say this is equivalent to vaccination. In our State we have a law or regulation to the effect that no child can be admitted to the public schools without furnishing satisfactory evidence of successful vaccination. Under that regulation we have had several cases of litigation. Children, who are not vaccinated, have applied for admission to the public schools, and the law has been invoked compelling the local Boards of Health or the School Boards not to admit such children. The courts have decided that inasmuch as no definition of vaccination has been made by the State Board of Health (the courts consulted the medical dictionaries, also Webster's and the Century), if a child with a certificate from a physician certifying that it had been vaccinated by inoculation, the child should be admitted to the public school. There are numbers of children going to our public schools who have been vaccinated legally by inoculation, who have not conformed to any of the methods that have usually been regarded as vaccination, and a resolution was introduced in our board meeting to define vaccination.

A committee report was adopted which defined vaccination as follows:

An inoculation, by scarification, puncture or injection beneath the epidermis, of a vaccine which produces, with some constitutional disturbance, the typical vaccine vesicle, which leaves, after the poek has healed, its characteristic scar.

Let us make an end, both medically and legally, of the "variolinum" nonsense.

"Of the Mutual Complete and Permanent Transfusion of the Blood," is the title of a leaflet

lying before us. As no epitome would improve the original we quote it verbatim and in full:

Brooklyn, February 13th 1903

Dear Doctor,

I did propose with letter February 8th 1903 to the New York State Medical Association a projet to graft together two men of different age, making two small wounds, each in a different individual, and putting the two wounds in complete contact. The best point is the tip of a finger which is vascularized enough, and leaves the most liberty of motion to the grafted men after the operation.

If there will be reunion, blood will be exchanged between the two men. If only a drop of blood is exchanged at each contraction of the heart, and we have 103680 contractions of the heart daily, consequently will be exchanged 5184 c. cm: in one day.

There will be a mutual, complete and permanent transfusion of blood between the two men.

If the vitality is a force, it will be at the same tension in the cells of the old man and in the elements contained in the blood of the younger.

With more vitality there will be more cellular functionality, and the reproductive power of the tissues will be increased, and consequently there will be an increased number of cells of new formation (young cells).

With the blood, all the organic glandular juices will be exchanged and will have their peculiar action.

If a virulence of a microorganism or of any x is an explanation of its vitality we have an example of the tendency of equilibrium of vitality between two nearly similar bodies in the action of the vaccin over the Small-pox, and of the attenuate virus of the Pasteur's method over the Rabies.

The graft must be kept for a long time, one year or more.

The temporary transfusion of blood, already made, cannot do much good, like a man anemic for insufficient alimentation, cannot have improvement with only one regular meal.

A prove could be obtained very quickly, grafting together two animals of the same species, one at the age of complete development of the skeleton and another at the age before that complete development, if the older grows.

Application of this method could be done to many diseases where the deficient function of an organ could be supplied by the healty grafted man.

A man with ulcer of the stomach grafted with another more aged, but with good health, could receive alimentation with the blood of the old man, and keep his stomach at complete rest.

If there is a relative immunity for the tuberculosis in the old age, and if rarely are found Koch's bacilli in the blood, we could graft a strong old man with an young man suffering from tuberculosis in that cases where many microscopic examinations of the blood and several inoculations in the animals have demonstrated the absence of bacilli in the blood.

This is a case of mutual utility because the old man could transfuse that conditions which did give him the immunity for the tuberculosis, and receive the increased reproductive power of his tissues from the young.

I am obliged to print my idea before a complete experimental work, for saving my rights of invention for the application which could be done in the improvement of industry of bringing-up animals, where the old ones could have more strenght and their flesh become more fit for eating with my method of graft, etc., etc.

The best point for the graft in the rabbit is the tail.

I put myself under the protection of the American laws, having full right of naturalisation, because I declared my intention to become Citizen of the United States of America the day 8 January 1901 and I arrived in this country in 1897 like ship's surgeon of the California S. S. of the Anchor Line Co. (See the Records of County Court of Kings County, State of New York).

Respectfully your truly.

But one comint appears necessary—a glance at the antivivisectionists, a pointed finger, and a low "Sic him!"

## EDITORIAL ECHOES

**Tuberculosis in Cleveland.**—1. Tuberculosis in Cleveland furnished, during the 7 years under consideration, 8.7% of the total deaths, 1.4% of the deaths between the ages of 20 and 25 years, and 2.6% of the deaths between the ages of 20 and 30 years. The mortality was 130 to each 100,000 of the estimated average population.

2. Of all tuberculous deaths 15.5% occur between the years 20 and 25, 30.3% between 20 and 30, and 50% between 23½ and 44 years.

3. Of all deaths 4.9% were male deaths from tuberculosis. Of all deaths from tuberculosis 56.6 were male deaths.

4. Of all deaths 3.8% were female deaths from tuberculosis. Of all deaths from tuberculosis 43.4 were female deaths.

5. In proportion to the total, the greatest number of male deaths is found between the ages of 25 and 29, of females between 20 and 24.

6. In proportion to the living population the greatest number of deaths occurs between 55 and 64 years.

7. A seemingly justified inference is drawn that marriage increases the liability to death from tuberculosis, and that this is true in the female sex alone, or in that sex to a greater degree than in the male. There seems to be a very real relation between the existence of a tuberculous process and marriage, in that the condition under consideration has a very marked tendency to postpone or prevent individuals so affected from entering the married state.

What should be done is clear. Tuberculosis should be overlooked like diphtheria, scarlet fever, measles, whoopingcough and other infectious and contagious diseases, and heads of families and medical attendants should be required to report to the health office all cases of tuberculosis coming within their knowledge. Earnest effort must be made to obtain the necessary legislation to secure this. The Health Office should disinfect tuberculous infected houses and distribute with judicious care, subject to the proper control of the physician, to the victims and their families information regarding the proper care and disposal of sputum and other discharges, as well as in the wellknown and equally neglected principles of personal and public hygiene, enforcement of which is so necessary in limiting the spread of this disease. The streets, sidewalks, public buildings and conveyances should be properly cleaned, protected and disinfected. We, physicians and laymen alike, must do our duty, and lead and direct public opinion and sentiment in the proper direction; report our cases of tuberculosis and throw our influence on the right side. The health department must be provided with the organization, power and means of carrying on the fight. We must stand behind it, give it our moral support, as well as see that it is provided with the ammunition and men-of-war. We must realize the fact that the health office is our creature and a true reflection of our own position in municipal sanitation. I need not remind you of the great need of sanatoria for the treatment of both curable and incurable cases of tuberculosis of all kinds, and of the good influence they would also have in the dissemination of correct ideas concerning the prophylaxis of the disease.—[*Cleveland Medical Journal.*]

A medical practice bill recently introduced into the Kansas Legislature proposes to abolish the State Board of Registration, and requires the State Board of Health to assume the duties of that body.

BOOK REVIEWS

**Textbook of Medical Jurisprudence and Toxicology.**—By JOHN J. REESE, M.D., late Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; late President of the Medical Jurisprudence Society of Philadelphia. Sixth edition. Revised by HENRY LEFFMANN, A.M., M.D., Professor of Chemistry and Toxicology in the Woman's Medical College of Pennsylvania; Pathologic Chemist to the Jefferson Medical College Hospital; Vice-president (British) Society of Public Analysis. Philadelphia: P. Blakiston's Son & Co., 1012 Walnut street, 1902.

In the editor's preface attention is called to the fact that since the publication of the last edition of this work the subject of toxicology has been much developed. The introduction of numerous synthetic organic bodies and their extensive use as household remedies have given rise to many instances of accidental and suicidal poisoning, and the extensive use of water-gas greatly increases the list of accidental deaths. Among new phases of treatment, free washing out of the stomach, many uses of potassium permanganate, the employment of alcohol in phenol poisoning, and the use of strychnin in morphin poisoning, are specially noted. The editor states that "the general character of the book as it left the hand of its distinguished author has been retained," but one sees at once that it has been thoroughly revised and rewritten, and so much new material has been incorporated with the text as to make it practically a new work. The English is clear and concise; the evidences of painstaking in the collection of data are so many that one must reasonably conclude that all the statements made are exact and trustworthy. The work is not merely a treatise on poisoning, but covers the whole ground of legal medicine. The method of examination of dead bodies, the determination of their identity, and of the identity of the living, the sources of error in medical and in legal inquiries as to the cause of death, and in fixing the responsibility therefor, are thoroughly considered. Abortion, rape, and various criminal procedures not resulting in death, are also studied. Insanity from the viewpoint of medical jurisprudence is clearly and admirably analyzed. In the section upon toxicology the various agents used in criminal, suicidal, and accidental poisoning are considered with reference to their identification, their effects, and the best methods of antidotal treatment. This section is especially noteworthy for its accuracy and fulness. There is probably no work that can with greater confidence be placed in the hands of students, and to which the physician may refer on emergency with equal certainty of quickly finding what he wants.

**The New International Encyclopædia, Vol. VI.**—Dodd, Mead & Co., New York, 1903.

The more important medical articles of this volume are as follows:

Diabetes	Ear
Diaphragm	Ear-trumpet
Diarrhea	Eczema
Diet	Elephantiasis
Digestion	Embalming
Digitalis	Embryo
Diphtheria	Embryology
Disease	E endemic
Disinfectants	E endemic
Dislocation	E enteritis
Dispensary	E epidemic
Dissection Wounds	E epilepsy
Diuretics	E epithelium
Double Consciousness	E erysipelas
Dropsy	E erythema
Dysentery	E ether
Dyspepsia	

Among the failures to cross-reference are these:

Dressings, surgical	E edema
Drug Eruptions	E electrotherapeutics
Duboisin	E emphysema
Dysphagia	E endarteritis
Dyspnea	E endometritis
Dystocia	E endoscope
Echolias	E enuresis
Ecechymosis	E eserin
Eclampsia	E esophagotomy
Ectopic Gestation	

The legal aspect of drowning is treated, the medical omitted. Electrocutation has half a column, but injuries from electric-

ity are not mentioned. The medical uses of the dynamometer are not spoken of. A serious error appears in the article on diabetes, in which no distinction is drawn between glycosuria and diabetes mellitus. Glycosuria is not always "a grave disease," and treatment is by no means always "unsatisfactory." Eponymic diseases should be mentioned in connection with biographic notices: Duhring's disease, for instance, is not spoken of under Duhring.

**Diseases of the Stomach.**—Their Special Pathology, Diagnosis and Treatment, with Sections on Anatomy, Physiology, Chemic and Microscopic Examination of the Stomach Contents, Dietetics, Surgery of the Stomach, etc. By JOHN C. HEMMETER, M.D., Philos. D. P. Blakiston's Son & Co., Philadelphia. Price \$6.00 net.

We deem it safe to assert that in the hands of the general practitioner no important organ of the body is treated so constantly and so blindly as is the stomach in its pathologic conditions, fancied or real. Medical works which deal exclusively with the stomach are not numerous. To those who are acquainted with the previous editions of this work the present edition needs no encomium. This edition comprises a volume of nearly 900 pages, and as the author states much emphasis has been placed upon the factor of differential diagnosis and new material has been added to the chapters on ulcer and carcinoma, and a new article on gastric lipase. There is not a chapter in this exhaustive work which should not be read by every general practitioner. Diagnosis and treatment of the diseases of the stomach have been taken out of the realm of empirics and placed upon a scientific basis, which fact will be duly appreciated by both internists and surgeons.

**A Course in Botany and Pharmacognosy.**—By HENRY KRAEMER, Ph.B., Ph.D., Professor of Botany and Pharmacognosy, and Director of the Microscopical Laboratory in the Philadelphia College of Pharmacy. Edw. Stern & Co., Inc., Philadelphia.

This book is designed for the use of students in pharmacy in order to enable them to recognize vegetable drugs and to give them so much of an introduction to the subject of systematic botany as will assist them in their special studies. The work seems to be well designed, and the design to be carried out with reasonable accuracy; it must therefore be useful. It is to be regretted that at times the author has permitted himself to print as sentences collocations of words in which one searches in vain for either substantive or predicate.

**Transactions of the Twenty-fourth Annual Meeting of the American Laryngological Association,** held at Boston, Mass., May 26, 27, and 28, 1902. New York: Rooney & Otten Printing Co., 1902.

The high character of the work of the American Laryngological Association has suffered no diminution of late years. Among specially interesting articles in the present volume are those by D. Braden Kyle, on The Chemic Pathology of the Saliva and Pharyngeal Secretion as a Means of Diagnosis; by Fletcher Ingals, on The Immunization Treatment of Hay-fever; by Bryson Delavan, on The Results of Treatment of Laryngeal Cancer by Means of the X-ray. John O. Roe contributes a timely warning as to Some Cautions to be Observed in the Use of Suprarenal Extract in the Nose, and S. W. Langmaid gives an interesting account of Nonsuppurative Cervical Adenitis. One notes with regret that Morris J. Asch is represented by an obituary instead of a contribution.

**The Public and the Doctor.**—By a Regular Physician. Published by Dr. B. E. HADRA, Dallas, Texas.

It is the comment and regret of every observing physician how little the general public understand and appreciate the ethics of the medical profession both as applied to the relation between physicians themselves and as applied to the proper relation between the patient, his friends, and the physician. A sad commentary upon this is the ubiquitous and thriving quack, and "cure alls" which are daily taken by the gullible thousands with almost "that faith which would move mountains." This little book is an effort on the part of an intelligent and dispassionate physician to break down in some measure this barrier of ignorance and misunderstanding. It is

a series of heart to heart talks with the patient and his friends, advising them in their relations with the doctor, urging the wise and proper choice of a physician and a perfect and neutral understanding. The book, however, is highly interesting and instructive to the physician, especially the beginner. If this little book was read in every household—and it is entirely appropriate for that purpose—a great change would soon be wrought.

**Anatomy of the Human Peritoneum and Abdominal Cavity Considered From the Standpoint of Development and Comparative Anatomy.**—By GEORGE S. HUNTINGTON, M.A., M.D. Published by Lea Brothers & Co., Philadelphia and New York.

It is well known that one of the most confusing and perplexing subjects in human anatomy is the peritoneum. It is rare, indeed, that the student comprehends it. Professor Huntington has accomplished a splendid work in completing this excellent book, which itself is a work of art. While the book is in no sense a work on embryology nor comparative anatomy, these are drawn upon largely by the author to illustrate with clearness the development of the human peritoneum and abdominal viscera. Neither pains nor expense have been spared in the illustrations, the work abounding in some 300 full-page plates, containing 582 plates in many colors. Some idea of the scope and method of presenting the subject may be had from the knowledge that the author has considered the subject in four principal parts with many subdivisions. They are: Part I.—Anatomy of the Peritoneum and Abdominal Cavity. Part II.—Anatomy of the Peritoneum and the Supracolic Compartment of the Abdomen. Part III.—Large and Small Intestine, Iliocolic Function and Cecum. Part IV.—Morphology of the Human Cecum and Vermiform Appendix. The author's long experience as professor of anatomy in Columbia University, New York, and his extensive researches in comparative anatomy has enabled him to speak with interest and authority on the many interesting and perplexing questions in the work under consideration. It will appeal especially to anatomists, obstetricians and abdominal surgeons. The medical profession and scientists in general owe Professor Huntington renewed obligations for the production of this splendid volume.

#### BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

**Abdominal Anatomy: The Anatomy of the Human Peritoneum and Abdominal Cavity Considered from the Standpoint of Development and Comparative Anatomy.**—By GEORGE S. HUNTINGTON, M.D., Professor of Anatomy in the College of Physicians and Surgeons, Columbia University, New York City. In one handsome quarto volume of 590 pages, including 300 full-page plates in colors and monochrome, containing 582 figures. De luxe edition; gilt top; uncut edges; \$10.00, net. Lea Brothers & Co., Philadelphia and New York, 1903.

**Manton's Obstetrics: A Manual of Obstetrics for Students and Practitioners.**—By W. P. MANTON, M.D., Adjunct-professor of Obstetrics and Professor of Clinical Gynecology, Detroit College of Medicine. In one 12 mo volume of 265 pages, with 82 illustrations. Cloth, \$1.00. Lea Brothers & Co., Philadelphia and New York, 1903.

**The American Year-book of Medicine and Surgery for 1903.**—A yearly Digest of Scientific Progress and Authoritative Opinions in all branches of Medicine and Surgery, drawn from journals, monographs, and textbooks of the leading American and foreign authors and investigators. Arranged with critical editorial comments by eminent American specialists, under the editorial charge of GEORGE M. GOULD, A.M., M.D. In two volumes.—Volume I, including General Medicine, octavo, 700 pages, fully illustrated; Volume II, General Surgery, octavo, 670 pages, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Per volume: Cloth, \$3.00 net; half morocco, \$3.75 net.

**Toxicology: The Nature, Effects, and Detection of Poisons, with Diagnosis and Treatment of Poisoning.**—By CASSIUS M. RETEY, M.D., Professor of Chemistry and Toxicology in Barnes Medical College, etc. Lewis S. Matthews & Co., St. Louis, Mo.

**The Nose and Throat in Medical History.**—By JONATHAN WRIGHT, M.D. Lewis S. Matthews & Co., St. Louis, Mo.

**The Life Within.**—Lothrop Publishing Company, Boston, Mass.

**Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition.**—By PROF. CARL VON NOORDEN, Senior Physician to the City Hospital, Frankfurt-on-the-Main. Authorized American edition. Translated under the direction of BOARDMAN REED, M.D., of Philadelphia, Professor of Diseases of the Gastrointestinal Tract, Hygiene and Climatology in Department of Medicine, Temple Medical College, Philadelphia. Parts I and II. E. B. Treat & Co., New York, 1903.

**Transactions of the Luzerne County Medical Society for the year ended December 31, 1902.** Volume X. E. B. Yordy Co., Wilkes-Barre, Pa.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**Medical Advertisements and Religious Publications.**—A recent announcement made by the advertising agent of the nine official organs of the Methodist Church of the United States asserts that after January 1, 1903, no medical advertisements whatever will be granted space in the journals under his management.

**To Prohibit Hazing.**—The National House of Representatives has adopted an amendment to the naval appropriation bill which provides for the punishment of hazing at the Naval Academy. It prescribes the same penalty of summary expulsion to midshipmen from the Academy at Annapolis that is now the law for the army cadets at West Point. In both cases any offender who may be expelled for the violation of the anti-hazing regulations is also ineligible for commission in the U. S. Army, Navy or Marine Corps until two years after the graduation of the class of which he is a member.

**Bubonic Plague.**—Surgeon-General Wyman, of the Public Health and Marine-Hospital Service, says that the last case of bubonic plague reported in San Francisco was on December 11, 1902, but that in conformity with the resolutions adopted by the mercantile joint committee the State has appointed seven new inspectors of Chinatown under the supervision of the Public Health and Marine-Hospital Service. These are in addition to the corps of inspectors already engaged in this work. It is said the city, State and United States authorities are working in perfect harmony, and every effort will be made to prevent a recurrence of the disease in any locality.

**Hospital Benefactions.**—BUFFALO, N. Y.: Announcement is made of a contribution of \$50,000 by Mr. Frank Good-year and of \$49,000 by Mr. William Hamlin as a fund to raise the debt of the Buffalo General Hospital. It is expected that \$100,000 additional will be raised by subscription to clear the remainder of the indebtedness. PHILADELPHIA, PA.: The late Miss Carrie S. Kinsey, of Bristol, Pa., bequeathed \$5,000 to the Philadelphia Methodist Hospital for the endowment of a free bed in memory of her father, the late William Kinsey. BOSTON, MASS.: The late Miss Emily E. Sears, of Boston, bequeathed \$5,000 each to the Home of the Good Samaritan, the Associated Charities, and the Children's Hospital.—*St. Mary's Free Hospital for Children:* Through a bequest of the late Charles A. Cowtoit two new wards were recently opened in this hospital.

**American Congress on Tuberculosis.**—Dr. Daniel Lewis, of New York, president of the American Congress on Tuberculosis, has issued, under date of February 18, 1903, a circular announcing that the next meeting will be held in St. Louis, Mo., July 18 to 23, 1904. The work of the organization is being pushed as rapidly as possible. To facilitate this the congress has been granted a charter, thus making it a legal body, and by this means greatly facilitating the work of reorganization on the lines mapped out at the last meeting, when it was decided that a radical reorganization should be completed by the officers elected. At this time in St. Louis will be held the International, or World's Congress on Tuberculosis, and to effect a complete organization on ethical lines a number of wellknown physicians have been asked to serve on the advisory committee to assist the council in preparing plans for the meeting. The lengthy list includes Surgeon-General R. M. O'Reilly, of the U. S. A.; Surgeon-General P. M. Rixey, of the U. S. N., and many other prominent physicians throughout the United States. The circular is signed by the secretary, Dr. George Brown, of Atlanta, Ga.

### NEW YORK.

**Against Infected Ice.**—A bill has been introduced into the New York Legislature prohibiting the cutting of ice for domestic purposes within 3,000 feet of any village, town, or city of more than 10,000 inhabitants, on the Hudson river. It also provides that in cities of over 1,000,000 inhabitants ice dealers shall obtain licenses from the Health Commissioner, and indicate by signs on their wagons whether they are selling natural or artificial ice.

**Hospital for Convalescents from New York Hospitals.**—It is reported that Miss Ethel Folsom, of New York City, will establish a home for convalescents from New York hospitals in the town of Lee, Mass. A large house and a tract of land has been leased and will be converted into a home from May to November for discharged patients of a number of hospitals. Each patient is to have the benefit of two weeks' recuperation in the Berkshires.

**Serum for Cholera Infantum.**—It is announced that the summer corps of physicians of the New York Health Department will use a specially prepared serum to combat cholera infantum during the coming summer. It is said that the mortality among infants from cholera infantum, notwithstanding the use of sterilized milk and other sanitary precautions, has caused bacteriologists to seek a specific remedy in a serum. Dr. Lederle, president of the Board of Health of New York, is

quoted as follows: "I have no doubt that it will be a success, but we will wait and see the results before we make any announcement. A cure for cholera infantum would mean a great deal to the mothers of the poor children. The summer corps did great work last year. There is no reason why they should not do even better this coming summer."

**Schools for Crippled Children.**—There are at present seven day schools for crippled children in New York City beside the one connected with the Hospital for the Ruptured and Crippled. These schools are managed by boards of women and are supported by voluntary contributions. Each has its wagonette or ambulance which brings the children in the morning, taking them home again after the sessions are over. There are about 400 children in attendance in these seven schools.

**Farm for Tuberculous.**—The committee on the Prevention of Tuberculosis of the Charity Organization Society now has 100 families in charge, in each of which there is one or more victims of tuberculosis. The committee asks for an immediate special fund of \$5,000 for the special relief of cases under its care. It is desired to rent in a suitable location a farmhouse, and to equip and maintain a boarding house in which accommodations can be provided under medical supervision for a number of the afflicted. Public contributions are asked for to assist in this charitable work.

**New Harlem Hospital.**—Plans have been filed for building this hospital, which will consist of a main building five stories in height with two four-story wings. The first floor will contain, in addition to the offices, the emergency wards; the second floor will contain male surgical and medical wards; the third floor the children's and female wards; the fourth floor the female surgical and maternity wards, and several laboratories; the fifth floor, with a glass dome in the roof, will be used as an operating theater. Each wing will have a roof garden. It is estimated that the building, when finished, will cost about \$300,000.

**Tent Hospitals for the Tuberculous in New York City.**—It is asserted that the Board of Health of New York City has decided to establish a camp where persons suffering from pulmonary tuberculosis can live and receive proper medical treatment. The plan is to select the site on high ground somewhere in the vicinity of the Hudson river. Several tracts are under consideration at various points above the high bridge. There is said to be 40,000 persons in the city of New York suffering from tuberculosis and since the cost of hospital construction is \$1,000 per patient it is obvious that the city cannot stand the enormous expense for hospital construction at the present time. In view of this the plan is to establish camps where tuberculous patients may have the advantage of fresh air, exercise, sunshine and proper diet for the treatment of this affection. It is estimated that the cost of a camp to accommodate 200 patients would be about \$75,000.

**Need of New Lunacy Laws.**—At a meeting of the Medical Society, held February 18, a committee appointed from the society to prepare a memorial calling the attention of the State Legislature to "the present incongruous state of our lunacy statutes, designed for the care and supervision of the insane in State asylums," made its report. The memorial calls attention to the extraordinary legislation adopted by the last Legislature, whereby a system which had been in force for over 50 years was suddenly revolutionized by displacing local boards of managers, which brought about an undesirable change in the management of public insane institutions. It charges that the new system opens the doors of our public charities to partisan politics and venal corruption. The memorial suggests that if a board of lunacy commissioners is created the power should be advisory only, and in no case whatever should it have executive power of any kind. The committee believes that the chairman of a lunacy commission should not be a medical man, as medical men of executive ability fit for such a position are very rare.

**To Abolish the Coroner's Office.**—The special committee appointed by the New York County Medical Association to investigate the office of Coroner and to confer with committees and other societies has made its report to the Academy of Medicine. It recommends the abolishment of the Coroner's office and says: "No one has yet been elected to the office in this city who has brought to the performance of his duties adequate knowledge of both professions (medicine and law) to give the best and most reliable results, and it is doubtful if such a person ever will be or ever can be elected." The final action of the conference was to resolve that the committees recommend to their respective associations such legislation as will abolish the office of Coroner and the duties of that office, as follows: 1. The duties of investigating the causes of death in all cases which now come under the jurisdiction of Coroner to the Health Department, which shall be authorized to organize and equip a bureau for that purpose and appoint the necessary officers. 2. The legal duties to the District Attorney's office. 3. The judicial duties of the inquest to the Magistrate's Court. 4. The duties, other than those pertaining to the inquiry into the cause of death and inquest, to the Chamberlain.

**For a New Bellevue Hospital.**—Dr. Brannan, president of the Board of Trustees of Bellevue and Allied Hospitals, has asked for an appropriation of \$3,000,000 for the erection of a new Bellevue Hospital. It is announced that the Board of Estimate is disposed to grant the request, or at least appropriate sufficient funds to begin the construction of the hospital. It is proposed to have the main hospital building in the center of the plot at the foot of East Twenty-sixth street. The administration building, smaller than the main hospital building, would front on First avenue with a grass plot between it and the hospital building. The insane ward, the ward for patients with contagious diseases, the tuberculous ward and the alcoholic ward will be connected with the main building by underground or covered overhead passageways. This would do away with transferring patients from one ward to another without any protection. The new hospital will have room for 1,200 patients. The present hospital accommodates about 900. The plot of ground which the hospital occupies is large enough so that the hospital can be enlarged if the needs of the city demand it.

**Typhoid at Ithaca.**—It is announced that the present epidemic of typhoid fever has been traced conclusively to a specific contamination of the water supply. This is furnished from reservoirs formed by impounding several large streams at a distance from the town. Upon one of these the water company is building a new dam, and a number of Italian laborers, employed upon the work, were allowed to establish their dwellings near the stream without proper sanitary precautions. An imported case of typhoid among these accounts for the epidemic. An official statement in regard to the prevalence of typhoid among the students at the Cornell University has been issued by the board of trustees. It states that no case of typhoid fever is known to have occurred among those who used exclusively the water supply of the university campus; this supply comes from Fall creek, which is a different source from the water supply of the city. No person in Sage College, in which more than 200 women students board and lodge, and which is supplied by this water, has had typhoid fever, and no case of typhoid has occurred in the families of the professors living on the campus. Typhoid fever has developed only among those students who live in other portions of the city which are supplied by the Ithaca Water Company with water from the Six Mile creek and from Buttermilk creek. The university authorities have made arrangements to enable the students to secure pure water, duly inspected. Artesian water has been placed in all the university buildings, where the students may draw it freely. Distributing stations are being established and students have been officially informed that they may have pure water free at the expense of the university if they do not desire to pay for it. To ensure pure water for the city and university not later than September 1, this year, the Board of Trustees has authorized the expenditure of \$150,000 for the establishment of a complete and adequate filtration plant. This offer has been accepted by the City Council.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**College of Physicians.**—The stipulations made by Mr. Andrew Carnegie in order that the college should receive from him the sum of \$50,000, have, it is reported, been complied with, and the gift is therefore assured. The additional \$50,000 has virtually been obtained, and efforts are being made to raise \$50,000 more. Definite action, however, has been postponed until April.

**Dentist Sued for \$10,000.**—A patient has brought suit in the Court of Common Pleas of Philadelphia against Dr. Barney R. Simmons, dentist, to recover \$10,000 damages. The patient asserts that one of the doctor's employes filled her tooth in such a negligent and unskilful manner that an abscess formed, necessitating an operation, which has marred her features to the extent of \$10,000. A verdict was rendered against the plaintiff.

**Spiritualists Win in a Litigation Over a Man's Will.**—Through a decision of the Supreme Court in an opinion rendered by Justice Potter, the First Association of Spiritualists of Philadelphia comes into the possession of an estate left to it by the late Alexander McIlroy, which amounts to \$30,000. The legal heirs of the estate had endeavored to show that during his life the dead man was insane, offering in evidence his peculiar beliefs in spiritualism. The court decided that a belief in spiritualism is not incompatible with complete sanity; hence the victory for the defendants.

**Sanitary Barber Shops.**—The Board of Health of Jersey City has adopted an ordinance to protect patrons of barber shops. It provides that the floors and woodwork in all barber shops shall be scrubbed at least once a week. The shop must be swept daily. No one shall sleep therein, and no skin disease shall be treated therein unless the barber be a licensed physician. Cleanliness on the part of the barber must be observed. He cannot blow short hairs from a man's neck after a haircut, but instead must use a towel or fine hair brush. Brushes, razors, combs, and other instruments must be sterilized in hot water or in a solution of formalin within five minutes after their use. Every customer must be provided with a perfectly clean sterile towel. Razors and razor strops shall not have the hands of the barber rubbed upon them nor his breath blown upon them during the process of sharpening. A penalty of \$10 is to be levied for each and every offence.

## SOUTHERN STATES.

**Additions to Freedmen's Hospital.**—Notice of an amendment to the Sanitary Civil bill has been announced, providing \$50,000 to the new hospital buildings at Freedmen's Hospital, and limiting the cost of such buildings to \$300,000. The amendment provides that these buildings shall accommodate 300 patients. The buildings are to be designed under the direction of the Supervising Architect of the Treasury and the Superintendent of the Treasury.

**Gifts to Johns Hopkins.**—President Remsen, of Johns Hopkins University, at the commemoration exercises announced that Dr. and Mrs. Herter, of New York, had given \$25,000 for the establishment of a lecture course in medicine, and that this sum would enable the university yearly to invite some eminent man in the field of science to lecture to the students; and further, that a pupil of the late Prof. Henry Rowland had offered to purchase for the university a complete laboratory on the subject of spectroscopy, the cost of which will be between \$5,000 and \$7,000. The offer was made on condition that the widow of the late Dr. Rowland would give to the university all the professor's books on the subject. She has signified her willingness to make the donation. The new library will be known as "The Rowland Library of Spectroscopy."

## WESTERN STATES.

**Calcium Salts to Cure Nervous Diseases.**—Jacques Loeb claims to have discovered that muscular and nervous diseases, such as St. Vitus' dance, paralysis agitans, locomotor ataxia, and insomnia, can be cured by the administration of calcium salts. His conclusion is that the presence of calcium salts in the muscles prevents their twitching, and that their absence leads to the various nervous disturbances mentioned; hence the administration of calcium salts as the remedial measure.

**To Assist in the Treatment of Scarlet Fever.**—The Bulletin of the Chicago Health Department for the week ended February 14, 1903, states that as the scarlet fever germ may be associated with those of whoopingcough, diphtheria, influenza, measles and other infections, it is important that its presence be shown by the culture and microscopic examination, and therefore in order to assist physicians in every way in the control and treatment of this disease, a bacteriologist has been provided by the department to devote his time exclusively to the examination of scarlet fever cultures, and culture outfits are furnished gratis for this purpose. Physicians can avail themselves of these facilities by sending their cultures to the city hall laboratory. Care should be taken to give complete clinical data, especially in cultures from throats in which scarlet fever is suspected.

## FOREIGN NEWS AND NOTES

## GENERAL.

**Needs for a Hospital in Manila.**—From Manila comes the news that Bishop Brent, of the Episcopal Church, has secured 6,000 signatures for a petition to the Philippine Commission requesting the establishment of a general hospital. Commissioner Ide has offered personally to subscribe \$10,000 for the endowment of free beds in the hospital. It is confidently expected that the institution will be secured.

**Sleeping-sickness.**—It is asserted that the mysterious sleeping-sickness which has been so prevalent in West Africa and which caused 50,000 deaths within the past year has proved to be a form of meningitis, similar to spinal-meningitis, but differing from the latter in that it is chronic and strangely fatal. It is apparently contagious but the means of contagion is as yet undetermined. The patient begins with a slight hebetude, which passes to coma and death. Thus far only negroes have been the victims and extensive areas have been practically depopulated.

## GREAT BRITAIN.

**Typhoid Fever in London.**—The Public Health Committee of the London County Council, appointed to investigate the cause of the prevalence of typhoid fever in the city and its surroundings, have practically demonstrated that it is due to the ingestion of infected shellfish. The committee therefore recommends that a law be enacted imposing heavy penalties upon all persons depositing or digging shellfish in infected waters.

## CONTINENTAL EUROPE.

**Tuberculosis Investigation.**—Chancellor von Buelow has sent to the Reichstag a memorandum on tuberculosis treatment, in which the following statistics gathered by the Imperial Health Office are presented: Out of 1,000 deaths in Germany of persons between the ages of 15 and 60, 316 die of tuberculosis alone. Persons under 15 and over 60 are seldom affected. The mortality of the whole population averaged 242 per 100,000

yearly, rising in the Bavarian Palatinate to 329, in Bremen to 337, and in Hesse to 314. The conditions in Germany are shown to be better than in France, Austria, and Russia, but worse than in Switzerland, Belgium, Denmark, Norway, and especially England. The Chancellor said the health office found that tuberculosis can best be treated in special hospitals, in which Germany now has accommodation for 30,000 patients. The statistics for 1896 to 1901 showed that, on the average, out of 100 patients treated, 87.7 were dismissed as cured or improved; 8.8 as no better; 3.1 as worse, and that 0.4 died.

## OBITUARIES.

**Thomas R. Councill**, of Easton, Md., died at the Baltimore City Hospital, February 18, aged 30. He was graduated from the College of Physicians and Surgeons of Baltimore in 1894, and was for three years resident physician at the Baltimore City Hospital. He was health officer of Talbot county, Md.

**D. M. Anderson**, at Venetia, Pa., February 16, aged 65. He was graduated from the medical school at Ann Arbor, Mich., in 1865. During the Civil war he was assistant surgeon of a colored regiment. At the time of his death he was serving his third term in the Pennsylvania Legislature.

**H. H. Hood**, of Litchfield, Ill., February 20, aged 79. He was graduated from the Jefferson Medical College, Philadelphia, in 1851. He served through the Civil war as a surgeon in the One Hundred and Seventeenth Illinois Infantry.

**Benjamin F. Eads**, in Marshall, Texas, February 1. He was graduated from the University of Pennsylvania in 1856. He was chief surgeon of the Texas and Pacific Railway and a member of the American Medical Association.

**Walter Pardee**, of New York City, February 13, aged 81. He was graduated from the Cleveland Medical College in 1860. He retired from the practice of medicine in 1882, since which time he has been an invalid.

**Arista O. Lucas**, in New Washington, Ohio, February 3, aged 37. He was graduated from the Western Reserve University, Cleveland, Ohio, in 1891. He was a member of the American Medical Association.

**Elizabeth MacFarland**, of Sharon, Pa., February 7. She was graduated from the Woman's Medical College in 1901. She had served as interne in the Philadelphia Lying-in Charity Hospital.

**Charles C. Bradley**, in Rock Rapids, Iowa, February 4, aged 82. He was graduated from the Willoughby (Ohio) University, medical department, in 1845.

**William T. Riddlemoser**, of Smithsburg, Md., February 18, aged 43. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1882.

**John R. Burton**, in Valdosta, Ga., February 7, aged 78. He was graduated from the College of Physicians and Surgeons, New York City, in 1848.

**Jacob Burger**, in Franklin Square, Ohio, January 31, aged 75. He was graduated from the Eclectic Medical Institute, Cincinnati, Ohio, in 1856.

**Charles L. Floor**, in Youngstown, Ohio, January 30, aged 44. He was graduated from the Western Reserve University, Cleveland, in 1882.

**Henry W. Allan**, in New York City, February 5, aged 48. He was graduated from the Bellevue Hospital Medical College, New York, in 1882.

**Lucien W. Curtis**, of Southbridge, Mass., died in Worcester, Mass., January 30. He was graduated from the New York University in 1848.

**Ashley A. Webber**, in Williamsburg, Pa., February 19, aged 40. He was a member of the dispensary staff of the Eastern District Hospital.

**John P. Agnew**, in Philadelphia, February 5, aged 69. He was graduated from the University of Pennsylvania, Philadelphia, in 1861.

**John Ash**, in Brighton, Ill., January 31, aged 84. He was graduated from the Philadelphia College of Medicine and Surgery in 1851.

**David M. Browder**, in Sweetwater, Tenn., February 5. He was graduated from the Eclectic Medical Institute, Cincinnati, in 1885.

**George H. Gilbert**, in Cleveland, Ohio, February 9. He was graduated from the Homeopathic Hospital College, Cleveland, in 1874.

**Charles A. Mahneke**, at Appleton, Wis., January 28, aged 55. He was graduated from the University of Berlin, Germany, in 1866.

**Samuel Gray**, in Laurel, Md., January 30, aged 72. He was graduated from the University of Maryland, Baltimore, in 1858.

**Archibald E. Covert**, in New York City, February 2, aged 82. He was graduated from the New York University in 1892.

**Emmett E. Dixon**, in Gainesville, Ga., February 1, aged 55. He was graduated from Atlanta (Ga.) Medical College in 1867.

**James J. Scollard**, of Clinton, N. Y., February 20, aged 76. He was graduated from the Albany Medical College in 1874.

**Charles C. Conway**, of Fredericksburg, Va., February 17, aged 70.

**H. H. Warburton**, at Santa Clara, Cal., February 9, aged 84.

**Francis H. Bankard**, of Westminster, Md., February 19.

**George Harris**, of Bridgeton, N. J., February 9, aged 59.

## COMMUNICATIONS AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

### THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH: ITS SCOPE AND PLANS.

To the Editor of *American Medicine*:—Inasmuch as many rumors concerning the Institute have been floating through the columns of the daily press, it has been thought best by the directors to give out for publication the following statement of the work and plans. L. EMMETT HOLT, *Secretary*.

The Rockefeller Institute for Medical Research was founded in 1901 by Mr. John D. Rockefeller, who gave for this purpose the sum of \$200,000. The aims of the Institute are the promotion of medical research, with especial reference to the prevention and treatment of disease.

It was thought wise by the directors of the Institute not at first to concentrate the work in any one locality, but to enlist the interest and cooperation of such investigators throughout the country as might be engaged in promising researches or who might enter upon new fields if suitable pecuniary assistance could be afforded them. It was the conviction of the directors that in this way it would be possible not only to stimulate and foster valuable contributions to science, but also secure important practical suggestions as to the lines along which the Institute might most wisely develop.

Among the large number of applications for assistance in carrying on original studies which relate to the cause, prevention, and cure of disease, and to the problems upon which new knowledge on these subjects must be based, over 20 have been selected. The directors have secured counsel in these selections from the heads of departments or others in the Universities of Harvard, Yale, Johns Hopkins, Pennsylvania, Columbia, New York, Chicago, Michigan, McGill, Wesleyan, California, and Western Reserve; and in many of these institutions work has been prosecuted. Two of the Rockefeller Fellows have been working in Europe. Some of the workers under these Rockefeller Institute grants, which vary in amount from \$200 to \$1,500, have completed and published their investigations; some are still engaged upon them.

It is the purpose of the directors from time to time to bring together in the form of volumes of collected reprints the results of these researches, which may be published in various technical journals. An arrangement has been effected by which the Institute will assume the publication of the *Journal of Experimental Medicine*, which will remain under the editorial supervision of Dr. William H. Welch, professor of pathology in the Johns Hopkins University, and president of the board of directors of the Institute.

At the end of the first year of practical work of careful study of the situation, it became clear to the directors that existing institutions in this country, while in many instances carrying on most valuable researches in medicine, do not afford adequate facilities for many phases of investigation which are of the utmost importance and urgency. This is in part due to the lack of sufficient endowment, in part to the large demands made upon the time and energy of the workers by their duties as teachers. It was further evident that such assistance as the Institute had thus far been enabled to extend to selected investigators in various parts of the country had fostered work of great actual value as well as of high promise and should be perpetuated along similar lines.

The directors, however, were united in the conviction that the highest aims of the Institute could not be secured in this way alone. Useful as such individual studies are and important as it is to enlist and to maintain the interest of research workers in established institutions of learning, it is not possible in this way to secure the unity of aim and the coordination and mutual stimulus and support which are essential to the highest achievements in research. These are to be secured, it was believed, only by the centralization of certain lines at least of the work of the Institute under a competent head or series of heads of departments, in a fixed place, with adequate equipment and permanent endowment.

There is no lack of men of sufficient training and experience ready to devote their lives to the solution of medical problems which bear directly or indirectly upon the welfare of mankind. The widely open fields of research are many. Some of these relate to the application of existing knowledge to the prevention and cure of disease; others to the development of new knowledge along various lines of science which more than ever before give promise of great significance in the problems of physical life.

In a broad sense, the directions and methods for the study of disease may be classified as morphologic, physiologic, and chemic; and the Institute, it was thought, should include departments providing for these divisions of the subject. For the morphologic study of disease there should be a complete equipment for pathologic-anatomic research. For the physiologic study of disease provision should be made for experimental pathology, for pharmacology and therapeutics, for the study of bacteria and other microorganisms with especial reference to their relation to the infectious diseases, and for other investigations in personal and public hygiene, including preventive medicine. Here belong especially the problems of infection and immunity, and here also in large part such studies as require access to patients in hospitals. There should be a laboratory well equipped for investigations in physiologic and pathologic chemistry.

It was the conviction of the directors that such an institute might wisely add to its aims in the direct increase of the knowledge of disease and its prevention and cure, a phase of activity which should look toward the education of the people in the ways of healthful living by popular lectures, by hygienic museums, by the diffusion of suitable literature, etc. For, in fact, the existing agencies for medical research for the most part stop short of those direct and widely diffused applications of newly won knowledge upon which the immediate practical fruitage of their work so largely depends.

In order that the causes and treatment of human disease may be studied to the best advantage, it was the opinion of the directors that there should be attached to the Institute a hospital for the investigation of special groups of cases of disease. This hospital should be modern and fully equipped, but it need not be large. It should attempt to provide only for selected cases of disease, and the patients would thus secure the advantages of special and skilled attendance, and such curative agencies as the Institute might develop or foster.

It was thought that an institute for medical research of the largest promise would require a central institution, fully equipped and endowed, and with capacity for growth, in which the more comprehensive studies demanding the coordinated forces of various phases of science could be carried on from year to year, while at the same time, by means of such grants of assistance as has been offered during the initial year, it should continue to make available the resources of special workers all over the country, as well as in Europe.

In view of the above considerations relating to its future in June, 1902, Mr. Rockefeller gave to the Institute the sum of \$1,000,000 for the purchase of suitable land, the erection of buildings, and the organization of a working force along the broader lines which had been projected. It is the purpose of the directors to proceed at once to the erection of a laboratory building which will provide for the present requirements, and will be capable of enlargement as the character and extent of the work of the Institute may develop. Negotiations for a suitable plot are now under way.

A small hospital will also be built in the immediate future, which will be maintained in close association with the experimental work of the Institute.

Provision will be made in the laboratory building for research in physiologic chemistry, pharmacology, and therapeutics; in normal and pathologic physiology, and in various phases of morphology, and for the study of bacteria and other microorganisms. It is hoped that the laboratory buildings may be completed and ready for the commencement of work in the autumn of 1904.

Dr. Simon Flexner, professor of pathology in the University of Pennsylvania, will direct the scientific work when the

building is completed. His colleagues deem it of the highest importance that the Institute has been able to secure so eminent an investigator as Dr. Flexner to shape the work of its early years. Dr. Flexner will spend several months abroad while the new buildings are in course of erection.

It is proposed to organize the various sections and departments into which the work of the Institute will naturally fall so that each of them, though in a measure autonomous, will still be so closely associated as to favor the conjoint investigation of comprehensive problems. Associated with the head of each of these departments it is proposed to have a staff of trained assistants.

Provision will also be made for research work by a group of trained men to be designated Fellows, Scholars, etc., of the Institute, under pecuniary grants of varying amounts.

Finally, opportunity will be afforded to suitable investigators not members of the regular staff of the Institute to pursue special lines of research.

The directors of the Institute are:

- Dr. William H. Welch, of Baltimore.
- Dr. T. Mitchell Prudden, of New York.
- Dr. Theobald Smith, of Boston.
- Dr. Simon Flexner, of Philadelphia.
- Dr. Hermann M. Biggs, of New York.
- Dr. C. A. Herter, of New York.
- Dr. L. Emmett Holt, of New York.

The officers are:

- Dr. William H. Welch, president.
- Dr. T. Mitchell Prudden, vice-president.
- Dr. L. Emmett Holt, secretary.
- Dr. C. A. Herter, treasurer.

## ETIOLOGY OF CANCER.

BY

ALEXANDER R. BECKER, M.D.,  
of Seattle, Wash.

Last spring I closed a prolonged and painstaking study of cancer with two positive convictions: First, that nothing whatever was then known regarding its etiology; and second, that the cause would ultimately be found to be chemic—perhaps I should say autochemic and a result of perverted katabolism.

The theories most in vogue at that time were Cohnheim's and the bacteriologic or protozoan. The former has never seemed to me more than plausible, or at most, suggestive, for it left so many points entirely unexplained, *e. g.*, it gave no hint even as to why the "included embryonal cells" should have lain quiescent for so long a time, nor what the immediate stimulant could have been. As for the latter, while it was easy enough to find and demonstrate the "cell inclusions" by proper technic in many cases of both sarcoma and carcinoma, they were entirely absent from other quite as typical cases, and could, moreover, be found in many other instances which were positively not malignant. The really exhaustive investigations of the Harvard Medical School Cancer Committee seemed to settle that matter for good and all with no remainder; and yet this was a severe disappointment, for since the early days of the germ theory of disease—say 25 years *et sequiter*—I have been hoping that a bacterial etiology would be discovered, with a consequent cure or at least mitigant. But it was not to be, and I can quite fancy Hueppe rejoicing at that.

But now comes Dr. Homer Wakefield, of New York, with his very remarkable paper on the "Pathology of Katabolism" (*American Medicine*, November 22 and 29, 1902), with a wealth of hypothesis to bewilder the unprepared mind, but so controlled by the most advanced biochemic knowledge and clinical experience and demonstration, and keen logic, as to demand the very best and closest study of the best pathologists everywhere.

An autohyperacidity—*i. e.*, subalkalinity—local or general, causing a suboxidation, which leads to subkatabolism and then stasis in the tissues, while anabolism goes on. There is nothing dramatic about that; no bacterium to hold up to opprobrium, or from which to manufacture an antitoxin and fame and wealth and decorations. And yet, does it not portray

a really usual action of nature whereby the slightest initial deviation may lead to the most various finalities?

I shall not consider the more general of his deductions, though the temptation is great, for he shows how the general condition of subkatabolism may make the system receptive to the pathogenic bacteria, may provide the indispensable "nidus" as we should have said in the earlier days.

But he declares the malignancy of a neoplasm to be practically a matter of degree; of a superlative or prolonged local hyperacidity, which produces a coexistence of adolescent and mature and degenerating cells, of living and necrotic matter, within a circumscribed area—a confused mass, both histologically and chemically, with contradictory efforts at life and products of death, and therefore fully capable of its clinical results.

By age and habit I am averse to hasty judgment, and yet I freely admit that this hypothesis and argument has aroused my real enthusiasm. Still, it is only as one of the old guard that I venture to express myself while awaiting the dicta of the masters of pathology.

## CLINICAL NOTES.

BY

J. McFADDEN GASTON, M.D.,  
of Atlanta, Ga.

*Distinguishing Features of the Subject.*—The extraordinary increase of therapeutic agents is what might be expected with the influx of many new preparations from the coal-tar series and the stimulus to produce alkaloids from standard crude drugs by the manufacture in the form of proprietary medicine. Some practitioners hold fast to the old remedies whose great virtues have been proved, while others prescribe only the newfangled pellets. The form in which remedies are prepared to render them palatable is notable, and the pellets, tablets, capsules, alcoholic mixtures of various kinds, all prove acceptable to patients who are not willing to swallow drugs of bad taste in a crude form. A few accredited medicinal agents are found to be so efficacious as to figure in almost every prescription which goes to a drug store, while others that formerly were in good repute are no longer given.

Our concern at present is to turn to account those medicines which may aid in preventing the development of disease in its initiatory stage. After any disorder is recognized and the diagnosis is clear it comes under the province of preventive medicine and should be dealt with accordingly. Any modification of diet, hygiene, quarantine or medicinal agents which cuts off the progress of disease comes under the head of preventive medicine.

All interference in cases in which the condition is favorable should be discouraged. Inactivity is, under such circumstances, the highest order of progress and comes appropriately under the head of prevention. This principle has had a practical application in the adoption of the first dressing and the after-treatment of the most conservative measures in Cuba and the Philippines. The limited array of mortuary statistics in gunshot wounds makes a most satisfactory showing for nonoperative treatment when it can be adopted. Everything about this class of wounds must be kept in an aseptic condition and neither probe nor finger should be used in exploring the wound. It is evident that in an abdominal wound with an ordinary bullet the Röntgen ray should be used to locate the ball and that there should be no great risk in removing it, but the results have not brought the statistics below the general average of mortality in great numbers of wounds inflicted by guns and other firearms.

*Ophthalmia.*—If ophthalmia neonatorum is properly treated at the earliest period after the birth of the child there is reason to expect a good result, and the small percentage of failures after preventive measures are employed shows the efficacy of such treatment. Formerly the midwife applied warm salt water to the eyelids and the face of the child, and since, it has been the practice of accoucheurs to apply a weak solution of silver nitrate to the outer and inner surface of the eyelids for some days. According to recent observers, of 1,030 children treated with a strong solution of boric acid and a 10% solution of protar-

gol not a case of ophthalmia occurred. This treatment is found efficacious by European authors and by some of the best practitioners of this country. Those not having experience with this mode of prevention will be surprised to find that pus is not found and that ophthalmia fails to develop. If the ophthalmia of conjunctivitis is not arrested by the prophylactic treatment, when the disease has to be combated as a fully developed disorder, there is but little hope of saving the sight of the child.

Hence the great importance of proceeding early with the use of the antidotal applications to prevent the progress of this malady. Whatever may be the origin of ophthalmia neonatorum, we must rely upon some early prompt application to save the sight of the child, and insist strenuously upon active measures of treatment in advance of the access of disintegration. It matters little what kind of medication may be adopted after the eye has undergone a destructive inflammation and blindness winds up the prognosis. The enactment of laws to punish the neglect of due precautions requisite to arrest this disease at an early stage has been urged and should be enforced. Howe, of Buffalo, cites statistics of Kostling to show that only 9% were affected after the use of prophylactic measures, and that a minimum was reached by the Credé method.

**Carbuncle.**—There has been some confusion of terms in the use of the words anthrax and carbuncle, due to the fact that the latter designation has been applied to two distinct morbid processes, while the designation of the same disorder by the word charbon is recognized by others. The use of the word carbuncle by general practitioners indicates a local manifestation of a constitutional disorder or of a dyscrasia, which at the outset corresponds in its development to phlegmonous inflammation, so that it has been taken for an ordinary boil. If allowed to run its course it forms an indurated circular area with multiple apertures that discharge a sanious fluid, and finally there is ulceration with disintegration of structure.

At the primary change in the organism preventive measures avail for the arrest of the carbuncle, and the internal use of calcium sulfid with local application of silver nitrate and adhesive plaster will jugulate the disorder and prevent further development. Those not having experience with the use of silver nitrate and adhesive strips in the treatment of multiple furuncle or of carbuncles will be surprised to know that a preventive of the formation of pus exists, so that the compression caused by the strips induces a healthy condition of the tissues in a few days. It affords me great satisfaction to vouch for relief experienced in my own person. I am familiar with the treatment of carbuncle recognized by the profession when the disease is in the advanced stage, but I have not resorted to these measures when a case has been brought to my attention at an early period, as the preventive process has met all the requirements. I have been employing this prophylactic procedure for more than 20 years, with the most satisfactory results. It acts so as to abort the fibrous disintegration and to promote the diminution of pus, restoring the structures to their normal condition. An early resort to prophylaxis may be relied upon for a good outcome in preventing further progress of this rebellious disorder. It only needs a faithful trial to convince the physician of its great efficacy in warding off carbuncle at the outset of the disease.

**Internal Secretions.**—In the *Medical Times and Register* the modern pharmacology of calcium sulfid is discussed by John Aulde, who claims that calcium sulfid modifies cellular activity, principally through the glandular apparatus (lymphatics), acting as an obstructive when in excess in the system, or when administered in doses too large to permit the necessary metabolic changes: consequently its distinct physiologic property, long recognized to promote suppuration when given in large doses, and to arrest or diminish suppuration when administered in small doses. He deems it of the utmost importance to adopt certain preliminary measures as a means of securing its normal therapeutic efficacy within its proper sphere of action. First, it is advised to administer it with nuclein from animal sources, separately or in combination, because of the known influence of this substance as a protoplasmic regenerator. The combination embraces a wide range of usefulness and in most instances its employment conjointly with alkaline, saline medication will be attended with a happy

effect. The capacity of protoplasm for storing oxygen to release it later as may be required and if necessary in the form of oxidized oxygen or ozone should be borne in mind. In addition should be noted as a special function of nuclein to increase the number of leukocytes in the blood stream and to enact the role of protoplasmic pabulum. We may refer to its physiologic properties: lymph-glandular stimulant, antisyphilitic and resolvent. In therapeutics: suppurative conditions, boils, abscesses, carbuncles, smallpox, and catarrhal affections, bronchitis, erysipelas, cystitis, laryngitis, and skin eruptions arising from suboxidation. In addition should be noted also the appropriate collateral and alternate treatment. Internal secretion is a wheel within a wheel that serves the purpose of a balance wheel in machinery. Unless this unseen power is kept in order the entire corporeal fabric becomes deranged; but if this element is properly regulated it prevents the development of disease. All alteratives do their work without perceptible disturbance of the glands, by virtue of their effect upon the internal secretions, and for this reason are generally recognized as blood purifiers.

**Malignant Pustule.**—This disease resembles syphilis in the manner of its involving first a local area, and next the whole system as a constitutional complaint. Although it is observed in the lower animals it may be communicated to man by inoculation. The philosophy of the extreme virulence consists of the series of changes that are allowed to take place from the original lesion. The French have known this disease by the name of charbon, and in England, Germany, and the United States a constitutional disease has been studied which differs essentially from anthrax or carbuncle, but which has been found to have the anthrax bacillus, which, when inoculated, repeats the disease. The peculiar and apparently insignificant beginning of pustule is another resemblance it bears to syphilis, as well as its subsequent course involving so many organs and such a long period of time. Treatment should be instituted at the earliest possible moment. Having guarded against infection or contact and used disinfectants, all the prophylaxis required has not been used; for the small vesicle may appear in spite of these within 24 hours of the contact, when the skin is thin and the abrasion is sufficient. Even when the ordinary period of incubation has passed, a malignant pustule may develop later. A period of incubation exists as in syphilis and other diseases. If the disease is attacked by local measures during this period of incubation a reasonable ground of prevention may be entertained, and the disease is capable of being eradicated from the body. For this purpose the thermocautery offers the greatest advantages and should be applied thoroughly to destroy all the diseased area. In case the disease has undergone changes of a more extensive character, the secondary stages may be treated in the same manner as erysipelas, by hypodermic injections of carbolic acid and glycerin. In all of these cases there is needed an alterative and tonic treatment before any symptoms arise, and the later nervous phenomena resulting from an impairment of the capillaries and the vasomotor nerves should be prevented by the use of strychnin, electricity, massage, and many other tonifying agents.

**Torpor of Liver.**—Any interruption in the discharge of biliary matter, whether the cause be spasmodic, organic, or mechanical, bring serious trouble in its train. The entrance of a calculus into the bile-duct is manifested by grave disturbance of the nervous system, and phenomena are soon developed which indicate the sympathy of the whole organism with the local difficulty. At the outset rigors alternate with flushes of heat, followed by cold sweats and the most intense suffering. The ordinary acute spasmodic paroxysms of pain in the right hypochondriac region, attended with the most distressing nausea and vomiting, are familiar to every practical observer of any experience. If the transit of this mass of indurated bile along the common gallduct from the gallbladder into the duodenum is effected promptly, all the trouble passes without any serious consequences. However, if the resistance to the progress of biliary calculus is great, and the delay in the canal is much protracted, constitutional disturbance is manifested, and local inflammation in the immediate proximity of the arrested body will speedily develop.

**Biliary Derangements.**—Great practical importance has

been attached to the derangement of the biliary apparatus, not alone from the temporary functional interruption of the flow of bile through the common bile-duct and cystic duct, but by its arrest in the gallbladder and the formation of gallstones. In the progress of these cases, it is found that hepatic colic, attended with acute pain, accompanies the obstruction. The bile may be arrested by catarrhal inflammation in the common or cystic ducts for a short time, and yield to treatment so completely as not to leave any constriction. It is not requisite to go into further details, yet the preventive measures are so effectual as not to demand radical surgical steps. As considerable discussion has arisen over the resort to cholecystenterostomy in the event of occlusion of the common ducts, it may be stated that Dr. Deaver, of Philadelphia, has in strong terms indorsed the operation by recommending it in preference to the other procedures which have been adopted.

*Appendicitis.*—The vermiform appendix affords another instance of obstruction which calls for the knife to prevent further trouble, and it would seem that appendectomy is one of the most frequent operations which surgeons have to perform in these latter days. It is very evident that this class of patients have, in years gone by, recovered by general treatment without operative measures of any kind. Even at the present day some patients have been cured by medication, while others have died from the use of the knife. The consensus of opinion among the physicians and surgeons who have met cases of this nature is in favor of early operation. Remarkably good results have attended the operation, and it may be claimed that the removal of the appendix prevents the return of appendicitis most effectually.

*Goiter (Basedow's Disease).*—Goiter is an enlargement of the thyroid gland, depending upon the surroundings of the individual as to locality, or as to habits, and by some is attributed to eating fish or to drinking snow-water. An isolated or sporadic instance appears occasionally in females without any indication of the origin, and the complication with exophthalmic symptoms is met in connection with cardiac disturbances. There are certain regions of the world in which large numbers of both sexes and of all ages are affected and a considerable portion of the tumors are of large size. I have seen a number of goiters as large as the head of the person whose neck was affected. But for our demonstration of preventive measures the treatment must be resorted to internally and locally in the earlier stages and I can give assurance of its prompt disappearance. The existence of goiter in women is most frequently brought to the physician's notice on account of the ugly deformity of the neck and generally they insist upon prompt treatment for its removal. I find there are not often indications for special surgical treatment even in the advanced stage of disorganization of the glandular structure. My observation of the internal use of concentrated preparation of Lugol's solution of iodine in doses of 10 drops, largely diluted with water, three times a day, gradually increased to double that amount, taken before meals, is that any further development is effectually prevented. For external applications the compound iodine ointment night and morning meets the demands for relief. I have found the tincture of iodine efficacious when employed by the galvanic current in the form of cataphoresis upon the positive electrode covered with cotton, on the one side of the goiter, and the negative sponge electrode upon the opposite side of the enlarged gland. It will appear evident that the electric current is the means of carrying the medication through the gland, and the agent will render the iodine effective in accomplishing the atrophic degeneration of the glandular structure. The current need not be so strong as to be painful, and a six cell battery will serve the purpose for cataphoresis. An application for 10 minutes is usually attended with redness of the skin at both poles of the battery, and may lead to such irritation as to require that the force of the current be made weaker.

When preconceived ideas are set aside by accurate observation of facts and the patient investigation of cause and effect in the development of epidemics, we may expect the dissemination of more correct views of hygiene and the application of more efficient therapeutic measures. The discussions as to

hygiene indicate such preoccupation in favor of special schemes as to preclude a just and fair appreciation of the data presented. The vast field of hygiene and prophylaxis may well engage the best talent, and in this age of specialists it should be elevated into a special department of study. He who cures the ills that flesh is heir to deserves undoubtedly grateful recognition from those who suffer, but he who stays the access of disease should receive the high and noble praise from mankind generally in their "well done, good and faithful servant."

## A COMMON CAUSE FOR MOST CONVULSIVE DISEASES.

BY

LOUIS FAUGÈRES BISHOP, A.M., M.D.,  
of New York City.

Attending Physician, Lincoln Hospital, New York.

I have been impressed with the fact that there must be some single diseased condition underlying all the different forms of convulsive diseases, or at least a series of causes of great similarity.

Last week I was called to a case of eclampsia. As I watched the convulsions I was struck once more with the precise similarity to the convulsions that I have so often seen in the epileptics who used to come for treatment to the Vanderbilt Clinic. The convulsions began in the right hand and then became general. In this case I delivered a premature child by version, and put the patient under large doses of morphia. There was only one general convulsion after delivery, and the patient is on the road to recovery.

I feel convinced that eclampsia is due to a poison which has its origin in connection with pregnancy, and the production of which often ceases after delivery. In this we have a clue, perhaps, to true epilepsy. I do not believe that localized spasm indicates necessarily that there is a local lesion in the nervous system. It simply means that there is one part of the nervous system that is more susceptible to the poison than other parts. Thus, in my case of eclampsia there was no reason why these convulsions should begin in the right arm, except an accidental susceptibility of the corresponding motor area to the poisoning.

Thus, on the other hand we see brains that are deeply scarred by injuries, and yet the patient does not suffer from epilepsy. It seems to me that all that local lesions do is to render that part of the brain more susceptible to the cause of epilepsy. Hence we must seek for the cause of epilepsy, not in the microscopic examination of the nervous system which has proved itself so barren, but in a study of the chemistry of the body and a study of toxic substances. We may find in the examination of the brain the cause of the susceptibility of a particular area but I believe there the limit discovery is reached. I have a strong impression that morphin has an antidotal action to the poison of the acute epilepsy that I have seen from time to time in pregnant women. My cases are not numerous enough to draw conclusions of great value, but I certainly have not that dread of the disease that many physicians have.

**Samuel D. Gross Prize.**—The Philadelphia Academy of Surgery announces that the Samuel D. Gross prize of \$1,200 will be awarded January 1, 1905. The conditions annexed by the testator are that the prize "shall be awarded every five years to the writer of the best original essay, not exceeding 150 printed pages octavo in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." The essays, which must be written by a single author in English, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 South Thirteenth street, Philadelphia," on or before January 1, 1905. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

ARE ANTISEPTICS OF ANY VALUE IN HAND DISINFECTION?<sup>1</sup>

An Experimental Study from the Surgical Clinic of Dr. Roswell Park.

BY

EDGAR R. McGUIRE, M.D.,  
of Buffalo, N. Y.

Assistant to Dr. Roswell Park's Surgical Clinic.

To the man who first taught us the principles of wound infection, whether Lemar or Lister, not only surgery but the world at large owes a debt of gratitude which it can at best repay poorly. He is the bright star in the scientific firmament of today, for his work ranks first among the great discoveries of science during the past century. While Lister's idea that wound infection was due to organisms in the air was but a portion of the truth, yet it paved the way for the Germans to show that wound infection was due to germs upon anything which came in contact with the wound, whether dust-laden air, hands, instruments, or dressing. With this discovery began the history of hand disinfection. The question at once arose, How shall the skin, instruments, and dressing be sterilized? The sterilization of the dressing and instruments, through a gradual process of evolution, passed from the early method of immersing in antiseptic solutions to the present ideal method of superheated steam or boiling. The skin, however, proved a more difficult task, and although men famed in science have devoted their best energies to the solution of this problem, we are today far from an ideal method.

Early ideas on the subject were such that about all that was considered necessary was to dip the hands in antiseptic solutions. However, in 1880, Floystrop, of Copenhagen, first formally introduced the nail brush, and this was probably the first seed sown of what later grew to be the mechanical side of hand disinfection. About this time Koch discovered the germicidal properties of corrosive sublimate, and in 1882 Bardeleben first used it to sterilize the hands. From this time on this newly-made king of antiseptics has ruled the domain of surgery with almost undisturbed sway. Many have tried to shake it from its high pedestal, some advocating alcohol, others chlorin gas, and others prepared soaps, but all in vain. Although the growth of seed sown by Floystrop was retarded somewhat by the advent of mercuric chlorid, Leopold in 1887 emphasized the importance of mechanical cleansing previous to the use of antiseptics. Later Furbringer made it a part of his method, also introducing alcohol. Gradually investigators began to realize the importance of the mechanical side of the procedure, until today it has become so prominent that the whole question of hand disinfection seems naturally to appeal to us under the two heads: (1) Mechanical cleansing alone; (2) mechanical cleansing followed by antiseptics.

Let us reverse the seemingly natural order, and consider first the question of antiseptics and their value in hand disinfection.

*Mercuric Chlorid.*—So completely has this antiseptic taken hold of the profession that its use might almost be said to be universal. After its introduction to surgery the flattering results of cultures taken from the hands by Kummell and others made it appear as though the ideal were reached. In 1889, however, Geppert took the first step in shattering this confidence by precipitating with ammonium sulfid the mercuric chlorid which was carried over into the culture. By these experiments he showed that what was believed to be the death of the germs was simply their inhibition, as

after the mercuric chlorid was rendered inert the germs grew as before. These experiments threw great light on the true value of mercuric chlorid, but even now it is very difficult to judge, because if a sterile result is secured with any method containing mercuric chlorid (1) all of the antiseptic may not have been precipitated; (2) the mercurial sulfid formed may possibly inhibit the growth; (3) the germs themselves may be carried to the bottom with the precipitate.

One feature regarding mercuric chlorid which has long been known, but which, as yet, has not been sufficiently appreciated in hand disinfection is the fact that it possesses no penetrating effect.

**EXPERIMENT I.**—A sterile piece of silk is dipped in a culture of staphylococci, and then immersed in liquid fat or grease which forms a coating around the germs. It is then immersed in a solution of mercuric chlorid 1-1,000, for a period of three days. Finally it is removed with sterile forceps, washed to get rid of the fat, and planted in bouillon. Growths will appear in 24 hours to 36 hours.

**EXPERIMENT II.**—A surface growth of staphylococci on agar is exposed to 1-1,000 solution of mercuric chlorid for 10 days; this is then poured off, and growths washed in sterile water or, better, the ammonium sulfid solution, to get rid of the excess of mercuric chlorid. Finally with platinum wire break up the colonies and plant again on agar and growths will appear in due time.

If the usual method of using mercuric chlorid is considered in this light, one sees the absolute foolishness of using it until the outer layer of loose epidermis, fat, dirt, etc., is removed by some means. When this outer layer is removed the germs are hidden in the small crevices of the skin and glandular structures, covered more or less by epidermal cells and in such a situation what possible benefit can accrue from using a substance which not only lacks penetrating effect but also has the property of forming an inert albuminate on the skin? It is evident the germs are not reached by the mercuric chlorid, but are simply incased, as it were, by this new albuminate layer. During an operation, what takes place under these circumstances?

The alkalinity of the blood and tissues neutralizes the effect of the mercuric chlorid and under constant manipulation this outer albuminate layer is neutralized and removed, thereby allowing the pent up germs to escape into the wound. In culture experiments this same condition exists, only it is necessary to use ammonium sulfid instead of the blood to neutralize the mercuric chlorid. When this is done there are found equally as many growths as there were previous to use of mercuric chlorid. As proof of this about 30 experiments were made in the following manner: The hands were scrubbed in running sterile water, with sterile brushes and sterile soap. Four to seven sterile brushes were used about three minutes each. At this stage cultures on agar were made from each hand. Then the hands were immersed for five minutes in mercuric chlorid solution 1-1,000. Next they were washed in running sterile water for one minute and finally soaked in ammonium sulfid solution. Then from the corresponding part of the hand used before, cultures were again made. On comparing results before use of the antiseptic with those after its use there was seen no appreciable difference, showing the complete failure of mercuric chlorid to render the hands any freer from living germs.

Thus far I have considered how much of the good claimed for mercuric chlorid does it accomplish? Considering the other side of the question it seems natural to ask, How much harm does it do?

While most investigators in hand disinfection differ greatly in the final results obtained, yet all agree on one point, namely, that keeping the hands as smooth and soft as possible is of prime importance in securing good results. Bloomberg, Schleich, Gottstein, and Haegler have laid special emphasis on this point. Possibly the occasional operator, if his hands are not susceptible to irritants, may use mercuric chlorid and still keep his

<sup>1</sup> Read before the Surgical Section, Buffalo Academy of Medicine, December 2, 1902.

hands in good condition, but operators or nurses in a large clinic cannot possibly do so. To be satisfied on this point one has but to examine the hands of the nurses in any large clinic where mercuric chlorid is freely used, and it will be seen the hands are so rough that the epidermis can readily be scraped off with a knife. One who has seen such hands will readily realize how impossible it is to get them even ordinarily clean, not to speak of sterile. Again, mercuric chlorid breeds a false sense of security in the cleanliness of the hands. The operator, through necessity or otherwise, infects his hands, and is in too big a hurry to resterilize them properly, so he simply dips them in mercuric chlorid, and with what a sense of security he again enters the open wound! What an appeasing effect mercuric chlorid seems to have, especially if it happens to be colored blue! And yet this confidence, in spite of the fact that his hands were probably covered with blood or perspiration. But, alas! we are but human. "We are but what our fathers have been." That same confidence which, in the early days, bound our surgical fathers to mercuric chlorid binds us today so tightly that it is with great difficulty we burst those bands asunder. I believe that in living tissue the action of mercuric chlorid is so hindered by the presence of epithelial cells, fat, sweat, soap, and dirt that chemic disinfection by it is usually nothing more than a farcical show of asepsis, and in the words of Schleich, "about as much good as making the sign of the cross over an open wound."

If, on the other hand, the operator would only realize the true value of mercuric chlorid, he would be much more careful in the mechanic cleansing of his hands. Having got his hands reasonably clean after much long-continued scrubbing he would be much more careful not to infect them, knowing how long it would take to cleanse them again. I know of no one thing in an operating-room which so breeds faulty technic and so weakens the links in our chain of asepsis as the presence of a basin of mercuric chlorid.

For a few minutes let us look at some of the experimental work that has been done on this subject. Drs. Kroenig and Bloomberg have carried out some very interesting experiments, which at first sight seem quite convincing regarding the use of antiseptics. I quote from them because their work appealed to me as the strongest argument yet put forth in favor of antiseptics. They scrubbed their hands (1) by the mechanical method of Schleich (that of marble dust soap); (2) by the alcohol method; (3) mercuric chlorid method; (4) a method using mercury ethylenediamin, the trade name of which is sublamin.

After the different methods of sterilizing they injected the cultures taken from the skin into white mice. The findings were as follows: (1) After Schleich method, 13 mice, all of which died; (2) after the alcohol method, 14 mice, of which 10 died; (3) after mercuric chlorid, 10 mice, of which 5 died. In only one of these were they able to recover the organism used in the spleen and other organs; (4) sublamin, 10 mice, none of which died.

It seems to me that in these experiments there are several fallacies which if corrected might alter the result to a considerable degree:

1. Their method of removing germs to the cultures. I do not consider removing the germs with sterile marble dust trustworthy.
2. Animal inoculations, since you cannot use organisms infectious to man, needlessly introduces another factor—the virulence of the germs.
3. The resistance of white mice to tetragenous infection and that of man to pyogenic infection are two quite different conditions.
4. They maintained when inoculating animals it was unnecessary to precipitate the mercuric chlorid or whatever antiseptic was used, because the conditions were the same as in an operation. This I cannot accept, as taking

cultures from the skin and injecting them into an animal is quite different from the constant manipulation of the hand in alkaline blood as occurs in an operation. In the one case the conditions are present which render inert the antiseptic used, while in the other this does not seem to be so.

On the other hand the unreliable results obtained by mercuric chlorid disinfection has been dwelt upon by Geppert, Paul, Schleich, Schaffer and others.

Schaffer is one of the latest investigators. He placed the alcohol method first; the green soap and scrubbing second; mercuric chlorid fourth; and sublamin fifth. One of his final conclusions was that antiseptics were of very little account in sterilizing the hands.

Therefore after carefully considering the evidence for and against the value of mercuric chlorid, I believe that in it we have a substance the use of which as a means of disinfecting the hands is not only questionable but is also distinctly harmful when improperly used. Let us then rise superior to our time honored prejudices in favor of mercuric chlorid and in the strength of truth and calm sober judgment banish mercuric chlorid from our armamentarium in sterilizing living tissues.

I wish it understood that whatever I have said in regard to the inefficacy of mercuric chlorid refers only to its use in sterilizing living tissue. I consider it an antiseptic *par excellence* for sterilizing substances, such as tables, floors, etc. Here the germs are readily reached and when this is possible mercuric chlorid is one of the best antiseptics we possess.

*Alcohol.*—In Europe alcohol is given a much more prominent place for hand disinfection than it possesses in America. While many European investigators are loud in their praises of it, yet they all seem to be at a loss to explain the reason for the good results. At present very few make any claim for it on the ground of its antiseptic value because that has been proved to be very slight. Koch found the spores of anthrax alive after 110 days' exposure to absolute alcohol. Schaffer found that staphylococci would grow after 20 minutes' exposure. Some insist that it must be used in concentrated solutions, while others say it must be well diluted to be of any value.

Its slight antiseptic value led some to seek a more reasonable explanation of its success. These argued that fat prevented the germ from being reached by ordinary methods and consequently the good results were due to its fat solving properties. Chemists, however, say that alcohol is a poor fat solvent. This can readily be demonstrated by washing greasy hands in alcohol, when the fat is seen floating on the top. This fat solvent theory is, moreover, shown to be untenable by the fact that ether, which is a much greater fat solvent, does not give such good results.

To what, then, can we ascribe the good results of cultures taken from the hand after alcohol disinfection? Alcohol has such a hardening effect upon the skin that the germs are literally locked in, and thus it is extremely difficult to remove them to the culture. This, to my mind, accounts for most of the good results; the germs are on the hands, but are not removed to the culture medium on account of the hardening effect of the alcohol. This point, of course, is nothing new, as nearly all investigators have taken this fact into consideration in their work. Kroenig maintained that 15 minutes' washing in sterile water was sufficient to remove this difficulty, but whether this is so or not we have no way of judging. The evidence for and against the use of alcohol is very conflicting. On the one hand we have the experiments of Kroenig and Bloomberg which have been mentioned, in which out of 14 mice 10 died, and also the work of Doederlein, Schleich, and others. While on the other hand we have Ahlfeld, Furbringer, Schaffer, and others who claim this is the very best method.

However, even admitting some degree of benefit is derived from the use of alcohol, its use in this country is

almost impossible on account of the expense. Schaffer found germs in the alcohol after prolonged washing in it, and therefore insists upon using three or four basins of fresh solutions of alcohol. You will readily see in a clinic where four or six people must sterilize their hands and each one use three basins of alcohol, the question of expense becomes such a serious objection that its use in this country outside of the well endowed hospitals is an impossibility.

*Cornmeal and Mustard.*—To Dr. Park belongs the honor of introducing this method to surgery. I have been associated so intimately with its use in Dr. Park's clinic that I feel I can speak authoritatively in regard to the clinical results obtained from its use. Clinically it has given results in his hands which I am sure cannot be surpassed by any other method. Koch, in his excellent treatise on antiseptics, says he found the oil of mustard to be germicidal in as great a dilution as 1-33,000. The use of ordinary commercial mustard in hand disinfection depends upon the fact that when made into a paste with water the oil is eliminated. It has never been claimed for mustard that it took the place of any of the other cleansing agencies, but that it possessed a few features which gave it a distinct advantage over all others. In the first place, mustard is absolutely non-irritant, in this respect standing almost alone among antiseptics, and further the tactile sensibilities of the skin seem to be increased by its use.

I found cornmeal to be an excellent culture medium, and consequently it must be sterilized before using. It has no antiseptic value, its use being simply a sort of currycomb, in a measure taking the place of the brush. In this connection I believe it is equally as efficacious as Schleich's marble dust and the powdered glass used by some others.

I investigated this combination very carefully, because I felt if it would sterilize the hands it would be superior to the other methods on account of the advantages mentioned above. Here again, however, as in the case of all methods containing antiseptics, I was doomed to disappointment. The mustard failed to give results experimentally for the same reason that other antiseptics failed, namely, that the skin is so constituted that antiseptics cannot reach the germs. Consequently, I believe the excellent results obtained clinically are due to the mechanical scrubbing with the cornmeal. However, as a means of removing foul odors from the skin, mustard paste is almost ideal.

Regarding the other antiseptics which are extensively used in hand disinfection, it is scarcely necessary to discuss each in detail. What has been said with reference to mercuric chlorid may, for the most part, be applied to the others. Potassium permanganate and oxalic acid, chlorin gas and sublamin, all present similar objections. Firstly, they are unable to reach the germs in the deep layers of the skin; secondly, all with the exception of sublamin are so irritating to the skin that they defeat the very purpose for which they are intended; thirdly, they decrease the resistance of the tissues; and fourthly, the false sense of security offered by their use renders them distinctly harmful.

Concerning sublamin, it is too soon to form any accurate judgment regarding its value. Since its introduction by Kroenig and Bloomberg in 1900 many German surgeons have commenced using it. It is claimed that it is equally as efficacious as mercuric chlorid and at the same time has not its disadvantages: (1) It does not form an albuminate with the skin and consequently has a deeper penetrating effect; (2) it is not irritating to the skin, even in concentrated solutions; (3) it is freely soluble in water. The experiments which I carried out with sublamin were scarcely numerous enough to be conclusive even to myself, but I did find that when I followed its use by ammonium sulfid I obtained growths in every instance. Similar results were reached by Schaffer in his experiments mentioned before.

*Mechanical Cleansing.*—It is a self-evident fact that all other things being equal, removing germs from the hands is better than killing them and leaving their dead bodies present. All investigators of recent date are agreed that a very essential part of any method is to get rid of as much superficial epithelium, fat, dirt, etc., as possible by mechanical scrubbing. Most of them believe that something more than this is necessary, but Schleich, however, goes a step further and claims that he is able to sterilize his hands completely by mechanical means alone.

We will all agree that the simpler any method is the better it will be, and consequently if Schleich was able to sterilize his hands by his simple one act method of washing two minutes with his marble dust soap we would herald it as a great boon to surgery. However, Paul and Sarway, Kroenig and Bloomberg, Schaffer, and others have investigated marble dust soap, and were unable to secure anything like similar results to Schleich, but found the results to correspond to those obtained by common soap, water and brush. The reason for the different results is explained by the manner in which cultures were taken by Schleich, namely, using the platinum wire to remove the germs and growing them on gelatin.

While the mechanical side of this question has been emphasized as far back as Furbringer in 1887, yet it seems that it deserves even more attention than most investigators are inclined to give it. There are many apparently minor points which are really important and to a considerable extent affect the result. In the first place, sterilizing the hands is such an important procedure that it should demand our undivided attention. One cannot scrub his hands with bacteriologic exactness and at the same time tell his co-workers about some interesting case. How often has an operator begun an operation when part of his hands remain untouched by the brush, as, for instance, between the fingers! Then, again, the one who listlessly scrubs his hands is exceedingly likely to spend most of his time on the nails, giving but a superficial wash to the rest of the hand.

The first part of any method of hand disinfection after the hands are apparently clean is attention to the nails. Considerable has been written about the difficulty of sterilizing this part of the hand. One man has gone so far as to advise the nonsensical method of cleaning the subungual space with iodoform gauze dipped in carbolic acid. Now why are the nails hard to clean? Simply because of the many crevices and points difficult of access surrounding the nail. The most difficult part of all is the subungual space and common sense gives us the remedy, namely, get rid of the space. By this I do not mean trimming the nails so that they project about  $\frac{1}{4}$  inch beyond the adherent part. Long nails neatly trimmed may be very pretty from the dainty society girl's standpoint, but to get such nails bacteriologically clean is an absolute impossibility. Nails should be cut so short that there is little or no space left. On examination of the nails of the operators in some clinics one would see subungual spaces  $\frac{1}{4}$  inch to  $\frac{1}{2}$  inch deep. What a relic of barbarism in the light of our present surgical knowledge! Nails properly trimmed are scarcely more difficult to clean than the rest of the hand. The nails themselves are smooth and the easiest part of the hand to sterilize.

Habits formed in childhood so ingraft themselves into our nature that in later years it is with difficulty we are able to discard them. Most of us were taught at our mother's knee the dirty habit of washing in a basin of water—and so today in spite of what surgical cleanliness has done to lift the veil from our eyes many surgeons still try to sterilize their hands in standing water with but one changing or perhaps not changing at all. Ordinary personal cleanliness demands that we wash in running water. Schaffer in his experiments used five different basins of sterile water, but even this is not suffi-

cient. Running sterile water is the ideal arrangement, and this can always be had, if not from a faucet, from a pitcher poured as needed by a nurse or some other disengaged person. Much better results can be obtained from hot running tap water than from sterile water not changed sufficiently often.

*Brushes.*—These intricate articles introduced by Floy-strop have come in for their share of criticism. It is claimed by those who are opposed to their use that they are a labyrinth of little tunnels, capillary tubes, dead spaces, and angles, and consequently are very difficult to sterilize. It is claimed further that they are contrary to general surgical principles, which insist on everything being plain and easily cleansed. These objections must be admitted, but on the other hand nothing has as yet been introduced which in any way takes their place. As substitutes for the brush, gauze, sand, powdered glass, and marble dust have each had their following. One and all have for their object the mechanical removal of germs from the skin and subungual spaces, and when considered in this light the brush stands preeminently superior to any of the others. That the brush can be sterilized is beyond question, as I have repeatedly taken cultures from all parts of it after boiling or steam pressure and invariably found them sterile.

Brushes, however, have been sadly misused. Examine the "scrub-up" room in most of our hospitals and what a deplorable sight one beholds. Some have so far forgotten the primary principles of disinfection that they use a dirty brush, one that has been repeatedly used without sterilizing. These same people have on exhibition three or four brushes for as many people to sterilize their hands, the brushes for the most part being used so long that they are useless. Then again, those are found whose consciences seem not to have entirely died and who appease it by soaking brushes in mercuric chlorid. What a blissful expression of ignorance in the presence of the surgical light of today!

Brushes should be sterilized by boiling or by steam under pressure. Then they are sterile, but to soak them in mercuric chlorid or any other antiseptic is useless. They should be placed on a sterile platter and covered by a sterile towel so placed that each brush can be readily reached without either infecting the hands or the remaining brushes. The necessity of frequently changing brushes in scrubbing the hands must be apparent to all. They should be changed three or four times during each sterilization, and therefore in a clinic where three or four people must have sterile hands there ought to be at least 12 to 16 brushes ready for use. Simply to use one sterile brush in cleaning the hands is a grave error, so apparent that it only needs mentioning to secure universal recognition. With brushes as cheap as they are today the question of expense need not be considered.

The green soap, or whatever soap is used, should be sterilized, as I have repeatedly obtained growths from the plain green soap. The soap should be placed in a wide, open, sterile bowl. How often the soap is in a narrow-necked bottle of some description, which renders it impossible to secure more soap without re-infecting the hands. In no instance should the hands touch the soap, but it should be removed as required by the sterile brush. After touching the hands, the brush must not again be put in the soap, as it is no longer sterile. One is only justified in putting his hands in the sterile soap when he is sure his hands are as sterile as the soap. To use soap in this way it is necessary to have it in the form of a liquid; the ordinary green soap can be diluted with water or alcohol.

In the clinic of Dr. Roswell Park the following precautions are taken in hand sterilization:

1. Running sterile water is used.
2. Green soap diluted with water and sterilized by heat is kept in a wide open bowl.
3. Two dozen brushes are kept constantly on hand; these are kept in a large open platter, covered by a

sterile towel and sterilized in the steam sterilizer. They are sterilized each time they are used, and three or four brushes are used for each sterilization.

4. Cornmeal is sterilized by heat.

5. Hands are scrubbed at least 10 minutes.

In my experiments, the cultures were for the most part grown upon agar. The germs were removed from the hands by means of a blade with a long stiff wire handle, so that force might be used in scraping the skin. From three to five minutes were used in removing germs from the hands, and visible portions of epidermis were removed for the culture. The usual method of making these cultures by means of the platinum wire I believe to be useless, as I have repeatedly obtained sterile results with the wire, when further scraping with the blade would give luxuriant growths. Another method found of value was that of using a sterile toothpick brought to a broad point, the end being dropped into bouillon. I mention these points because I find very little upon this question in the literature.

The chief aim of these experiments was to decide: First, whether it were possible by improved technic in scrubbing to sterilize the hands completely by mechanical means alone. Second, whether if by following this with various antiseptics it were possible either to render the hands sterile or to lessen to an appreciable degree the number of germs found on the hand.

In regard to the first question I was under the impression that by strict attention to the nails, using running sterile water, sterile soap, and frequently changing the brushes, I could render the hands sterile.

To ascertain the solution of the first question I carried out about 100 experiments as follows:

1. The hands were washed in ordinary soap and water to secure ordinary cleanliness.
2. Nails were cut short and trimmed properly.
3. Hands were scrubbed for three minutes with sterile brush, running sterile water, and sterile green soap.
4. No. 3 was repeated for varying number of times.

The length of time required for scrubbing varied. It always was over 10 minutes and occasionally reached 30 minutes. Brushes were changed every three minutes and the scrubbing was systematic—nails, backs of fingers and hands, palmar surface, and, finally, between fingers—so that no part of the hand received more attention than the other.

I thought these experiments were a fair test in deciding if it were possible to sterilize the hands by mechanical means alone. The result left no room for doubt, as I was unable to secure a sterile result in any instance. I did find, however, that the longer I scrubbed under aseptic precautions the fewer the colonies obtained. Some investigators have found an occasional sterile result after mechanical cleansing alone, but I believe this was due either to less care in removing germs from the hand to the culture or to the fact that some antiseptic had been recently used and not neutralized.

Sweating the hands seems to play a very important role. So far as I am aware it is about the most successful way of removing germs from the deep to the superficial layer of the skin. This has a very important significance, showing, first, that a profuse sweating followed by mechanical scrubbing would render the hand much nearer sterility, and second, that the operator whose hands perspire freely infects a wound much more readily than the one whose hands scarcely perspire at all. The value of rubber gloves to such an individual can scarcely be estimated.

In regard to the second question, I carried out in all about 100 experiments.

The technic was as follows:

1. I scrubbed my hands after the manner described.
2. Took cultures on agar.
3. Exposed my hands to the following antiseptics without reinfection between the scrubbing and immersion in the antiseptic: (a) Mercuric chlorid 1-1,000 for

five minutes; (b) potassium permanganate two minutes, and oxalic acid until decolorized; (c) mustard paste five minutes; (d) acetozone five minutes in a solution made by dissolving 15 grains in two quarts of water used at the end of 36 hours; (e) mercury ethylenediamin or sublimin 1-1,000 five minutes.

4. Took cultures from the corresponding part used for mechanical scrubbing.

In each and every instance, when I neutralized the effect of the antiseptic on the hand previous to taking the culture I secured approximately as many colonies as I did previous to its use. This seemed to answer the question definitely, and led me to believe (1) that antiseptics do not materially lessen the number of living germs and (2) that the value of any method depends entirely upon its ability to mechanically remove germs from the hands.

A fervent admirer of some pet method insists that his method has proved itself to be adequate because he seldom if ever sees pus. In his enthusiasm he forgets there are scores of operators getting results equally as good, using an entirely different method. To what do these men ascribe their good results? One faithful to the memory of his early education still bends the knee in fervent adoration to that former king of antiseptics, mercuric chlorid. Another whose faith in his early teaching seems to have waned somewhat, now swears allegiance to absolute alcohol; while still another insists that alcohol must be diluted to be of value. From all this antiseptic chaos emerges one bright ray of light, namely, all methods have one and only one point in common, mechanical scrubbing. Consequently does it not seem to be good reasoning to assume that their good results must be due to their one common feature, mechanical cleansing. Schleich, convinced of the truth of this, boldly invited infection by operating on pus cases just previous to clean ones, using only mechanical cleansing of the hands.

I firmly believe that owing to the peculiar structure of the skin the germs become embedded in and around the epithelial elements to such an extent that antiseptics do not reach them, and consequently their value is practically nil. In addition to this the false sense of security they offer renders their use distinctly harmful.

The vital question for the future to decide is to what degree of sterility is it necessary to bring the hands?

So many features enter into this question that at present it is impossible to answer it satisfactorily, for instance, the virulence of the remaining germs for man, the possible attenuation of the remaining germs, and the resistance of the tissues to infection. That the remaining organisms were virulent in animals was proved by Kroenig and Bloomberg, and that they are occasionally virulent in man is proved by the occasional unexplained death and the occasional suppurating wound. Concerning the attenuation of the germs on the skin and the resistance of the tissues we know but little.

While at the present time surgical results are uniformly good, nevertheless every honest operator has his occasional suppurating wound. Just so long as this is so, and we are unable to say definitely from what cause, we are in duty bound to protect that one wound by perfecting our technic in every possible particular. Consequently I believe until we can definitely eliminate infection from the hands we ought to make ourselves the more secure by encasing the hands in that which we know to be absolutely sterile—rubber gloves.

#### CONCLUSIONS.

1. Absolute sterility of the hands is impossible by any method.

2. There is no royal road to sterilizing the skin—nothing takes the place of long and vigorous mechanical scrubbing.

3. The longer the hands are scrubbed under aseptic precautions the nearer the approach to sterility.

4. The use of antiseptics on the skin is, at least, questionable; under the usual conditions, it is distinctly harmful.

5. When the true value of antiseptics is understood we will have cleaner hands, due to more conscientious scrubbing.

6. The use of rubber gloves, while not ideal, is the nearest approach to it.

7. The operator whose hands perspire freely ought to wear gloves in every case, regardless of all objections to them.

In closing I wish to express my gratitude to those connected with both the surgical clinic and the Gratwich Laboratory for the many courtesies shown me in this work.

### CHRONIC SPHENOID ABSCESS.<sup>1</sup>

BY

LEWIS S. SOMERS, M.D.,  
 of Philadelphia.

While the comparative inaccessibility of the sphenoidal sinus and the difficulty often encountered in endeavoring to recognize pus collections in this locality either alone or in conjunction with that of the other nasal accessory sinuses have seemingly rendered chronic empyema a rare affection, yet careful necropsies have shown that it is more frequent than is usually considered; its clinical rarity resulting from the often indefinite symptom-complex and the resultant treatment of the nasal obstruction and suppuration as a cause and not a result. Undoubtedly many cases of sphenoidal sinusitis are treated as nasopharyngeal catarrh, while in case the other sinuses are involved the symptoms are overshadowed and not recognized, or as aptly phrased by Lermoyes, "Sphenoidal sinusitis is not rare, only the diagnosis is rare."

In order to obtain a better appreciation of the symptoms and their individual value as factors in the diagnosis and treatment of the condition, it is necessary to keep in mind the relation of the sphenoidal sinus to the nasal chambers, to the nasopharynx, and to the cerebral cavity. Originally the upper posterior portion of the olfactory fissure, it is rudimentary or absent during early childhood, but develops and increases in size commensurate with the other accessory sinuses. Usually it is separated from the posterior group of ethmoid cells by a common wall and is of irregular shape, often with communicating smaller sinuses on one or both sides, while it extends from about 6 mm. back of the vomer in the nasopharynx, forward to the cribriform plate of the ethmoid bone; a portion of the lateral walls of the sphenoid forming in part the inner wall of the orbit.

<sup>1</sup> Read at the Allentown meeting of the Pennsylvania State Medical Society, September 16, 1902.

The most dependent portion of the sinus is on a horizontal line drawn anteroposteriorly through the nose and cutting the sphenoid bone at its junction with the lower border of the vomer, while above lies the cranial cavity, separated from the sinus only by a thin paper-like wall, often containing dehiscences covered only by the brain membranes, and in immediate proximity lie the optic nerve and chiasm, the internal carotid artery and cavernous sinus. The intimate relations, therefore, both with the nose and nasopharynx inferiorly and with the cranial cavity above, render the sinus of considerable import in the presence of suppurative processes here. Especially is this so on account of the nature of its walls, as the anterior, upper and lateral, are thin and compact, while the posterior and inferior walls are thickened by the addition of a layer of spongy osseous tissue.

As regards the presence of serious complications of sphenoid empyema, the superior wall plays the most important part, while in its relation to the nasal chambers and surgical aspects the anterior wall is preeminently of the greatest import. The anterior wall presents two features of paramount importance in this connection, the first, that through it the interior of the sinus may be gained, and secondly, it contains the natural opening for the drainage of the sinus. From the nasal spine to this wall, which is rarely more than 1 mm. or 2 mm. in thickness, measures about 7 cm., while the ostium sphenoidale is usually from 6 cm. to 8 cm. from the inferior rim of the nostril. Generally situated close to the nasal roof and nearer to the lateral wall than to the septum, it is often possible to enter it with a slightly curved probe, the opening in the bone being larger than that in the mucous membrane, as the latter often reduces it to a mere slit. In its relation to the turbinated bodies the opening is to be found above and behind the posterior end of the middle turbinal, and in 50 specimens Holmes found that in 39% it was possible to enter the sinus with a probe, while in 61% it was impossible. Very rarely, however, can the opening be seen, and then only in cases in which the nares are unusually patulous, the turbinals small, and good illumination is obtained, while in an occasional case of atrophic rhinitis it can also be seen and easily probed.

While the symptoms may be severe enough to lead one to anticipate a fatal termination, such is not commonly the case, and it has been my experience that such grave symptoms are quite unusual. Of all the symptoms, not one is as constant as the presence of pus in the olfactory fissure; the posterior ends of the turbinals, especially the middle, is covered with greenish crusts, and when these are removed fluid pus is found beneath, while the tuberculum septi is also difficult to recognize on account of being covered with the dried and inspissated pus. In the majority of cases that I have seen, the purulent discharge was most prominent high up posteriorly near the roof of the nose and between the middle turbinal and septum on but one side. A certain amount of pus always flows into the anterior nasal chamber, while another portion, if the discharge be profuse, flows into the pharynx, where it is apt to crust, sometimes this being the most annoying feature of which the patient complains. In addition to the presence of inspissated pus in the vault of the pharynx, and especially when it is most marked on one side, a significant symptom is the flowing of the purulent material down the posterior wall of the pharynx and which on examination can be traced to the body of the sphenoid bone and into the posterior nasal chamber. The choana on one side is apt to be blocked on arising in the morning from the pus which has accumulated during the night, and in the efforts to remove it nausea and even vomiting may be produced. The effect of the retention of the pus is shown by the exacerbation of the symptoms, and when the drainage is completely blocked grave evidences of meningitis may develop, while the

duration of the disease is at the same time protracted by the irritation of the retained degenerating pus products. While the purulent discharge is most annoying to the patient and while occasionally the symptoms of atrophic rhinitis may develop, even accompanied with ozena, yet the odor is rarely perceptible to any one but the patient, and then when noticeable is usually accompanied with partial anosmia and disturbance of taste from the closure of the olfactory fissure, both by the pus and the swelling of the mucous membrane.

Next to the purulent discharge pain is the most constant symptom, and while it may be variable in site and character as a dull, diffuse headache or neuralgic in character and localized, it is from time to time present in every case in which drainage is at all interfered with, and I believe is often quite accurately localized by the patient in the sphenoidal region. When neuralgic in character it may involve the supra or infra orbital nerves, or even the entire distribution of the fifth nerve, usually on one side, and may then become intermittent, or when necrosis is well marked constant in character. The patient is very apt to refer the pain to the center of the head and complain of stiffness of the neck, the former being intermittent in character and when very severe may produce nausea and vomiting, while should the purulent discharge cease entirely from closure of the sphenoidal opening the severity of the pain becomes greatly augmented and presents the constant throbbing characteristics of abscess formation, and sleep becomes impossible.

The objective nasal and pharyngeal symptoms are quite constant, the root of the nose is somewhat swollen and broader than normal, and the nasal interior shows the well-marked changes of chronic rhinitis. The mucous membrane, especially of the middle turbinal, is hypertrophic and swollen, and polypoid degeneration may be partially in evidence or even well formed polypi may be present, but usually connected with a complicating sinusitis, especially of the ethmoid cells. The membrane of the posterior part of the septum is also swollen, adding to the closure of the respiratory cleft and enhancing the difficulty of breathing through the affected side, while if the sinus becomes much distended this is additionally increased by its encroachment upon the postnasal space. The pharynx presents nothing characteristic of the sphenoidal affection, but the posterior wall is red, dry and glazed from the destruction of the epithelium by the constant presence of the pus and the results of the impairment of respiration subsequent to the nasal obstruction.

The ophthalmic symptoms when present are of interest as indicating the serious phase of the disease by the development of increasing pressure and the extension of the pus collection. With the extension of the inflammation anteriorly associated with venous alterations, photophobia, turgescence of the lids and conjunctivas may develop, with the later appearance of restricted motion of the eyeball, strabismus, ptosis and even exophthalmos from the development of a serous exudation into the cellular tissues of the orbit, or from an extension of the pus forward and the development of an orbital abscess. More frequently, however, the necrosis and pressure is exerted upward and sudden blindness ensues, which may become permanent, as in a case of Sanford's, in which the patient became blind from the sphenoid abscess a number of years before death ensued, while again it may be but temporary, as in a case reported by Holmes, of blindness of the left eye and later recovery of vision by the liberation of pus from the sinus. The pressure on the optic nerve may be only sufficient to lead to partial impairment of vision, or it may be complete with typical choked disks of optic neuritis, while the amaurosis is peculiar, inasmuch as it comes on suddenly, often developing within a few hours, and the peripheral field of vision is invaded before the central field is affected.

Were all cases of fatal meningitis subjected to autopsy it would undoubtedly be found that the intracranial complications of sphenoidal abscess were much more frequent than is generally supposed, as in quite a number of reported cases the meninges became infected or there was thrombosis and suppuration of the cavernous sinus with fatal hemorrhage; the most frequent fatal termination, however, being that from a consecutive meningitis.

As an illustration of the symptom-complex of sphenoidal abscess without ophthalmic or cerebral complications, the following case presents a typical picture:

T. D., male, aged 28 years, was first seen on March 9, 1901, when he complained of a purulent discharge from the nose and pharynx and an intolerable headache, which had compelled him to cease work. With the exception of measles during childhood he had never been ill, and his physical condition was excellent. From his fourteenth year he has suffered almost constantly from a dull headache, which he locates in the middle of his head below the vertex, and from this time until his twenty-fourth year severe attacks of headache would occur from two to three times a week. From this latter age until the present time he states that the pain in the head has been constant and always located in the same position, far back at the top of the nose and immediately under the center of his head. There is a thick, yellow, purulent discharge from the nose, somewhat limited in quantity, which has been present for about four years, but previous to this the nasal discharge had but little color and was watery in character, at times being profuse, while at others it was scanty or entirely absent. For certain periods, often so long as three weeks in duration, the discharge would cease entirely or be greatly diminished in amount, and then the localized headache would increase in intensity until he was incapacitated and was unable to sleep on account of the severity of the pain. This would last from three to five days, when a free purulent discharge would ensue, a portion of the pus escaping from the nose, but the greater part would run down the pharyngeal wall, and the intense headache would cease, to disappear entirely if the discharge was profuse and long continued, but if it became somewhat scanty or inspissated a dull pain would continue and remain until retention would again take place.

Examination showed the pharynx and nasopharynx to be sclerotic, dry and red and with the mirror a small amount of pus could be seen high up on the posterior wall coming from the location of the sphenoidal sinus. The nasal septum was red and congested, especially at its posterior and upper aspects, and the middle and inferior turbinals were much congested and bright red in color, but were readily reduced in size by the application of a solution of the suprarenal gland. After the swelling had been reduced in this manner the location of the sphenoidal opening could be fairly well ascertained by tracing the pus covering the posterior part of the middle turbinal upward and backward, and no difficulty was experienced in inserting a silver probe into the sinus through the natural opening, although the tissues of the base of the sphenoid and in the canal of the sinus were much swollen and inflamed. The probe was allowed to remain *in situ* for a few minutes and on its withdrawal quite a profuse flow of pus ensued which continued for several days with almost complete disappearance of the headache. This favorable condition lasted for three days, when the flow became scanty in amount and a severe attack of headache ensued, not so bad as it had been, however, and it lasted but a few hours, when the pus again discharged with complete relief from all pain.

The nose was kept fairly free from pus with cleansing solutions and with a long cannula the sinus was washed out at intervals of two to three days with a warm saline solution. This was continued for two weeks with relief from all of the symptoms, when there was again a temporary cessation of the discharge and severe pain of several hours' duration; other than this the headache was greatly diminished in intensity and for the better part of the time entirely absent. On account of the hyperemic condition of the mucous membrane covering the anterior wall of the sinus, it was impossible to cleanse it thoroughly or to ascertain accurately the condition of its walls, but a few weeks later the parts had more nearly approached the normal and under the frequent application of a solution of adrenal gland it was possible to explore the sinus, and denuded bone was found in small quantity on the anterior wall around the opening. This was removed with hook and curet, the opening was enlarged to provide for free drainage, and for several months after this he was free from severe attacks of pain, while the dull ache would be present at times, but never severe enough to cause him to complain. Whenever the sinus was irrigated, although but a small amount of solution was used at each washing, pain was always produced identical with that caused by retention, but it would immediately disappear so soon as the fluid was withdrawn. Two months later and under continuous treatment he no longer complained of pain, except an occasional dull ache of a few hours' duration; the nasal condition was normal except for some congestion of the middle turbinal, which readily disappeared on the application of supra-

renal solution, and the discharge of pus had entirely ceased, being replaced by a serous fluid.

While this case presented evidences that made the diagnosis of sphenoidal abscess readily recognizable, such is not always the case and is rather the exception than the rule. While suppurative conditions of the nasal accessory sinuses have a number of symptoms in common it is especially the posterior group of ethmoid cells which differs but little in its symptomatology with empyema of the sphenoidal sinus. Lennox Browne has classified this most clearly when he divides the signs of sphenoidal suppuration into the presumptive, such as pain and ocular disturbance; the probable signs, as the presence of pus between the septum and middle turbinal; on the superior and middle turbinal; on the vault of the pharynx and by changes in the olfactory fissure as bulging in its depth and the presence of mucous polypi; while the certain signs are the presence of pus flowing from the sphenoidal ostium, the location of the source of the pus by an exploratory catheterization, and finally an exploratory puncture. Practically the recognition of this affection depends upon the presence of pus or mucopurulent secretion obtained from the ostium, or through an artificial opening in the anterior wall, and as empyema here is associated more or less with the same condition of the other sinuses probing and aspiration must be considered the final tests of a complete diagnosis. With the symptoms in part or whole present in a given case as previously enumerated the diagnosis at first resolves itself into one of exclusion by the elimination of disease of the other accessory sinuses, and should there be an empyema of one or more of these in addition to the sphenoidal affection the problem becomes a most complex one and considerable study will be required before it can be solved.

When the nasal fossa is patulous and the rhinopharynx will tolerate a mirror much has been gained in the recognition of the affection, but usually the reverse is the case, as the posterior end of the middle turbinal acts as an obstructing body and will have to be removed before the conditions become favorable for the detection of the source of the purulent discharge. By exploration with a probe or a delicate bulbous sound it is sometimes possible to penetrate the anterior wall safely if it be necrosed and detect the presence of pus either adhering to the probe or following it through the puncture which has been made; most scrupulous care, however, should be taken in making an exploratory puncture on account of the danger of penetrating the superior wall in the region of the sella turcica and it is advisable in these difficult cases, in which the olfactory fissure is in great part obstructed, to avoid operative procedures of any nature until a portion at least of the middle turbinal has been resected and visible evidence of pus in the suspected locality has been obtained. Usually, however, the sphenoidal opening can be found by passing the probe backward along the middle turbinal, but often the stoma is situated higher and more laterally and it will be necessary to curve the probe outward and seek for the opening above and external to the posterior end of the turbinal body. Should pus follow the withdrawal of the probe of course the diagnosis at once becomes established, but in the absence of such a sign it is well to insert a slender cannula into the opening and with a weak antiseptic or saline solution endeavor to dislodge any inspissated pus that is probably present. In using either the probe or cannula, and especially the former, for diagnostic purposes, care should be exercised that the middle turbinal be used as a guide in its introduction, for if it should be held too much in the vertical line and too near the anterior end of the turbinal the dangerous area marked by the nasal roof is apt to be encountered and serious consequences may ensue, but by elevating the tip of the probe just posterior to the center of the turbinal this danger is entirely avoided.

When the pain, as in the case here recorded, is con-

stantly or mostly limited to the sphenoidal region, it becomes a valuable feature of diagnostic import, but in the majority of cases that have come under my observation this localization was the exception rather than the rule, and more frequently the pain is referred to the various parts of the trifacial nerve, and instead of aiding only renders the diagnosis more difficult. Finally, as a complex of symptoms, the discharge of pus into the postnasal space, deepseated pain in the head, sudden blindness, exophthalmos and strabismus, would indicate disease of the sphenoidal sinus, with a possible involvement of the posterior ethmoid cells.

It is not desired here more than to outline the usual method of treatment of this condition, and while the principles involved embrace the free drainage of the sinus and the cleansing of the parts, there are three methods by which the sinus may be entered, (a) the natural intranasal route; (b) through the frontal sinus; and (c) by way of the maxillary sinus. It is only the usual method of treatment, that through the intranasal route, that I will mention, and although the treatment is essentially surgical, at least as regards the question of drainage, the local topical treatment bears an essential part in any success that may be obtained. In but a small number of cases, and then but rarely, the method advocated by Furet may be used when, in addition to the sphenoidal suppuration, there is a maxillary sinusitis; when the sphenoidal sinusitis is complicated with cerebral involvement, and rapid and thorough operation is required; and in individuals with narrow or deformed nasal fossas through which it is impossible to reach the sphenoid. This method consists essentially in entering the sinus through the maxillary antrum, which is opened by the Caldwell-Luc operation, and the nasal wall is excised back to the sphenoid, into which a large opening is made, and the parts are then treated as indicated by the conditions present, the wound finally being packed and sutured.

If the sinus can be probed or an opening made in the anterior wall below the natural stomata without removing the middle turbinal, this preliminary procedure can be dispensed with, but usually the posterior end at least will have to be removed, both to enable one to obtain sufficient room to open the sinus properly and also to allow of free drainage. Should polypi be present, they must be removed, and the nasal fossa should be made as clear as possible by the correction of irregularities and the reduction of inflammation; under these conditions the opening of the sinus does not present any special obstacles and becomes much easier than is generally supposed. With patulous nares, the next step is to evacuate the pus through the natural opening, or if this is not feasible, to make an artificial opening as near the floor as possible. The opening should be made in the anterior wall with a gouge, sharp hook, etc., and but little force is required, as the wall in this situation is quite thin; the best place to open the sinus being near the median line or almost against the vomer, and about 6 mm. above the point where the inferior border of the vomer articulates with the sphenoid bone. When the wall is resistant, it may require drilling, and then great care should be exercised, while the distance from the anterior wall of the sinus to the edge of the nares should be carefully measured and a sufficient distance allowed on the drill to insure penetration of the wall without danger. After the opening has been made, it should be enlarged toward the floor of the sinus, and as it has a strong tendency to contract and greatly diminish in size, it should be made sufficiently large to counteract against this and allow of free drainage.

The sinus is then irrigated with a weak antiseptic or normal saline solution, the latter being preferable, and the mucosa of the interior is treated as indicated either with a weak trichloroacetic acid or zinc chlorid solution. If the mucosa of the upper and external walls is diseased it is treated with the solutions mentioned, while the

other portions of the sinus are cureted gently as no risk with careful handling is involved here, the cureting of the anterior wall and floor often producing beneficial results without further treatment. The parts are then irrigated after any necrosed bone has been removed, so far as safety will permit, and as the necrosed area is usually on the anterior wall it can be removed with perfect safety, while the sinus may be packed with iodoform gauze, but it has seemed best in my experience to obtain drainage by gravity and omit packing. So long as there is a discharge of pus, irrigations are continued, daily at first and gradually increasing the interval until the secretions come away clean, while if the tissues are unduly sensitive, thorough cocainization may be required for a few days, but this is not usually necessary after the sinus has been freely opened. Usually the operation is followed by prompt relief from the pain, and in the majority of cases that have come under my observation no especial difficulties have been observed in their treatment, while usually the suppuration has been more easily controlled than that of the ethmoid cells, especially when that of the latter is extensive.

## CHRONIC DIARRHEA.

BY

EDWIN ZUGSMITH, M.D.,  
of Pittsburg, Pa.

When the chyme passes the ileocecal valve and enters the colon it is fluid in consistency and gradually, as the contents are propelled along the large intestine the watery elements are withdrawn and the feces assume solidity. This is constant in health and unless the quantity of fluid feces entering the colon is unusually large, or the colon itself diseased, the anal extremity of the bowel is not called upon to permit the discharge of any but solid feces. When, however, the colon is affected by disease which interferes with its function of absorption, or which renders that function impotent through increased peristaltic action, diarrhea results. It follows therefore that chronic diarrhea implies chronic colonic disturbance, which, I believe, is always inflammatory in its nature. For this inflammatory condition of the colon a variety of causes are assigned, some of them acting primarily upon the lower bowel, but in most instances it will be found that sufferers from chronic diarrhea either have or have had some digestive disturbance; that is, interference with the digestive activity of the stomach, the liver, or the pancreas.

The function of the liver in digestion is apparently not very important. So far as known its influence is indirect, affecting chiefly the products of digestion and without power to change either the proteids into peptone, or the carbohydrates into maltose, but entering perhaps into the emulsifying and digesting of fats.

The stomach has for its prominent function the changing of nitrogenous bodies into peptone, and possesses besides an active milk-curdling ferment and one exerting some influence over fats. The gastric juice except as modified by active saliva has practically no effect upon starches and sugars. Its action is not always complete, even upon proteids, against which the main digestive energy of the stomach is directed, and much of the albuminous food ingested passes through the pylorus only partially changed, to be rendered completely absorbable in the bowel through the agency of the pancreatic juice.

The pancreas secretes a fluid upon which falls the brunt of digestive work. Proteids, carbohydrates, and fats, all are subject to its influence and are completely changed into substances capable of being absorbed. At

times, and not uncommonly, the pancreas is the sole digestive organ at work, the stomach for one cause or another failing to produce any gastric juice. Even then there is no deterioration of health if the case is uncomplicated, but if to the failure of gastric secretion, and indeed, even to normal gastric secretion, there is added pancreatic disturbance the general health begins to fail and bowel symptoms manifest themselves. Secretory changes in the digestive organs do not arise spontaneously but are dependent on many causes.

Very little accurate knowledge exists bearing on the nerve mechanism which governs the secretory activity of the stomach, liver, and pancreas, but if one may judge from the large number of cases of faulty digestion of apparently nervous origin and explicable by no other theory, the existence of such a mechanism is certain and its influence of great importance. It is more than coincidence that a large portion of cases of chronic diarrhea occur in persons who lack nerve stability.

Besides nervous influences, other causes exist to prevent digestive secretion, for the organs concerned are subject to organic changes which affect either the gland structures themselves or produce obstruction of their excretory ducts. Very often the primary focus of such change is in the stomach or adjacent bowel, some catarrhal condition there, extending so as to include the liver and pancreas. Indeterminate efforts have been made to attach etiologic import to bacteria.

The onset of chronic diarrhea is usually insidious, although the initial symptoms may be more or less acute. It is not uncommon for the laity to look upon loose bowels as a sign of health, and consequently the beginning of the trouble may pass unnoticed; and it is not until diarrhea becomes severe, or digestive symptoms or failing health develop prominently that advice is sought. Usually the patients are under weight, although not necessarily emaciated, for many obese individuals suffer from chronic diarrhea. The appetite is often good and the tongue clean, and frequently it is fissured. Nausea and vomiting occur in a minority of cases; belching of gas is more common; bloating and heaviness after eating is very frequent; but decided gastric pain is unusual. Heartburn and sour eructations occur if hyperchlorhydria is marked. The epigastrium is tender, and gastric secretion, while not uncommonly presenting an excess of acid, in the majority of instances is under the normal in digestive activity. The percentage of cases of chronic diarrhea occurring in achylia gastrica is very large. Mucus is nearly always a marked feature of the gastric contents. The bowel symptoms stand out prominently. Two to four or five movements a day is the usual number. They occur mostly or even entirely in the morning after rising, and not at all at night unless the case is very severe. The total amount of material passed is very large, while the character of it varies greatly. The first movements are formed perhaps, or mushy; the succeeding ones grow progressively more watery and smaller. All contain mucus, and the final one may consist entirely of it. Occasionally the passage assumes the form of small mucus-covered balls lying in a quantity of liquid composed of water, shreds of mucus, and granular fecal matter. The color, like the number of the stools, is variable, being light brown or yellow as a rule, but at times growing quite dark or almost white. These differences occur in each patient from day to day. It has been assumed that the usual light color of the stools is due to faulty bile-production, and while this no doubt is true to a degree, the fact must not be overlooked that at least two other influences are at work. These are, first, that the healthy bowel contents are lighter in color at the inlet than at the outlet of the large intestine, showing that darkening must in some way be connected with colonic retention, and when transmission through the colon is rapid, as in diarrhea, the change to darkness has not time to occur. The second influence is that the presence

of excessive amounts of fat causes the feces to assume a yellow color, furnishing another reason for believing a defective pancreas commonly causes chronic diarrhea. In cases in which the inflammatory action has produced ulceration, or in which it is more intense, blood appears in the stools. Food particles appear in various degrees of digestion, sometimes being plainly visible to the naked eye, but more often showing only through the microscope. Gas passes from the bowel in excessive amount, being sometimes foul and sulfurous, and sometimes without odor. Microscopic examination of the feces almost invariably detects undigested food particles. At times starch granules, meat fibers and fat crystals, may all be found at the same examination, while again but one of these can be noted. Most frequently fat crystals appear, next starch granules, and least frequently meat fibers. Fermentation tests develop an excessive amount of gas.

The skin about the anus is at times excoriated from the irritation of acrid discharges, and some cases are attended with a constant leakage of thin mucus through the anus. The sphincter ani is tight and hypertrophic in cases of long standing. Inside, the rectum is found red and coated with mucus, and ulcers often are detected. Soft feces can be seen passing from the sigmoid into the upper rectal chamber, and at times the mucous membrane of the sigmoid is prolapsed into the rectum.

Inspection of the abdomen generally shows marked bloating, while palpation discovers a diffuse tenderness most marked about the epigastrium, and over the line of the colon, particularly at the cecal region and over the sigmoid. Very often the cecum can be felt as a rounded mushy resistance, and the sigmoid contracted and in spasm can be followed for several inches. Even the transverse colon can occasionally be traced by touch. The urine shows nothing characteristic. The specific gravity is often high (1,020+). Indican may be present. The subjective symptoms are numerous, indefinite, and variable, consisting of a feeling of exhaustion, evanescent pains, a state of general nervousness, lack of energy and ambition, and the like. There is no rise of temperature.

The prognosis of chronic diarrhea is, in my experience, not so bad as one might be led to believe from the statements in some of the textbooks. Many patients are cured entirely, more are benefited to such a degree that so long as they are careful of their diet and manner of living they have no symptoms; while others, careless of treatment, live on indefinitely, troubled only by the inconvenience of their disease. A small proportion, and this usually among the neglected or poorly treated patients, goes from bad to worse, and finally dies from chronic diarrhea.

Treatment for this condition requires careful attention to detail, and persistence. The indications are two—to correct the digestive fault which has been primarily the cause of the trouble, and to repair the damage that has already been done. Of prime importance are the questions of diet and hygiene. The diet must be strict and carefully selected, with reference to idiosyncrasy, state of gastric secretion and microscopic examination of the stools; careful attention must be given not only to the kinds of foods allowed, but also to the mode of their preparation. In severe cases it may be necessary to restrict the diet to milk alone, or to egg water, in other cases it will answer to cut off those foods that are generally conceded to be difficult of digestion, while all grades occur between these. Irritants, such as pepper, mustard, vinegar, and the like, are not permissible; foods leaving bulky waste after digestion, such as fruit, cabbage, and so on, are inadmissible, while cold or frozen foods, like sodawater and icecream, must be prohibited. Dishes prepared by cooking in fat, as all fried articles are, and those having fat cooked in them, as in pies and cakes, are also to be eschewed, while pure sugar may often be allowed in small quantity with foods.

Of drinks in common use, tea on the whole is the best, cocoa and ginger ale are allowable, and when alcohol is desirable Tokay wine or good brandy should be preferred.

Under the hygienic measures should be included the use of water externally, rest, exercise, massage, travel, and residence at health resorts. Bathing is important, and should be indulged in daily, and one who chooses to individualize will find advantage now in one method of application and now in another, until he has applied every variety of bath at his command.

As to rest, it is advisable to place patients having severe cases in bed and to keep them there perhaps for weeks. Patients having milder cases may be advised to retire to bed early and remain there late in the morning, resting a while again during the afternoon. Between times light exercises should be employed, those being chosen which do not cause strain on the abdominal muscles or increase the intraabdominal pressure. Exercise must always be graded cautiously to the endurance of the patient and with the knowledge that if he is allowed to go beyond that point much harm will result. When massage is employed the abdomen is to be exempt. I have known blood to appear in the stool from a failure to appreciate the advisability of this.

Mere travel is to be deprecated as a therapeutic measure in cases of chronic diarrhea. The strain of looking after one's belongings and the irregularity of living are not such as to bring that equanimity that is so necessary for the peaceful working of the various bodily functions, yet sea voyages are of value in this respect, and when there is combined with the travel a residence at some well equipped health resort which offers opportunities for obtaining the other means of relief, the conditions are the best possible.

Mineral waters are of advantage, those containing calcium salts being the most generally useful. Hydrochloric acid as an aid to gastric digestion and as a stimulant to pancreatic and intestinal secretion is frequently of great value and the bitter tonics, particularly nuxvomica and calumba, serve a good purpose. As a rule preparations of arsenic are not well borne, and alteratives on the whole are not of much value. It is useless to prescribe iron for the anemia while the diarrhea continues. Nonabsorbable oils, particularly castor-oil and less effectively the petroleum preparations, are of advantage in soothing the inflamed bowel. Injections of boric acid, of silver nitrate, oily preparations containing other medicaments, such as iodoform and bismuth, are of great value, while ulceration within reach of the proctoscope can be treated under the eye by stronger applications as the conditions demand. In severe obstinate cases, when ulceration of the colon is located high up, the establishment of a temporary artificial anus on the right side has been proposed.

## CANCER STATISTICS IN THE TWELFTH CENSUS OF THE UNITED STATES.

BY

HARRIS MOAK, M.D.,

of Albany, N. Y.

Instructor in Pathology, Albany Medical College.

Probably the one statement in the report regarding the subject of cancer that will excite the most concern is this: "In comparison with 1890 there was a decided increase in the deathrates due to cancer and tumor, from 15% in the cities in the registration States to 27% in the rural districts." This bare statement is certainly cause for alarm. But searching further through the report we find other statements which are deserving of much attention in connection with the foregoing.

The table on page 79, Part I, "shows a very regular decrease in deathrate at each age up to 60 years, and an increase in the rates at each age above 60." Page

112 gives a table showing the number of deaths from certain causes in the registration area per 100,000 of population, and from this table it will be seen that the increase was confined to the following causes: pneumonia, heart disease, diseases of the kidney, apoplexy, cancer, old age, influenza, diseases of the stomach, peritonitis, suicide, septicemia, diabetes, burns and scalds, cerebrospinal fever, and gunshot wounds. All others decreased. "This table also shows a very close correspondence in the relative proportions of deaths from these causes in the United States as a whole. They indicate an increase in the relative mortality from diseases most frequent in adult life and advanced age, and a decided decrease in mortality from diseases incident to infancy and youth."

Page 115: "The greatest increases in the rates per 100,000 of population occurred in disease of the kidney (24), influenza (17.7), apoplexy (17.6), heart disease (12.2), cancer (12.1), and old age (9.1). Increases from these conditions were greater in the rural districts than in cities."

Of these six diseases the census report curiously reduces to terms of percentage only the figures showing the increase of cancer and tumor. This is especially misleading. If we reduce all these figures to terms of percentage we have the increases as follow: Disease of the kidney 40%, influenza 28.5%, apoplexy 36%, heart disease 10%, cancer and tumor 23%, old age 20%. Thus we see that it is necessary to reduce all deathrate increases to the same terms for proper comparison.

We have reduced the increases both to terms of 100,000 population and also to percentages, and they both show that the opening statement, that there is a decided increase in the deathrate from cancer and tumor, loses most of its force. It is alarming when taken alone, but when compared with the other diseases is not particularly so. Proceeding to those portions of the report which treat more in detail regarding each disease we find many points of interest when we compare these diseases which "are most frequent in adult life and old age." In the following tabulation we will not include diseases of the kidney, as there is nothing in the brief report which has not already been considered.

Summarizing this table we notice a close similarity under the different heads among these five diseases.

They are most frequent in rural districts and least frequent in cities. The highest proportions are among the foreign whites. The registration States are much the same for both the highest and lowest proportions. The mothers were born mostly in the same countries both for the highest and lowest proportions. The mothers of whites over 60 were born mostly in the same countries. The greatest mortality was after 65 years of age. They all have in a very striking way the same geographic distribution over the United States. Attention is especially directed to the registration areas where cancer and tumor are most frequent.

It is found that the States and portions of States which comprise these areas are just the places where the greatest number of people are living after the age of 55 or the age of greatest frequency of cancer and tumor, and equally it is shown in a striking manner that cancer and tumor are least frequent in those areas where the fewest people are living after the age of 55.

The foregoing statements are easily proved from the figures on page 690-1, Part I of the report.

### CONCLUSIONS.

I. Cancer and tumor have not increased in any greater proportion than several other diseases "common in adult life and old age."

II. The geographic distribution of cancer and tumor corresponds almost exactly to the geographic distribution of people of greatest age. Cancer and tumor are therefore most frequent in those sections where old people are most numerous.

	Influenza (P. 141).	Apoplexy and Paralysis (P. 196).	Heart Disease and Dropsy (P. 206).	Cancer and Tumor (P. 181).	Old Age (P. 164).
Most frequent in.....	Rural districts.	Rural districts.	Rural districts.	Rural districts.	Rural districts.
Least frequent in.....	Cities.	Cities.	Cities.	Cities.	Cities.
Highest proportion among	Native whites of native parents.....32.3 Foreign whites.....31.8	Foreign whites.	Foreign whites.	Foreign whites.	Foreign whites.
In the registration States—deathrate highest in	Rhode Island and Connecticut.	Maine and New Hampshire.	Dist. of Columbia and New Hampshire.	Vermont and Maine.	Vermont.
In the registration States—deathrate lowest in	Michigan and New York.	Michigan and Rhode Island.	Michigan and Connecticut.	New Jersey and Michigan.	New Jersey and New York.
Deathrate greatest among those whose mothers were born in	Ireland, England and Wales, Scotland.	Ireland, France and Scotland.	Ireland, France and Scotland.	France, Scotland and Germany.	Scotland, Ireland and France.
Deathrate lowest among those whose mothers were born in	Hungary, Bohemia, Russia, Poland and Scandinavia.	Russia, Poland, Italy and Scandinavia.	Russia, Poland, Hungary, Bohemia and Scandinavia.	Russia, Poland, Italy, Hungary and Bohemia.	Italy, Russia, Poland, Hungary and Bohemia.
Highest in white persons whose mothers were born in—					
Age, 45-64.....	Ireland, Scotland and United States.		Ireland, Scotland and Germany.		
“ 65 and over.....	Ireland, Scotland, England and Wales.	Russia, France, England and Wales.	Ireland, Bohemia and “other foreign countries.”	Russia, “other foreign countries” and Scotland.	Bohemia, Ireland and Scotland.
Lowest in white persons whose mothers were born in—					
Age, 45-64.....	Russia and Hungary.		Poland, Hungary and United States.		
“ 65 and over.....	Russia and Poland.	Poland, Bohemia and Scandinavia.	Poland, Italy and Hungary.	Poland, Hungary and Scandinavia.	Hungary, Italy and Russia.
Greatest mortality at the age of	65 and over.	65 and over.	65 and over.	65 and over.	
Average age at death—					
1900.....		63.2.	54.3.	57.2.	81.8.
1890.....		62.5.	52.7.	56.1.	82.5.
Proportion greatest in the following registration areas	Southern Central Appalachian region, South Atlantic Coast region, Southern interior plateau.	Northeastern hills and plateaus, Central Appalachian region, North Atlantic Coast region, heavily timbered region of the Northwest.	Pacific Coast region, heavily timbered region of the Northwest, prairie region.	Pacific Coast region, Northeastern hills and plateaus, prairie region, heavily timbered region of the Northwest.	Northeastern hills and plateaus, North Mississippi river belt, heavily timbered region of the Northwest.
Proportion lowest in the following registration areas	Northern Mississippi river belt, Western plains, Great Northern lakes.	Southern Mississippi river belt, Gulf Coast region, Southwest Central region.	Southwest Central, Southern Mississippi river belt, region of Western plains.	Southern Mississippi river belt, Southern Central, Southern interior plateau.	Southwest Central region, Southern Appalachian region, Middle Atlantic Coast region.

**AN INTERESTING MODIFICATION OF TECHNIC IN PENROSE'S OPERATION FOR NEPHROPEXY.**

BY  
FRANK DONALDSON, M.D.,  
of Los Angeles, Cal.

The changes in technic in the brilliant operation for fixation of the kidney designed by Penrose, and which we give herewith, should be credited to Dr. Milbank Johnson, of Los Angeles. In an article on the treatment of floating kidney, Dr. Beyea<sup>1</sup> says: “The principle which to my mind is ideal and quite essential in the operation of nephropexy is to avoid any direct injury to the kidney parenchyma or capsule. Further, the operation should avoid extensive cicatricial change in the lumbar incision.” These are the very points which Dr. Johnson's modifications of technic effect.

In the Penrose-Beyea operation the ends of the catheters are brought out through the main incision and tied over an oblong pad of gauze with which the wound is covered. These ends therefore act as a foreign body, which tends to prevent the healing of the wound on the one hand and does not allow of a delicate tension and complete control of the kidney on the other. This may be made plain by referring to Fig. 2; the rubber drainage tube used by Beyea tends to pull apart at A, the kidney cannot be brought into absolute approximation with the wall of the back. Dr. Johnson makes no change in the preliminary part of the operation.

The patient is placed prone, with the Edebohls' kidney cushion under the abdomen; the usual incision is made along the outer border of the erector-spinal muscles for about 3½ inches; the fibers of the latissimus dorsi are separated just over the outer border of the erector spinal. With reference to the ilio-hypogastric nerve which Edebohls holds is likely to be injured at this stage of the operation, Dr. Johnson thinks that the nerve may be disregarded, as he has found in all his cases that the resulting anesthesia from cutting the same passes away completely in a few days. The sheath of the quadratus lumborum is next opened in the direction of its fibers; the perirenal fat is thus exposed, the space of Gerotta is entered and the kidney separated as far as necessary by blunt dissection from its fatty capsule.

Dr. Johnson's procedure from this point is as follows:

He makes an incision the length of the kidney through the fatty capsule, the latter being dissected from the kidney but not removed. He then makes four openings about 15 mm. on either side of the main incision, A B C and D, Fig. 3. These incisions of course go through skin, fascia, and muscle. The catheter is then passed through the opening A, on through the fatty capsule a few millimeters to the side of the main incision in the same, around the kidney proper about 1 cm. from and above the ureter and renal vessels and out through the fatty capsule and the opening B on the opposite side. Similarly, a second catheter is introduced through the opening C and brought around below the ureter and vessels of the kidney and out through the opening D. The incision in the fatty capsule is then closed and the main muscular incision brought together with continued sutures of catgut and a subcuticular silk worm-gut stitch for the skin. The operator is now ready to manipulate the catheters. There is of course absolute freedom of movement and taking one end in either hand the kidney may be placed in relatively any position toward the abdominal wall which the operator sees fit; in other words he can get the exact tension on the kidney he desires. Having satisfied himself that the organ is properly placed, the ends of the catheters are clamped together. Emerging as they do from the side of

<sup>1</sup>American Medicine, September 21, 1901.

instead of through the original wound, they tend to draw together the sides of the same instead of forcing them apart as is the case in Penrose's method. This may be made plain by referring to Fig. 1.

The method of bringing out and fixing the ends of the catheters greatly facilitates the healing and the

Fig. 1.—A, fatty capsule.

Fig. 2.

dressing of the wound and certainly more nearly approaches Beyea's ideal of what an operation for nephropexy should be, that is, the avoidance of any direct injury to the kidney parenchyma or capsule, and of extensive cicatricial changes in the lumbar incision.

Fig. 3.

Dr. Johnson is inclined to believe that this distribution of the catheter B leads to stronger cicatricial attachments and that the kidney is more firmly fixed thereby. He says that in all of the six cases in which he has used the above modifications the patients have borne the

presence of the foreign bodies (the catheters) better and that there was less discomfort than in those cases in which he had brought the catheters out directly through the main incision. He finds it advisable to renew the strip of gauze under the catheters on the second day, at which time all exudation has ceased, as such a procedure greatly assists the healing of the wound. Instead of using a rubber drainage tube he employs soft and smooth German rubber catheters (which are removed as in Beyea's operation on the twenty-first day). The ends of the catheters are wrapped and have a silk loop to facilitate their passage through the capsule and muscular layers of the abdomen.

## BRIEFS ON PHYSICAL TRAINING.

BY

G. FRANK LYDSTON, M.D.,  
of Chicago, Ill.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's Hospital.

No. 2.

### The Individual Equation in Physical Training.

I desire to express my unqualified disapproval of the measurement standard of individual capacity, as applied in many institutions in which physical training is taught. The comparative measurements of individuals are as fallacious standards by which to prescribe certain forms of exercise as could be well imagined. The idea that an individual of a given height and weight should present such and such measurements of the neck, chest, arm, forearm, thigh, and calf is, to me, the height of absurdity. It might as well be argued that an individual with a certain size of cranium should be the possessor of a nose or ears of certain definite proportions, or that an individual of a given height and weight should have feet and hands of a certain size. This rule will do very well in art, but it is a rank fallacy in physiologic training. The symmetry standard should be individual.

Chest measurements are particularly fallacious as determining chest capacity and the proper size of chest relative to the general measurements of a given individual. Much depends upon the conformation of the chest as to the relative degree of lung capacity and the proportionate measurements relative to the rest of the body. In certain individuals the chest, while presenting relatively small measurements when compared with their general measurements, is round and long, so that expansion is largely a matter of diaphragmatic movement rather than of lateral movement of the chest walls, and the moderate expansion is compensated for by the considerable chest area. Such individuals may present a very slight difference between extreme inspiration and extreme expiration, and yet have a pulmonary capacity greater than many whose chest measurements are far superior to theirs. The relative strength of the chest walls and degree of elasticity of the lung tissue itself are factors to be reckoned with independently of the chest measurements. There is something amusing in the competitive spirometer tests of the lungs in different subjects. There are certain individuals who, according to tape measurements, have enormous chest capacity, yet show up very unfavorably when compared with certain narrow-chested, spindling individuals, so far as the spirometer test is concerned. That the spirometer test is fallacious, I freely admit, still it is of value in making comparisons in this particular direction.

The attempt to develop the measurements of a given individual up to an arbitrary standard of proportionate development has wrecked many a man who, while not

designed by nature to become an ideal athlete, might have been put in an ideal condition of physiologic development by rational methods of training.

The first step in any given case should be to determine as nearly as possible the inherent individual muscular capacity. No effort should be made to develop the subject so his proportionate measurements will correspond with even an average arbitrary standard. If the subject has a long, narrow chest, narrow shoulders and small bones, with naturally small muscular development, any attempt to develop proportionate measurements to correspond with a given standard will result in disaster. In brief, the end and aim of physical training is, as expressed in a previous paper, to develop the natural physical capital of the individual to its highest degree. The standards for A and B may vary widely. An attempt should be made to get out of each subject the best that is in him, not to build on muscle or give strength beyond his inherent capacity.

Specialism in muscle building is justifiable only in so far as it tends to bring up any given portion of the body to the relative—*i. e.*, the symmetric—proportions normal to the particular individual. The subject of specialism in athletics is too broad for discussion here, especially if it be remembered that I am discussing, not athletics for prowess in any field whatever, but athletics as a therapeutic resource.

In beginning the training of adults, the occupation should be taken into serious consideration. More than 25 years' experience and observation of physical training have convinced me of the importance of this point. My having experienced both the benefits of proper training and the evils of improper training, should give a certain amount of weight to this opinion. I am convinced that the muscles of the highly trained athlete are out of place, useless, and perhaps injurious, to the man whose occupation in life is of a sedentary character. In advising adults to train, it is, in my opinion, always essential to take into serious consideration the physical necessities of the patient's occupation, whatever it may be. Unused muscular fiber becomes in time degenerate muscular fiber. Unused visceral capacity results, first, in functional, and finally in organic, disturbance of the viscera.

Before prescribing a course of training, another point bearing upon the individual equation is of the greatest importance. A little experience in muscle building will enable the physician to determine fairly well the developmental capacity, so to speak, of the muscular system of any given subject. Individuals with relatively short heavy bones and correspondingly short tendons, and thick-bellied muscles, must be handled very carefully. In the majority of such patients all that is necessary is to make supple and bring under perfect volitional control such muscular fiber as they already have. A more "intelligent" and useful quality of muscle is what is needed, and mere increase of muscle would be superfluous, even were it not injurious. Individuals of the class I am describing tend to become muscle and joint-bound, a condition familiar to every athlete, and which depends upon muscular and ligamentary hypertrophy and stiffness due to over-development. The system of exercises that should be prescribed for such persons should be entirely different from that which is proper for the long-boned, long-tendoned individual, the bellies of whose muscles are relatively short and thin as compared with the bones and tendons. Such individuals have naturally more supple muscles, and their joints present greater mobility than in the case of those described under the first head. It will probably be necessary to reiterate this point in a subsequent paper.

In prescribing a course of muscle training care is necessary to gauge as nearly as may be the vital resistancy of the subject. The endurance of persons of apparently equal muscular strength varies considerably. Conscientious study of each case as the course of training progresses gives most valuable information in this respect.

No. 3.

### The Athletic Habit and Its Evils.

A discussion of therapeutic resources, however valuable it might otherwise be, is of little use if the possible evils of its injudicious application are not considered. A very serious mistake in prescribing training is, I believe, the failure to differentiate the student, professional man or individual of sedentary habits in general from men whose occupation involves muscular exercise. Prolonged observation has convinced me that the muscles of the professional athlete or the blacksmith are not only unnecessary to men whose daily occupation require no high degree of muscular development, but are absolutely injurious. Not only is this true so far as exaggerated muscular development is concerned, but it applies with special force to the structural and functional visceral capacity of the large-muscled man, a capacity which has developed *pari passu* with the growth of muscle. Large muscles unused are pernicious, it is true, but an immense unused visceral capacity is still more so. Muscular degeneracy does not necessarily produce serious results, save in the case of the heart, but visceral degeneracy is a much more serious matter. A big arm with a fine biceps, triceps, and deltoid development may be very pretty to look at, but such arms have oftentimes cost their owners their lives.

An important point to which attention has not been called, so far as I know, is this: Individuals in hard training necessarily demand more food, and food richer in proteids than those who do not train. Proper digestion, assimilation, metabolism and elimination depend here upon the maintenance of a large amount of muscular exercise. Frequently in my experience athletes have become markedly lithemic whenever they stopped training for any length of time. The demand for nitrogenized food and food in large quantity does not subside immediately upon cessation of the usual amount of exercise. The accumulation of crude products of tissue metabolism is an inevitable result when the athlete goes out of training, if he does not markedly modify the quality and diminish the quantity of his diet.

Independently of the question of overstrain, a high degree of physical development is often fatal, if for any reason the subject is compelled to cease his muscular work and adopt a sedentary life. One of the greatest pugilists that America ever produced, John Dwyer, of Brooklyn, quit his regular occupation to enter the counting-room—he died within a year of tuberculosis. The explanation in this case was simple enough: the immense lungs which were necessarily an advantage in the prize-ring fell into disuse in the counting-room. Disuse meant degeneration, and degeneration meant a lack of resistance of which tubercle bacillus was not slow to take advantage. I have had under my professional observation several lesser lights among professional athletes, in whom a similar result occurred from the cessation of training.

In my own experience—and I have often trained to excess—the training habit has been as hard to break, when necessity has compelled me to do so, as the habitual use of narcotics and alcohol seems to be in most individuals. On several occasions when I have been compelled to cease training for one reason or another it has required many months for my system to become adapted to the new conditions. The time arrives in the lives of all athletes when the exigencies of one's occupation, or advancing years, associated with the lack of enthusiasm incidental to the middle period of life, bring about a cessation of active training. In many instances the result is disastrous, and while, in common with a number of others whom I have known, I have seen no particularly disastrous results in my own person, the instances in which the opposite is true have been so numerous in my experience that I am convinced of the correctness of my position. Every physician athlete

with whom I have been associated in the past 25 years has coincided with me in the foregoing views.

One of the marked evils of systematic training is the fact that constipation very often results when the muscular work ceases. The digestive function is very much disturbed, in many instances, by the cessation of the hard, systematic muscular work. Functional disturbance of the liver is very often met in athletes out of training. I have noted in certain individuals some particular form of athletics was absolutely necessary to maintain the normal hepatic function; thus, in one case the individual was compelled to indulge vigorously in boxing to avoid hepatic torpor. The movements involved in excessive sparring seemed to have an especially stimulating action upon the liver, and a few days' cessation of the violent exercise produced considerable disturbance. The evils outlined in this brief paper are not necessarily due to athletic overstrain, although confessedly in some instances rather difficult to dissociate from it. There are so many cases, however, in which muscular overstrain is directly responsible for disaster that I have reserved that subject for discussion in a separate paper.

### THE USE OF TRUTH AND FALSEHOOD IN MEDICINE: AN EXPERIMENTAL STUDY.<sup>1</sup>

BY

RICHARD C. CABOT, M.D.,

of Boston, Mass.

Two years ago, at the meeting of the Association of American Physicians at Washington, Dr. E. G. Janeway, then president of the association, chose for his presidential address the subject of "Truth in Medicine." Unfortunately, the address was never delivered, for President Janeway feeling keenly the responsibility of putting through the long schedule of papers assigned to the first morning session, omitted his own part of the program and contenting himself with a few introductory remarks started us at once on our morning's work. Only a hint of what he meant to say was vouchsafed to us. The subject, he said, "could have been handled under such heads as *truth in statistics; truth in diagnosis; truth in pathology; truth in therapeutics.*"

I have often regretted that Dr. Janeway's modesty and conscientiousness induced him to deprive us of this address. Still oftener I have speculated on what he would have said had the occasion seemed to him propitious. For the subject seems to me one that ought to be discussed by medical men. The results of experience should be compared according to the methods that have proved useful in the investigation of other topics. But as time has passed and Dr. Janeway has not returned to the topic, I have ventured to take up the hints and outlines which he furnished us and fill in, in my own fashion, the structure which I imagine he might have reared. Yet though he deserves credit for the plan of investigation which I have followed, it goes without saying that no one but myself is responsible for any opinion here expressed.

I approach the subject of truth in medicine, not from the point of view of scientific method, nor of metaphysic analysis, but of professional ethics. I do not ask "how can we find truth," nor "what is truth," but "how far should we speak the truth in dealing with our patients, our colleagues, or anyone else." "Are lies ever in place? If so, under what conditions?"

My method is experimental, the only one in which reasonable men place confidence, the only sound scientific method. I do not ask you to consider what, on general principles or according to authority or tradition, should be our course in this matter. As indicated in the title of my lecture I have made an experimental study of two different hypotheses on the sub-

ject, submitting them to the test of experience, trying how they work, as any candid person must, if he wishes to make the fairest judgment in his power on any question. I have been working on this subject during a considerable part of the last eight years, and my conclusions, however faulty they may be, must be criticised like any other piece of scientific work only by those who have repeated the experiments on which they are based.

I began, as was natural, with the hypothesis on which I had been brought up. My medical training included some few lectures on medical ethics, but in matters of ethics, example far more than precept was the guide to the Harvard medical student of my day. Only once during my course was the rule for truth-speaking in medical matters directly stated.

"When you are thinking of telling a lie," said the teacher, "ask yourself whether it is simply and solely for the patient's benefit that you are going to tell it. If you are sure that you are acting for his good and not for your own profit, you can go ahead with a clear conscience."

The lies that the medical profession agree in condemning whenever the question arises are those told for personal and private gain. The magazine article representing work never performed and written solely for advertising purposes, is a lie that no one approves. The diagnosis of diphtheria when the physician knows the case is merely one of tonsillitis, is not justified by the increased fees which his frequent visits entail. There is no disagreement of opinion among physicians about such lies as these.

But the lies which are usually defended among physicians are of a different type and may be illustrated by the following quotations:

"The young physician in our day has some advantages in competition with older men. People sometimes consider a young man more up-to-date than his elders. Still there are some alleviations in growing old. When you don't know what's the matter with a patient you can enjoy the luxury of saying so. When you're young you have to know everything, for if you say you don't know, the patient is likely to chuck you out and send for some one else who does."

That *truth in diagnosis* is possible for the older physician, but not always for the younger, seems to be the moral of this quotation.

To speak the *truth in prognosis* is even harder. In the course of a lecture on the prognosis of heart disease, I once heard the following story:

A business man past middle life was found to be suffering from some form of heart disease. His wife inquired about the diagnosis and hearing it was heart disease she asked: "Isn't it true that he may drop dead suddenly?" The doctor had to confess that this was a possibility. "The consequence was," went on the story-teller, "that day after day she sat at her window about the time that her husband should be returning from business, watching to see whether he would come home on his feet or in an ambulance."

"Now," said the narrator, "when you get into practice, gentlemen, whatever you do, don't do that. Don't make a woman's life miserable because you can't keep a fact to yourself."

Surely it seems as if this is the place for a good straight lie. I thought so when I heard the story and made up my mind that whatever blunders I made in dealing with any patients I might have, this one I would avoid. But I found it more difficult than I had anticipated. It was not very many years before I saw in consultation a case the duplicate of that just described. Mr. B. had angina pectoris, aortic regurgitation, cardiac hypertrophy, in short, general arteriosclerosis affecting especially the heart and kidney. After I had talked over the case with the attending physician and was about to return and say a word to the family, my colleague said: "There's one thing I must warn you about. Mrs. B. is an excessively nervous, excitable woman, of no stamina at all. She gets hysterical on the slightest pretext, and when that happens she makes every one else in the house sick. If she heard what's the matter with her husband she'd go all to pieces. So you'll be very guarded in what you say, won't you?" To this I readily agreed. Remembering my lesson, and we went downstairs where Mrs. B. was waiting

<sup>1</sup> Delivered as one of the Cartwright Lectures at the Academy of Medicine in New York, December 30, 1902.

to hear the result of our deliberations. She placed a chair for me and then planted herself in another, squarely facing me and very near. "Now, first of all," said she, "I want to know whether you are going to give me a straight and true answer to everything I ask you?" Having just promised the family physician that I would do nothing of the kind, I was so taken aback that I hesitated a moment. "That's enough," said Mrs. B., getting up. "I don't care to hear anything more."

I did not blame her. She had fairly caught us in our attempt to trick her. But the anecdote shows that the path of the medical man conscientiously trying to shield people from pain and trouble is sometimes a difficult and thorny one.

By means of these examples I hope I have succeeded in getting before you the problems that I wish to discuss.

I propose next to examine the matter more in detail, considering: (1) truth in diagnosis; (2) truth in prognosis; (3) truth in treatment.

By telling the truth I mean doing one's best to convey to another person the impression that one has about the matter in hand. One may do one's best and yet fail, but that is not lying. I once spent half an hour trying to convey to my parlor girl my impression about how to build a fire, but when she next tried to build one it appeared that the only idea she had received was that of packing kindling wood into the fireplace as tightly as she could and piling logs on top without a chink or cranny anywhere for a draught. Clearly I did not succeed in conveying my impression to her, yet I suppose no one would accuse me of lying to her. I had merited the cowboy's epitaph:

"He done his damndest; angels could do no more."

A true impression, not certain words literally true, is what we must try to convey. When a patient who has three fine rales at one apex and tubercle bacilli in his sputum asks, "Have I got tuberculosis?" it would be conveying a false impression to say "Yes, you have," and stop there. Ten to one his impression is that tuberculosis is a disease invariably and rapidly fatal. But that is not at all your impression of his case. To be true to that patient you must explain that what *he* means by tuberculosis is the later stages of a neglected or unrecognized disease; that many people have as much trouble as he now has and get over it without finding it out; that with climatic and hygienic treatment he has a good chance of recovery, etc. To tell him simply that he has tuberculosis without adding any further explanation would convey an impression which in one sense is true, in the sense, namely, that to another physician it might sound approximately correct. What is sometimes called the simple truth, the "bald truth" or the "naked truth" is often practically false—as unrecognizable as Lear naked upon the moor. It needs to be explained, supplemented, modified.

Bearing in mind, then, that by truth speaking I mean the faithful attempt to convey a true impression, and by lying an intentional deception, however brought about, let us take up the question of

#### I.—TRUTH AND FALSEHOOD IN DIAGNOSIS.

The common conception of a doctor's duty in this matter, and one according to which I practised medicine for the first five or six years after graduation, is something as follows:

"Tell the truth so far as possible. But if you are young and not yet firmly established in practice it won't do to let the patient or his family know when you are in doubt about a diagnosis. If you do they will lose confidence in you and perhaps turn you out."

That is what is implied in the frank and refreshing confession of a middle aged and successful physician whose words I have already quoted: "The great advantage of getting old is that when you don't know, you can enjoy the luxury of saying so."

The first experience that made me doubt whether it was necessary for a young practitioner to pretend omniscience in order to retain his patients' confidence was the following: I had the opportunity of driving about a large town some 25 miles from Boston with a young physician only a year or two my senior. He took me on his regular rounds and we saw farmers and the grocer's wife, the hotel-keeper's daughter and the blacksmith's baby, as well as one or two well-to-do people.

The great majority of the cases were in families of very limited education, the kind of folks that we think of as subsisting mostly on pies and patent medicine. But what made each case an eye-opener to me was the utter frankness of the doctor with the families. Diagnosis, prognosis, and treatment were given with an absence of subterfuge and of prevarication that astounded me, and what even more surprised me was to see the way the patients liked his frankness. I never have seen manifested more implicit confidence in a physician than during that drive. He never forced his doubts or his suspicions upon his patients, but when they asked a straight question they got a straight answer. A baby had a fever. "What's the baby got?" asked its mother. "Can't tell yet," said the doctor; "may be going to break out with something tomorrow or it may be all right in a day or two. We shall have to wait and see." There was no talk of "febricula" or "gastric fever." Not once did I hear him say that a patient was "threatened" with any disease. He knew that Nature makes no threats and that no honest doctor ever foists his ignorance upon "Nature" by charging her with making a "threat."

I asked him the obvious question: "How can you be so frank with your patients and yet keep their confidence?"

"Because they know," said he, "that whenever anything unusual comes up that I can't handle or that puzzles me I have a consultant. So when I say that I know, they believe me, and when I say I don't know and yet don't get in a consultant they understand that nothing of any seriousness is the matter, and that they don't need to worry. Lots of men are afraid to call a consultant because they're afraid the family will think the less of their ability. But it makes the family feel a great deal safer to know that I don't pretend to know everything and stand ready any moment to call in some one that knows more than I do. I've seen a man lose a family because he *didn't* have a consultant, but never because he did."

"Don't the families ever object to the expense of a consultant?" I asked. "No," said he, "it's perfectly easy to get good consultants at low prices if you explain the family's circumstances to them."

As a result of that conversation I began cautiously to try the experiment of telling the truth, whether I understood the case thoroughly or not. I never had reason to regret it, and I am every year more firmly convinced that the young doctor, even when practising chiefly among uneducated people, does not need to pretend omniscience merely because he is young and his patients ignorant. The truth works just as well for the pocket and a great deal better for the community and for our own self-respect.

"A certain profession of dogmatism," said Sir Frederick Treves in a recent address<sup>1</sup> to medical students, "is essential in the treatment of the sick. The sick man will allow of no hesitancy in the recognition of disease. He blindly demands that the appearance of knowledge shall be absolute, however shadowy and unsubstantial may be the basis of it."

This declaration has the great merit of frankness. But how would the doctor like to have his patients hear those words? How would he like to be caught by his patients in the act of passing on to medical students such little tricks of the trade as this? It is true that his address may never come to his patient's ears; he may never be found out. But is it good for us as professional men to have our reputations rest on the expectation of not being found out?

I doubt beside whether (as Dr. Gould<sup>2</sup> has pointed out in an admirable editorial) we "succeed in humbugging the patient's relations and friends by the devices which apparently suit the patient. Among intelligent laymen, far more frequently than is supposed, one finds that such sham certainty without the reality of knowledge and conviction is at once detected. Doctors make a great mistake when they think their deceits really deceive. Then there is the patient who recovers. When he is well the false diagnoses, the changes of dogmatic opinions, and of medicines, the blind alley of proved errors, these are thought over."

It is getting steadily harder to deceive the public. I

<sup>1</sup> British Medical Journal, 1903.

<sup>2</sup> American Medicine, November 1, 1902, p. 681.

recently heard a very prominent and representative citizen of Boston commenting upon the medical bulletins on President Roosevelt's leg. "Of course," he said, "no one ever believes these bulletins. The doctors give out only so much as they think fit, in order not to alarm the public unnecessarily. The result is that the public never believes the bulletins and is always more or less anxious."

Now, I do not believe that the truth was in any way tampered with in the bulletins either of President Roosevelt's or of President McKinley's illness. I believe these bulletins gave the strict and accurate truth. But I think it is generally admitted that such bulletins do not command the respect which they usually deserve. Business men and others to whom it may be of vital importance to get reliable information about the illness, are especially apt to "discount" the bulletins of the group of physicians in attendance on a man whose life is of great importance financially. We all remember how persistently the general public believed that King Edward's illness of last summer was due to malignant disease, and not to the "perityphlitis" mentioned in the bulletins. How can we blame the public for not believing the doctors in attendance on the King when one of them, Sir Frederick Treves, is willing publicly to advocate the systematic deception of patients? His words I have quoted. It is true that he does not advise deception under conditions like those of King Edward's illness, but how is the public to know just when and how far the doctor will think it best to deceive? Such discrimination is especially difficult in a country like England, where the public cannot help knowing that what is "given out" concerning foreign affairs, especially in matters of diplomacy and war, represents only so much of the truth as the officials think it best for the public to know.

I have been speaking of the disadvantages of trying to deceive a patient or those interested in him with regard to the diagnosis. I have argued so far that it is not necessary to assume absolute knowledge in order to impress the patient's mind and hold his confidence, and that owing to the increasing scepticism of the public, it is becoming more and more difficult to fool the patient at all.

Very few Americans like to lie. They would rather tell the truth if they could, but there are cases in which the voice of duty itself seems to tell us that we must lie. To prevent the breaking up of a family, to save a life, are we not to lie? A husband confesses to you the sin that has resulted in disease for him. The wife, suspecting something, catches you on your way out and asks you point blank what ails her husband. Can you tell her the truth? Well, suppose you tell her a good, round, well-constructed lie. What are the chances of her believing you? If she has got to the point of suspecting her husband, are her suspicions likely to be quieted permanently by your reassurances? Is there not a fair chance that she knows enough of the usual customs of physicians when placed in this position to discount what you say?

Then the truth in such matters very often comes to light sooner or later, and if it does, the wife is apt to let a number of persons know what kind of a trick you have played her. Of course, there are many such cases in which the truth never is found out, but I ask again, is it a good thing for us as professional men to be living in the hope of not being found out?

## II.—TRUTH AND FALSEHOOD IN PROGNOSIS.

That it is a bad thing to lie about a prognosis we all admit, as a general rule, but there are cases when it is not easy to see what harm it does when the good that it does is very evident indeed.

A patient has gastric cancer. He is told that he has neuralgia of the stomach, and feels greatly relieved by the reassurance, for the effect of psychic influences is nowhere more striking than in gastric cancer (as the cases quoted in Osler's textbook show). Meantime the truth is told to the patient's wife, and she makes whatever preparations are necessary for the inevitable end. Now what harm can be done by such a lie as this? That sufferer is protected from those anticipations and forebodings which are often the worst portion of his misery, and yet his wife, knowing the truth and thoroughly approving of the deception, is able to see to it that her husband's financial affairs are straightened out and to prepare, as well as may be,

for his death. Surely this seems a humane and sensible way to ease the patient's hard path, and who can be the worse off for it?

I answer, "Many may be worse off for it, and some must be." The patient himself is very possibly saved some suffering. But consider a minute. His wife has now acquired, if she did not have it already, a knowledge of the circumstances under which doctors think it merciful and useful to lie. She will be sick herself some day, and when the doctors tell her that she is not seriously ill, is she likely to believe them?

I was talking not long ago on this subject with a girl of 22. "Oh, of course, I never believe what doctors say," was her comment, "for I've helped 'em lie too often and helped fix up the letters that were written so that no one should suspect the truth."

In other words, we have added to the lot of one person, the sufferings which we spare another. We rob Peter to pay Paul.

But it is not likely that the mischief will be so closely limited. There are almost always other members of the family who are let into the secret, and intimate friends, either before or after the patient's death, find out what is going on. Then there are nurses and servants from whom it is rarely wise or possible to keep hidden the actual state of affairs. All told, I doubt if there are less than a dozen souls on the average who are enlightened by such a case in regard to the standards of the physician in charge and so of the profession he represents. I have heard such things talked over among "the laity," and, as a rule, not one, but several cases are adduced to exemplify the prevailing customs of medical men in such circumstances.

We think we can isolate a lie as we do a case of smallpox, and let its effect die with the occasion that brought it about. But is it not common experience that such customs are infectious and spread far beyond our intention and beyond our control? They beget, as a rule, not any acute indignation among those who get wind of them (for "how," they say, "could the doctor do otherwise?"), but rather a quiet, chronic incredulity which is stubborn, just in proportion as it is vitally important in a given case to get at the real truth, as in the case of King Edward before mentioned.

You will notice that I am not now arguing that a lie is, in itself and apart from its consequences, a bad thing. I am not saying that we ought to tell the truth in order to save our own souls or keep ourselves untainted. I am saying that a lie saves present pain at the expense of greater future pain, and that if we saw as clearly the future harm as we see the present good, we could not help seeing that the balance is on the side of harm. It is intellectual short-sightedness.

I have told fully my share of lies, under the impression, shared I think, by many of the profession, that it is necessary in exceptional cases to do it for the good of the patient and his friends, but since I have been experimenting with the policy of telling the truth (at first cautiously, but lately with more confidence), I have become convinced that the necessity is a specious one, that the truth works better for all concerned, not only in the long run, but in relatively short spurts, and that its good results are not postponed to eternity, but are discernible within a short time.

In vindication of my belief let me tell you the sequel to one of the stories before related. You will recall that I prepared "to be very guarded in what I said" (as the technical phrase is) to a lady whose husband had angina. The attending physician, who had known the lady for years, and who represented entirely the views of her family, assured me that she was too delicate and too unstrung by neurasthenia to be capable of bearing the truth about her husband. If she knew that he might die suddenly and at any time, she would brood and fret over the knowledge until she became so querulous and unhinged that all the family, the sick husband included, would be made miserable. You remember how I made up my mind to conceal the truth from her if I could, and how she upset all my calculations by asking me suddenly whether or not I would tell her the whole truth so far as I knew it. Consider a moment the difficulties of that situation.

"Will you give me a true answer to every question I ask you?" I could scarcely be expected to pop out a prompt "yes" when I had just promised the family physician not to do

anything of the sort. Of course I could not say "no," and if I hesitated an *instant*, I had betrayed my intention of deceiving her. What would you have done?

As a matter of fact I hesitated a bit, as I think anyone but a most practised liar or a hidebound truth-teller would have done. "That's enough," said she; "that's all I want to hear." But of course I couldn't leave it there, so I pulled myself together and made a clean breast of the whole thing. I told her just what I thought and what I expected, including all that I had promised the doctor not to tell. Now you will remember that the attending physician who had known her intimately for years had warned me that she could not bear this sort of news—that she would brood and worry over it, until she had made herself and everyone else in the house miserable. So when she cornered me and got the truth out of me, I made haste to get out of the house, and thanked my stars that I did not have to stay behind and pick up the pieces of the nervous wreck to which my plain, unvarnished tale must needs reduce the poor lady.

Several weeks after, I met the family physician and learned that for some mysterious reason the expected collapse on the part of the neurotic wife had never arrived. Everyone was still expecting her to go to pieces, but as yet she had got along about as usual. In point of fact she has never met their expectation. It is now nearly four years since the dreadful truth was told her and no breakdown has occurred.

After that most astonishing experience I began cautiously to tell the truth in similar cases, when intimate friends or relations of the patient declared that the truth could not be borne, and when I had no knowledge of the patient's character to set against that of his closest friends. It has been, on the whole, the most interesting and surprising experiment that I have ever tried. The astounding *innocuousness of the truth* when all reason and all experience would lead one to believe it must do harm, has surprised me even more than the remarkable tolerance of febrile patients for alcohol. It seems as if when the pinch comes and the individual has to face stern realities, some species of antitoxin is spontaneously and rapidly developed whereby the individual is rendered immune to the toxic and deleterious effects of the nervous shock!

Those of you who are familiar with Ehrlich's side-chain theory will remember that a group of cells, say those of the nervous system, acquires immunity against a given toxin, because the cells stimulated by the presence of the toxin, produce with great rapidity an *excess* of those very "receptors" or vulnerable points in virtue of which they are sensitive to toxic action. These new-fledged surplus "receptors" then break away from the parent cell, and swimming free in the blood-stream, meet the toxins, close with them before they reach the neural cells, save these precious cells from injury, and render the toxins harmless.

So may we not conceive that under the stimulus of the first sting and nettle of hard truth, the nervous system of the patient produces rapidly an overplus of free "receptors"—*rises to the emergency*, as we ordinarily say, and so is rendered immune against the otherwise depressing effects of full knowledge? Indeed, Ehrlich's theory might be described as an application to single groups of cells of that tendency to rise to an emergency, to fight when cornered, to supply an imperious demand, which we see often enough in men and in nations.

But whatever the theory, the fact has been brought home to me as it can only be brought home by actually trying the experiment; the fact, namely, that patients and patients' friends exhibit an astonishing power to stand the full truth, an amazing immunity against its depressing effects. No one ought to believe this who has not tried it, any more than you ought to believe what I have said<sup>1</sup> about the action of alcohol until you have repeated my experiments. All that my say-so ought to accomplish is to make someone ready to try the experiment; to take the risks which we must always face if we are to get ahead, and see whether he can verify my findings.

One precaution, however, must be borne in mind. Anyone who is familiar with experimental work knows that the difficulty of verifying another's experiment is often due to failure to repeat just that experiment and no other. A certain blood-

stain is highly lauded. You try it and cannot get the results which its inventor claims for it. But very often you fail because you have not exactly followed the details of his technic.

So here, if you try to repeat my experiments I trust that you will notice just what it is that I recommended you to try. I am not recommending that we should explain to every mother in full detail the etiology, pathology, course, and prognosis of her baby's illness. I have never tried that experiment, and I should suppose it would be a very stupid, useless, and probably harmful thing to do. I do not believe in cramming information down peoples' throats or trying to tell them what they cannot understand properly, any more than I believe in button-holing every acquaintance in the street, and giving him a detailed account of what I consider his faults and failings.

But if my friend asks me for an opinion of his first literary productions, and if I think that they are dreadful rubbish, I do not consider it friendship to say pleasant things of his style and thereby encourage him to pursue literature as a calling. I do not give my opinion unless it is really asked for. But if it is, I do not believe in lying to save anyone's feelings. It does more harm in the end.

So in medicine, if a patient asks me a straight question I believe it works best to give him a straight answer, not a rough answer, but yet not a lie or a prevarication. I do not believe it pays to give an answer that would justify a patient in saying (in case he happened to find out the truth):—"that doctor tried to trick me." I have heard a patient say that, apropos of a lie told by one of the most high-minded and honorable physicians I know, and I do not believe it advisable for any of us to expose ourselves to the chance of rousing that sort of indignation in a patient.

A straight answer to a straight question is what I am recommending, not an unasked presentation of the facts of the patient's case. He may not care to know those facts any more than I care to know the interesting details of dental pathology in which my dentist might wish to instruct me; I leave all that to him. Just so my patient may very properly prefer to be told nothing about his disease, trusting that I shall do my best and let him know when there is anything for him to do in the matter.

But a straight answer does not mean for me what is often called the "blunt truth," the "naked truth," the dry cold facts. The truth that I mean is a true *impression*, a fully drawn and properly shaded account such as is, as I well know, very difficult to give. I know one physician (and a splendid type of man he is, too), who, when he sees a case of rheumatic endocarditis, and is asked for a prognosis, is apt to say something like this: "Well, I'm mighty sorry for you, but your trouble is incurable. Your heart is damaged past repair and there is not much of anything to be done except to take salicylates during the acute attacks and hope that the process will become arrested spontaneously before long." "Is it likely to get worse?" asks the patient. "Yes, I'm afraid it is."

Now in one sense that is all true, but the impression that it will convey to the patient is not true, not at all what I mean by telling the truth. I would rather a physician would tell this sort of truncated, imperfect and very distressing truth, than give the patient a smooth and pleasant assurance that he can be cured and that all will go right provided he does so and so.

But better than either a misleading half truth or a pleasing lie, is an attempt so to answer the patient's question that he shall see not only what he can't do and can't hope for, but what he can do and what there is to *work* for hopefully. That his heart-valve is sclerosed and perhaps useless is true, and in that sense, to that extent, he is incurable; the sclerosed heart-valve is there once for all, and yet by accommodating himself to his diminished heart power, the patient can gradually educate to a considerable extent, both his heart and the rest of himself. His heart can be made to adjust itself to its maimed state and to put forth, in spite of it, a good deal more power than it would have done without the educational process; and the individual by learning to take the best advantage of all the power he has, can accomplish, not all that he *could* in health, yet perhaps as much as he actually *would* have done, allowing for the amount of

<sup>1</sup> In the second Cartwright lecture delivered on the previous evening.

wasted time and wasted opportunity that has often to be deducted from the effective power of a healthy man.

Because this kind of explanation is so difficult and takes so much time, we are apt to shirk it and give the patient either a rough half-truth or a smooth lie. In our free dispensaries one can witness any day a rich and varied assortment of these two methods of shirking a difficult and tedious explanation; the rough half-truth and the smooth lie are dealt out by the shovelful and students watch and make their choice between these two pitiful makeshifts according to their temperaments, often in entire ignorance of any *tertium quid*. For it is particularly in dealing with uneducated people, such as frequent dispensaries, that we distrust the power of truth and the possibility of conveying it. In this field I have made many experiments both with lies and with the truth. I know very well that the truth is sometimes next to impossible to convey, owing to differences between the patient's vocabulary (or in habits of mind) and the physician's, but on the other hand the lie may do more harm, for there is more chance of its being implicitly believed.

To refuse to answer questions is now and then a necessity and need not involve any falsehood. For example, to balk meddling inquiries by an outsider is often our business. Then there is the patient about to undergo an operation, who sometimes catechises us about the details of the operation and sometimes had better remain ignorant about it until after it is over. On the other hand, if the patient's mind is already occupying itself with a definite, but exaggerated picture of the horrors of the operation, a prosaic explanation of the real facts may act as a sedative.

Not infrequently we need to choose our time well, if a piece of painful truth has to be communicated and it may be necessary to avoid giving the patient a chance to cross-question us at a time when we consider him temporarily below par. I have heard a patient say: "The doctor didn't mean to let me get that out of him today," but without any bitterness or sense of being tricked by his physician, for the fact that the doctor avoided being questioned presaged that if cornered he would not tell a lie.

I have said that in my experience patients and their families often develop a most astonishing power to rise to the emergency and to bear the hard truth when it has to be told. But I cannot say that this is always so. There may be cases, I suppose there are such, when the patient does not react from the shock of a cruel truth, but is made worse by it. It is said that such a shock sometimes turns the scale and brings death.

Ought we to persist in telling the truth even when we believe it may kill the patient? Could any effect produced by a lie be as bad as the loss of a human life?

Before answering this question directly, let me ask you to consider a somewhat fanciful hypothesis. Suppose it lay in our power to let loose into the atmosphere a poisonous gas which would vitiate the air of a whole town so that the whole community would gradually suffer in efficiency, in physical and moral fiber. Would it not be worth a human life to save a whole community from such a deterioration?

Now a lie seems to me to do something like that. By undermining the confidence of man in man it does its part in making not one but every human activity impossible. If we cannot trust one another, we cannot take a step in any direction. Business, social relations, science, everything worth doing depends on mutual confidence. It is the very air we breathe. To poison it is to do a far worse thing for society than could result from the loss of a single life. So that though I believe that it is extraordinarily rare to be able to save a life by a lie, it seems to me that the remedy, the lie, is worse than death.

### III.—TRUTH AND FALSEHOOD IN TREATMENT.

In discussing truth and falsehood in diagnosis and in prognosis I have dealt chiefly with spoken truth or spoken lies. In the domain of treatment the true or false impression is often conveyed without words.

I do not know who it was that defined a quack as "one who pretends to possess or to be able to use powers (either of diagnosis, prognosis or treatment) which in fact he *knows* he is without." If we think over the various forms of quacks familiar to us—Dr. Munyon, with all those specifics which he

knows he does not possess; the cancer curers, those who advertise to cure "weak men," Francis Truth, who cheats his dupes with all-healing handkerchiefs sent through the mails at \$5 apiece—we see that they all pretend to possess knowledge about valuable medicines or other remedies which they know they do not possess.

Now I was brought up, as I suppose every physician is, to use *placebos*, bread pills, water subcutaneously, and other devices for acting upon a patient's symptoms through his mind. How frequently such methods are used varies a great deal I suppose with individual practitioners, but I doubt if there is a physician in this room who has not used them and used them pretty often. It never occurred to me until I had given a great many placebos that if they are to be really effective they must deceive the patient. I had thought of them simply as a means of getting rid of a symptom and no more a lie than hypnotism or any other form of frankly mental therapeutics.

But one day a patient caught me in the attempt to put her to sleep by means of a subcutaneous injection of water. "I saw you get that ready," said she, "and there is no morphin in it; you were just trying to deceive me." I was fairly caught and there was no use trying to bluff it out, so I merely protested that my deception was well meant, that it profited me nothing, that it was simply intended to give her a night's rest without the depressing effects of morphia, etc.

"Of course I see that," she said, "but how am I to know in future what other tricks you will think it best to play me for my good? How am I to believe anything you say from now on?"

I did not know what answer to make at the time, and I have never been able to think of any since.

But water subcutaneously does not differ in principle from any other placebo. If the patient knows what you are up to when you give him a bread pill it will have no effect on him. If he is dyspeptic he must believe that you consider the medicine you give likely to act upon his stomach and *not merely upon his stomach through his mind*. Otherwise it will do him no good. Suppose you said to him: "I give you this pill for its mental effect. It has no action on the stomach," would he be likely to get benefit from it? In short, it is only when through the placebo one deceives the patient that any effect is produced. It is only when we act like quacks that our placebos work.

But what harm, you may ask, does a placebo do? Admitting that it is a form of deception and that if you are detected in it the patient and his friends are likely to lose confidence in you, what harm does it do so long as you are not found out?

Well, as previously said, I do not think it is a good thing for any man to succeed only so long as he is not found out, but there are other objections to the use of placebos which I will next try to explain.

The majority of placebos are given because we believe the patient will not be satisfied without them. He has learned to expect a medicine for every symptom, and without it he simply won't get well. True, but who taught him to expect a medicine for every symptom? He was not born with that expectation. He learned it from an ignorant doctor who really believed it, just as he learned that pimples are a disease of the blood, that shingles kills the patient whenever it extends clear round the body, and that in the spring the blood should be "purified" by this or that remedy. It is we physicians who are responsible for perpetuating false ideas about disease and its cure. The legends are handed along through nurses and fond mothers, but they originate with us, and with every placebo that we give we do our part in perpetuating error, and harmful error at that. If the patient did not expect a medicine for his attack (say of mumps) we should not give it, yet we do all we can to bolster up his expectation for another time, to deepen the error we deplore.

But here, as everywhere, experiment is the test. I have for the past few years been trying the experiment of explaining to the patient why he does not need a drug, when there is no drug known for his trouble. It takes a little more time at first, but one thorough explanation serves for many subsequent occasions. One has only to remind the patient of what we have gone over with him before. When the occasion for a drug

really comes, the patient has far more confidence in its workings.

We feel these things acutely when a patient comes to us who has been previously under the care of another physician. How refreshing to hear the mother of a child sick with measles say, "Well, I don't suppose he needs any medicine, does he? The disease has to run its course, I suppose, and nursing is the main thing." That mother has been given the truth by her physician instead of placebos, and has become accustomed to realities as easily as most people learn to believe outworn errors. On the other hand, we see now and then a patient into whose mind it has been carefully instilled by some physician that every draught of fresh air must be avoided like a plague, that every symptom needs a drug, and that a visit from the doctor every few days is a necessity to salvation.

But the habit of giving placebos has another evil result. It gives the patient indirectly a wrong idea, a harmful idea of the way disease is produced and avoided. If symptoms can be cured by drugs, it is impossible to bring to bear upon the patient the full force of that most fundamental principle of therapeutics: "To remove a symptom remove its cause." That a man can be made well "in spite of himself" as the patent-medicine advertisements say; that is, in spite of violating the laws of health, is a belief produced as one of the by-products of the way we hand out placebos, especially in our hospitals and dispensaries.

No patient whose language you can speak, whose mind you can approach needs a placebo. I give placebos now and then (I used to give them by the bushel) to Armenians and others with whom I cannot communicate, because to refuse to give them would then create more misunderstanding, a false impression, than to give them. The patient will think I am refusing to treat him at all; but if I can get hold of an interpreter and explain the matter, I tell him no lies in the shape of placebos.

Before I close this lecture I want to speak of one further point which my experiments with truth and falsehood have brought home to me. When I have plucked up courage and ventured to tell the truth in hard cases, I have been surprised again and again to find how the chances and accidents of nature have backed me up. Everything seems to conspire to help you out when you are trying to tell the truth, but when you are lying there are snares and pitfalls turning up everywhere and making your path a more and more difficult one.

I will sum up the results of my experiments with truth and falsehood, by saying that I have not yet found any case in which a lie does not do more harm than good, and by expressing my belief that if anyone will carefully repeat the experiments he will reach similar results. The technic of truth telling is sometimes difficult, perhaps, more difficult than the technic of lying, but its results make it worth acquiring.

**Legislation to Limit Kissing.**—A bill has been introduced into the Minnesota Legislature declaring that it shall be unlawful for one person to kiss another unless he has proved that he is free from contagious or infectious disease, and further that a certificate from a physician declaring a person to have a weak heart, shall constitute a bar to the indulgence of kissing, and violation of the proposed statute is accounted a misdemeanor, punishable by a fine of from \$1 to \$5 for each offense.

**Mortality of Michigan During January, 1903.**—There were 2,856 deaths returned to the Department of State, corresponding to a deathrate of 13.5 per 1,000 population. The number returned was 190 more than that registered for the preceding month, and 32 more than the number registered for January, 1902. There were 550 deaths of infants under 1 year, 178 deaths of children aged 1 to 4 years, both inclusive, and 906 deaths of elderly persons aged over 65 years. Important causes of death were as follows: Tuberculosis of lungs, 170; other forms of tuberculosis, 25; typhoid fever, 48; diphtheria and croup, 58; scarlet fever, 36; measles, 13; whoopingcough, 40; pneumonia, 382; influenza, 39; cancer, 140; accidents and violence, 126. Typhoid fever and diphtheria slightly decreased in the number of deaths as compared with December. The deaths from external causes were also considerably less. Scarlet fever and whoopingcough showed marked amounts of increase. Pneumonia was considerably more fatal, and the number of deaths from cancer exceeded any month during the previous year. There were 7 deaths from smallpox, and 1 death was reported from hydrophobia in the city of Detroit.

7. Acute Sinusitis. J. A. STUCKY.
8. Cutaneous Therapy: Some of the Newer Methods. CHARLES W. ALLEN.
9. Radiotherapeutic Observations. JOSEPH ZEISLER.
10. The Prognostic Value of Tubercle Bacilli in Sputum. LAWRASON BROWN.

**1.—Chemistry of the Tropicins.**—Lyons discusses the nature of the bases in the several mydriatic drugs and their conversion through manipulation into one another. The name of tropicins has been given to combinations of tropin with various organic radicals, forming new synthetic alkaloids, the name applying to the natural alkaloids as well. The property of mydriasis does not belong to all the artificial tropicins, although possessed in a high degree by some of them. From the great variability in strength of the mydriatic drugs, reliable assay processes are desirable. So long as we are in doubt whether there are important therapeutic differences between the different principles an assay that determines only total alkaloids leaves much to be desired. The alkaloids themselves are easily changed by the chemicals used in extracting them. A wide field is open for useful experiment. [H.M.]

**2, 3.**—See *American Medicine*, Vol. III, No. 25, p. 1060.

**4.**—See *American Medicine*, Vol. III, No. 25, p. 1058.

**5, 6, 7.**—See *American Medicine*, Vol. III, No. 25, p. 1059.

**8.**—See *American Medicine*, Vol. III, No. 25, p. 1061.

**9.—Radiotherapeutic Observations.**—Zeisler believes that electric shocks from the tube play only an incidental role. Whoever is after electric action will use a hard tube. The soft tube is rich in x-rays, which are absorbed by the upper layers of the skin. Static machines are hardly fit for dermatologic purposes. A good induction coil only is to be considered. The essential element in determining the energy with which we work is the character of the light, irrespective of either voltage or amperage. He recommends a self-regulating tube. From using the soft tube he has never had any ulceration or sloughing. He uses thick sheet lead lined with flannel to protect parts adjacent to that treated. In treating the face he always covers the eyes and hair. He reports most encouraging results in lupus vulgaris and erythematosis, scrofuloderma, hypertrichosis, sycosis, acne, epithelioma, psoriasis, lichen planus, eczema, pruritus, keratosis palmaris, clavus, hyperidrosis nasi, and dermatitis staphylogenes. Zeisler agrees with those who attribute to the rays a special affinity for pathologic cell formations, which, under the influence of the rays, undergo metabolic changes and even entire disintegration. [H.M.]

**10.—Prognostic Value of Tubercle Bacilli in Sputum.**—If tubercle bacilli are found in one specimen it proves tuberculosis of the respiratory tract. That no bacilli are found in one examination is of little value. At least four or five specimens should be examined after the patient is directed how to collect the sputum. If the numbers steadily decrease in a series of examinations at intervals sufficiently long the patient may be improving, but the constitutional symptoms and local signs give much more accurate information. If on repeated examinations large quantities of tubercle bacilli are found the disease has probably advanced to cavitation. The morphology of the bacilli affords little or no ground for prognosis, but the short bacilli are suggestive of a more active process. The arrangement in clumps is more apt to be found in the severer cases, but may occur in all. [H.M.]

Boston Medical and Surgical Journal.

1. Observations Upon Long-distance Runners. J. B. BLAKE and R. C. LARRABEE.
2. Pulse, Weight, and Temperature. J. B. BLAKE and D. D. SCANNELL.

3. Report on Pulse Tracings Taken from the Marathon Runners in the Races of 1900, 1901, 1902. ALLEN CLEGHORN.
4. The Blood. RALPH C. LARRABEE, WILDER TILESTON and WM. R. P. EMERSON.
5. The Hearts. RALPH C. LARRABEE and LAWRENCE W. STRONG.
6. Kidneys. JOHN M. CONNOLLY.
7. Medical Treatment of Intestinal Obstruction. THOMAS F. HARRINGTON.

1.—**Long-distance Runners.**—Blake and Larrabee condense the data collected by a large number of observers who examined the contestants in the Marathon races in the vicinity of Boston, the course being 24 miles in length. The pulse rate was always increased somewhat, the least in the best trained, and in those who finished slowly. In some instances it was almost as slow as at the start. Loss of weight varied from 2 to 7 pounds. Before the start the temperature varied, sometimes reaching 100.6°. After the finish mouth temperature was sometimes raised, often normal, and occasionally subnormal owing to holding the mouth open. The rectal temperature was invariably raised, reaching once 7° above normal. Pulse tracings were dicrotic. The blood showed a leukocytosis resembling that of inflammatory diseases. Hearts invariably showed enlargement before the start, increased at the finish. Murmurs, generally systolic, heard at the start were attributed to nervous excitement. Concerning the nature of those at the finish there is considerable doubt. The urine showed in every case active hyperemia, probably from the toxins of fatigue, the condition disappearing one week after the race. The amount was lessened, the color and specific gravity were higher, the reaction more acid. Albumin was present with hyaline, granular, and epithelial casts and blood. Urea was not increased, and chlorids diminished. [H.M.]

2.—**Pulse, Weight, and Temperature.**—According to Blake and Scannell the pulse rate seemed to depend on three factors: The condition of the heart; the character of the exertion, particularly in the last few minutes of the race; the time which elapsed between finish and observation. At the start men differed much in composure; at the finish all were stolid with fatigue. The maximum loss of weight was less than in football or rowing. The heaviest and lightest who completed the race weighed respectively 155 and 104 pounds. Observations through three years on 45 men show that mouth temperature is not reliable. No evidence was obtained that subnormal temperature depends on overtraining or extreme fatigue. Cleghorn reports the method employed in taking pulse tracings. The results were uniform, the curve being normal at the start and pointing to enormously low arterial tension at the end, in some cases being extremely dicrotic. This is probably due to a combination of blood concentration, the action of the "depressor nerve" in dilating the arterioles, and dilation from fatigue products. [H.M.]

4.—**The Blood.**—Larrabee, Tileston, and Emerson found that in the white counts the greatest increase was in the polymorphonuclear neutrophiles, these being more numerous relatively and absolutely at the finish. In the mononuclear elements the percentage of large forms, as compared with small ones, was invariably increased. Eosinophiles were relatively and absolutely decreased. Mast cells showed similar changes. No abnormalities were noted in the reds. The leukocytosis was of the inflammatory type. Larrabee and Strong record but one case in which a murmur was detected at the finish which was not present at the start. In all three races some were cyanotic at the finish, others pale. Enlargement of the heart at the beginning is due to hypertrophy from training. The authors discuss the causes of dilation and murmurs, and believe that all the changes manifested were physiologic. [H.M.]

6.—**Kidneys.**—Connolly found albumin to persist for at least 36 hours. The amount was greatest in the first quantity passed. Reduction of Fehling's solution in two cases was probably not due to sugar. The main physical characteristics of the contestants were as follows: Height, medium or less; weight, 110 to 140; chests not unusually large nor expansion great; legs of medium length; muscles never remarkably hypertrophied, but firm and fat-free; feet large, broad, and free from signs of compression. Unpleasant results of longest duration were blisters on the soles of the feet. [H.M.]

7.—**Medical Treatment of Intestinal Obstruction.**—

Harrington classifies the causes of obstruction which can be considered medical as impactions of fecal matter, foreign bodies, intussusception and neoplasms. He describes the symptoms. When foreign bodies have been swallowed castor-oil must not be given as peristalsis may cause more injury. Give oatmeal, unbolted flour, cornmeal or mashed potatoes. Examine the rectum frequently. In intussusception chloroform the child and inject two gallons of warm water. Bellows are not as safe. Opium is not contraindicated when there are impacted feces, as narcosis may relax the bowel. After evidences of peritonitis subside it is safe to give castor-oil, calomel or repeated enemas of warm water. The stomach should be washed three or four times daily. Surgical interference is warranted in three days if symptoms do not abate. Taxis is often helpful. Distention may be tapped, if extreme. Statistics are not encouraging to surgical interference in obstruction due to cancer and other incurable diseases, and there is little to endorse exploratory laparotomies. [H.M.]

### Medical Record.

February 21, 1903. [Vol. 63, No. 8.]

1. The Treatment and Care of Tuberculous at Their Homes, and the Urgent Need of Local Sanatoriums. S. A. KNOPF.
2. The Present Status of Surgery of the Gallbladder and Bile Ducts. WILLIAM J. MAYO.
3. Postoperative Malaria, with a Report of Two Cases. JOHN T. MOORE.
4. Trachoma in the Public Schools of New York. WALTER EYRE LAMBERT.

1.—**Treatment of Tuberculous at Home; Need of Sanatoriums.**—Knopf considers sanatorium treatment the ideal one, unless the patient is so situated that identical treatment can be inaugurated at home. He describes receptacles for sputum, and discusses the etiquette of coughing, the proper clothing, the prohibition of tobacco, the arrangement of the patient's rooms, diet, the value of massage in improving digestion, the necessity for making life interesting, the need of comfort in chairs, etc., the importance of minute instructions as to walking and breathing exercises, the value of solartherapy and hydrotherapy, and of some of the newer drugs. He concludes with an argument and appeal for more sanatoriums. [H.M.]

2.—**Surgery of the Gallbladder and Bile Ducts.**—W. J. Mayo says the active gallstone, as regards necessity for operation, is analogous to chronic relapsing appendicitis. He is of opinion that they should be removed by early operation, which is less dangerous than subsequent risk without operation. He and his brother have operated on 250 such cases out of a total of 454 gallstone operations, with a mortality of less than 1%. In over 2,000 such cases in the hands of six surgeons there has been no recurrence of the stones. In the 454 cases they found cancer in 21 (5%). In 49 cases there was stone in the common or hepatic duct, with or without jaundice. In 26 cases the symptoms pointed strongly to gallstones but at operation none was found; instead there was a chronic cholecystitis, and evidently plugging had caused the symptoms. Incising the thickened bladder and drainage is the proper treatment. The "ideal" operation—closure of the gallbladder without drainage—must be resorted to in any case with caution, since the presence of gallstones is indicative of infection. It should be reserved for most part to the latent cases which are usually found in operations for other affections. Kehr says the hepatic ducts require drainage in 37% of cases, which the author thinks none too high. In choledochotomy the incised duct should be left open for drainage after the stone is removed, as suggested by Davis. [A.B.C.]

3.—**Postoperative Malaria.**—Moore, of Galveston, says malarial parasites may exist in the blood and yet there be no temperature phenomena, and it is these cases which show the tendency to relapse or to rise in temperature after operation, or any other procedure which lowers the resisting power of the individual. Malarial parasites may exist for a long time in the blood even when quinin is being taken. The only absolute test is the microscope. The blood of every patient in a malarial district should be examined carefully before operation unless the case be one of emergency. The author cites two cases which after operation had a temperature unexplained by the condition of the wounds, but which yielded readily to antemalarial treat-

ment after the parasites had been found in the blood. The author is of opinion that many patients have been subjected to operation for vague symptoms which, had a microscopic examination been made and quinin treatment instituted, would have readily subsided. [A.B.C.]

4.—**Trachoma.**—Lambert notes that in 36 schools inspected 13% of the pupils were excluded on account of contagious eye diseases, principally trachoma. In some cases the diagnosis may have been faulty, but the vast majority required special treatment. An ideal solution of the problem of isolation would be the setting apart of certain institutions for care of these cases. The best that can now be done is exclusion from the school. In connection with this the Board of Health has a corps of trained nurses to visit the homes, explain the seriousness of the condition, direct where the children can be taken for treatment, and instruct as to the danger of contagion. [H.M.]

### New York Medical Journal.

February 14, 1903. [VOL. LXXVII, No. 7.]

1. Rudolf Virchow: An Appreciation. CHARLES L. REID.
2. Residual Urine. HENRY EWING HALE.
3. The Etiologic Significance of Heberden's Nodes. EDWARD M. MERRINS.
4. On the Local Effects of Aurantia and Its Treatment. W. MOSER.
5. The Influence of the Mind Upon the Body. JOHN B. HUBER.

1.—**Virchow.**—This address by Reid is an appreciation of the life and labor of Rudolf Virchow. It is exceedingly interesting and should be read in the original, as it does not lend itself to abstracting. It is one of the most admirable addresses of its kind that it has ever been our pleasure to read. Its scholarly, lofty, and philosophic tone shows that its author possesses not only wide learning along historic lines, but also a deep insight into human nature and human problems.

2.—**Residual Urine.**—Hale tells of a method of procedure which enables some patients to avoid what would otherwise be residual urine, thus avoiding cystitis and the necessity of catheterization. One cause of residual urine may be the hypertrophied middle lobe of the prostate behind the internal orifice of the urethra. Thus the internal aspect of the base of the bladder is divided by a transverse dam into an anterior and posterior pocket. The former is drained by the urethra, while the latter is not so drained in the upright position. When such a condition is found the patient is directed to void his urine twice daily while in the knee-elbow position. Patients in whom the bladder wall has lost its tonicity derive no benefit from such directions. [C.A.O.]

3.—**Heberden's Nodes.**—Merrins has reviewed the literature of this subject and finds these nodes reported in such diverse conditions as gout, carcinoma, dilation of the stomach, rheumatoid disease, congenital syphilis, and old age. He calls attention to the fact that in nearly all of these conditions there is some mechanic, chemic or toxic irritant in the system. There is also impaired general vitality, and if this is accompanied by disturbed innervation, as in rheumatoid disease, the more frequent is the occurrence of Heberden's nodes. The author concludes that these nodes are simply evidences of structural degeneration dependent upon one or more of the factors above mentioned, that they may occur in any condition where such factors are present, but that they are most likely to occur in those chronic diseases where morbid, bony changes form the principal feature of the disease, as in gout and the osteoarthritic variety of rheumatoid disease. The presence of these nodes, therefore, may be a help to diagnosis, but they should never be regarded as conclusive evidence of any particular disease, nor are they of sufficient pathologic importance to constitute a separate form of rheumatoid disease when they appear as isolated phenomena. [C.A.O.]

4.—**Aurantia.**—Moser reports a case to show the local effects. The patient's hands came in contact with a concentrated solution of the product. Small vesicles, swelling, and intense pruritus followed. There was no pain, and not much reddening. Later large bullas formed and the process of healing was that of a severe burn. [C.A.O.]

### Medical News.

February 21, 1903. [Vol. 82, No. 8.]

1. Functional Disorders of the Biliary Secretion and Their Treatment. H. RICHARDSON.
2. The Treatment of Tuberculosis. CHARLES WILLIAM HEITZMAN.
3. A Contribution to the Surgery of the Internal Saphenous Vein. WILLIAM FRANCIS CAMPBELL.
4. Empyema of the Accessory Sinuses of the Nose. J. H. WOODWARD.
5. A New Sputum Slide. JAMES RAE ARNEILL.

1.—**Disorders of the Biliary Secretion.**—H. Richardson says it has been shown that the so-called chologogs of the pharmacopeia do not increase the flow of bile, but that the bile acids do increase this flow. Kehr's statistics show that 10% of persons in Germany have gallstones; in England it is estimated at 5%, and in the United States at 7½%. In melancholias gallstones is the rule, whereas they are almost unknown in maniacs. They have been occasionally found in the newborn, 2.4% of the cases occur under 20, 3.2% between 20 and 30, 11.5% between 30 and 40, 11.1% between 40 and 50, 19.9% between 50 and 60, and 25.2% over 60 years of age; they may be said to occur in one out of every four persons over 60, due to the increased formation of cholesterolin and the decreased expulsive power of the gallbladder. The mortality in operation upon noninfected cases is about 3%; in infected cases it may rise to 25%. The best means of preventing the formation of stones is a hygienic life, plenty of exercise, and when there is a tendency to deficient biliary flow, the administration of 5-grain capsules of sodium glycocholate three times daily, laxatives and the drinking of plenty of water. [A.B.C.]

3.—**The Surgery of the Internal Saphenous Vein.**—Campbell, of Brooklyn, says the ligation of the internal saphenous vein in Scarpa's triangle for varicosities along its course below the knee is now being much resorted to, but frequent inability to find the vein at the proper place for ligation has led to trouble. He has operated on 50 cases and as a result of careful observation he lays down a rule for finding the internal saphenous at the proper point for ligation. Find the spine of the pubes. From this point project a line 3½ inches long at a right angle to Poupart's ligament. The end of the line marks the point for the center of the incision, which should be about one inch long and parallel with the fold of the groin. The ligation will be near the saphenous opening and above the last important tributary of the vein. [A.B.C.]

4.—**Empyema of the Accessory Sinuses of the Nose.**—Woodward describes the anatomic relationship of the various accessory sinuses, *i. e.*, the maxillary, sphenoidal, ethmoidal, and frontal. Inflammation of the accessory sinuses may be either primary or secondary, acute or chronic. The greater number of cases are secondary to some intranasal condition. Many acute cases terminate in complete resolution, even though the inflammation may have been pyogenic in character from the outset. Others become chronic; and it is probable that the greater number of chronic pyogenic inflammations in these regions begin as an acute infection. The exanthemas, diphtheria, acute coryza, trauma, and especially influenza, are the causative factors of nearly all cases. Exception should be made of pyogenic inflammation in the maxillary antrum, for it is commonly due to extensive caries of the teeth. [A.B.C.]

5.—**New Sputum Slide.**—By the usual method the examiner's fingers are likely to be smeared. To overcome this Arneill has devised the following: From a thin window pane slides 5 inches by 1½ inches are cut; one end is slowly heated in the blast and bent to furnish a handle, and allowed to cool slowly. By means of a file lubricated with sweet oil the sharp edges are rounded off. This handle prevents contact with the sputum and the slide can be used in scraping the latter from the plate. [H.M.]

### Philadelphia Medical Journal.

February 21, 1903. [Vol. XI, No. 8.]

1. Tropical Diseases: Fifth Lecture in a Course on Tropical Diseases. Captain CHARLES F. KREFFER.
2. The Toxemia of Pregnancy. WILLIAM H. WELLS.
3. Uterine Carcinoma: Its Treatment by the Combined Use of the Finzen Light and the Röntgen Ray. GEORGE G. HOPKINS.
4. Report of a Case of Transverse Myelitis in a Newborn Infant. ALBX-ANDER HEON DAVISSON and D. J. MCCARTHY.
5. Retinal Hemorrhages: An Aid to the Early Recognition of General Arterial Degeneration. HENRY C. HADEN.

**1.—Abscess of the Liver.**—Kieffer discusses the most important complication or sequel of tropical dysentery, suppurative hepatitis. Abscess of the liver is more apt to occur in the tropics, owing to the more common distribution of the chief etiologic factor, the ameba coli; and the predisposition to suppurations arising from the very common occurrence of passive congestion of the liver in the white settlers in tropical climates. Traumatic, pyemic and tropical abscess are detailed. Malaria, chill and exposure are important factors in the etiology of tropical abscess, but the greatest of all is the abuse of alcohol; 20% to 25% of the cases of severe amebic dysenteries eventuate in abscess of the liver; 85% of all tropical abscesses are due to infection from the ameba coli. Rarely severe hepatitis, running a rapid course to suppuration, begins almost with the first symptoms of dysentery, and again abscess may not take place until one or two years subsequent to the dysentery. In 90% of the cases of single abscess when the patients were operated upon early recovery ensued. In cases of spontaneous rupture into the most favored location, the colon, 50% recover. Kieffer has done three consecutive operations for three apparently distinct abscesses in one case, with ultimate recovery. The diagnosis is quite difficult unless the abscess is large and the signs so prominent as to be unmistakable. The common error of diagnosis is to call these cases malaria. [F.C.H.]

**3.—Uterine Carcinoma.**—Hopkins believes that we have in the combined use of decomposed light and the Röntgen rays a method of treatment that promises more for this class of sufferers than any operative, local or constitutional measure yet devised. This method is the combined use of the Finsen light and Röntgen rays, the principal dependence being the Finsen radiance. The penetrating power of the Röntgen rays speaks for great caution in its use in this region, especially in recurrent cases in which hysterectomy has been done. An hour's exposure to the Finsen light and from five to eight minutes' exposure to the Röntgen rays is a good proportion. This proportion has given good results and as yet has not produced any undesirable symptoms or done any injury. [F.C.H.]

**4.—Transverse Myelitis in a Newborn Infant.**—Davisson and McCarthy detail the history and postmortem findings of a case of transverse myelitis in a newborn infant. It was at first thought that the paralysis was due to a defective development of the dorsal portion of the spinal cord; but a more complete examination leaves little doubt that the condition was the result of some assault to the nervous system after complete cord formation. The caliber of the cord, as evidenced by the pial tube in this area, suggests that the spinal cord had filled this tube in the normal process of development and as a result of a hemorrhagic process, softening of the cord and resorption of degenerated cord substance, there was a loss of contour of the cord, giving the flattened (dorsal) cord. [F.C.H.]

**5.—Retinal Hemorrhages.**—Haden concludes that retinal hemorrhages associated with high arterial tension, and accompanied by transitory albuminuria, are significant of beginning widespread arterial degeneration; that in those cases of so called physiologic or transitory albuminuria occurring in active, healthy young business men or students, in those who are working under forced pressure, ophthalmoscopic examination should be made for retinal hemorrhages; when retinal hemorrhages occur without albuminuria, the patient should be kept under observation, the urine to be examined from time to time and the quantity passed noted. In case of finding these conditions, it is our duty to warn the patient of his condition and, as Osler says, "gain his intelligent cooperation," and preserve his life and usefulness. Two cases are detailed. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN      A. O. J. KELLY

### EDITORIAL COMMENT

**Chronic Acetanilid Poisoning With Marked Alterations in the Blood.**—An instructive instance illustrating the value of blood examinations is afforded by a case reported by Stengel and White.<sup>1</sup>

A woman 25 years of age had for some years been suffering with insomnia and dental neuralgia, and had been taking a variety of drugs. When first seen, she had intense cyanosis, without any dyspnea or coldness of the surface, and marked acne of the face. The cardiac area was enlarged and there was a systolic murmur audible over the entire precordia. The absence of dyspnea, coldness, and edema aroused the suspicion that the patient was suffering with some form of blood poisoning or with an abnormal commingling of venous and arterial blood. The first surmise was rendered almost a certainty by the blood examination, which revealed a marked reduction in red corpuscles and an increase in the leukocytes. Stain preparations showed a large number (over 32,000) of nucleated red corpuscles per cmin. Further investigation of the history revealed the fact that the cyanosis had been present for over five years, different physicians having made different diagnoses; among others, a valvular heart lesion, a perforated intraventricular septum, and a mediastinal tumor had been diagnosed. On one occasion, while the patient was in the University Hospital, a box of compound acetanilid capsules (containing acetanilid, 3 grains; caffeine,  $\frac{1}{2}$  a grain; and sodium bicarbonate, 2 $\frac{1}{2}$  grains) was discovered in a package sent to her by express. She denied having taken this medicine, but she also denied having received it. The nurses recalled that similar packages had been received before. Subsequently the patient confessed that she had taken acetanilid tablets almost continuously since her entrance into the hospital, sometimes as many as 15 or 20 a day. She further admitted that she had taken large quantities of the drug during the last four or five years. The acetanilid was withdrawn, and rapid improvement ensued. The heart dulness diminished, the cyanosis disappeared, and the sounds became entirely free from any murmur.

The effects of acetanilid, phenacetin, nitrobenzol, and other poisons of this type, as described in the reported cases, are cyanosis, profound depression or collapse, and unconsciousness; but, as a rule, dyspnea and subjective symptoms have been slight or wanting. In the acute cases, the blood changes have not been marked; but in subacute or chronic poisoning, striking and characteristic alterations in the blood have been discovered. These consist in morphologic changes in the red corpuscles, and in the appearance of nucleated cells in large numbers. Many of the erythrocytes show a granular change, which causes the hemoglobin to separate from the stroma and to collect in a denser mass or masses, the rest of the corpuscles becoming paler than normal. There is also a great variation in the size of the different red cells. The blood-plaques and the leukocytes are usually increased in number. An interesting feature in Stengel and White's case is the disappearance of all indications of cardiac disease. This is only another illustration of the indisputable fact that even the most marked signs of valvular disease need not be due to endocarditis, but may be produced by functional conditions. This in the case under discussion was probably a dilation of the heart. The widespread use of proprietary headache powders and tablets, many of which contain acetanilid or its congeners, renders the occurrence of poisoning in acute as well as chronic forms an ever-present possibility, and physicians should remember the revelatory powers of a blood examination, particularly when cyanosis is the most striking morbid feature.

### REVIEW OF LITERATURE

**Fatal Gastric Hemorrhage.**—Tiegel<sup>1</sup> reports three cases of fatal hemorrhage from the stomach; two of them were in patients previously apparently well, the third had been suffering with chlorosis and mitral insufficiency for some years. In all of them the hemorrhages were sudden and unexpected, and death occurred within a few days of their onset, due to recurrence of hemorrhage and collapse. The interesting point in all three cases lies in the fact that the seat of the profuse bleeding was found in very slight alterations of the gastric mucous membrane, which were discovered only after prolonged search, and before certainty could be claimed for them they had to be verified by microscopic diagnosis. In two cases the ulcers were but three mm. in diameter, in the third case it was the size of a lentil, but in every case an eroded bloodvessel was found within the ulcerated portion. These cases teach the fact that the diagnosis of "capillary hemorrhage" and "gastric hem-

<sup>1</sup> University of Pennsylvania Medical Bulletin, February, 1903.

<sup>1</sup> Münchener medicinische Wochenschrift, November 25, 1902.

orrhage without pathologic basis" can only be made after the most searching macroscopic and microscopic examination has failed to reveal the site of the hemorrhage. [E.L.]

**Esophageal Carcinoma Simulating the Clinical Picture of Aortic Aneurysm.**—Kuckein<sup>1</sup> gives in detail the case histories of two patients, who at autopsy were found to be afflicted with carcinoma of the esophagus, but who during life were believed to be suffering with aortic aneurysm. There were many symptoms justifying this diagnosis; the chief among them were radiating, paroxysmally occurring pains, coming on without apparent cause, and dyspnea due to compression of the trachea. Both conditions were present in both cases. The first case presented complete left-sided recurrent paralysis. Difficulty in swallowing was completely absent in the first case, due to the unilateral position of the carcinoma; in the second patient it improved in the late stages of the disease, probably due to increase of the lumen from ulceration. The first case presented slight pulsation of the chest wall. In both cases an expansile shadow was seen in the skiagraph, which later was found to be due to the pulsation of the aorta against the solid growths. One patient had bloody expectoration. The cachexia was not marked in either patient. The diagnosis was based upon the general combination of symptoms, which certainly leaned much more toward aneurysm of the arch of the aorta than carcinoma of the esophagus. [E.L.]

**Sanitary Legislation as Applied to Tuberculosis.**—Taylor<sup>2</sup> states that sanitary measures must not be harsh in character. Patients must be enrolled in a university extension course against tuberculosis. Notification is absolutely necessary. The orphans of tuberculous parents, specially those found in tenements, are fit subjects for State care. If removed to a hospital and found free from tuberculosis they should be transferred to a colony in a healthy rural district. [A.G.E.]

**Examinations Concerning the Amount of Albumin Digestion in the Stomach of Man With and Without Simultaneous Administration of Carbohydrates.**—To determine what percentage of the albumins is digested by the stomach of healthy adults, Heinrich<sup>3</sup> gave his subjects 200 cc. of strong bouillon on an empty stomach; this was removed an hour later and after centrifugating a portion of it, the nitrogen of both liquid and solid portions was determined after Kjeldahl's method. He performed in all eight experiments, and found that when meat alone was given one-third of the albumens was dissolved during the first hour. This took place without liberation of free hydrochloric acid. When carbohydrates were added to the proteid diet, proteolysis was facilitated, the increase averaging 10%. [E.L.]

**The Differentiation of Diphtheria Bacilli from Pseudodiphtheria Bacilli by Agglutination.**—Schwoner<sup>4</sup> reports his results in the following conclusions: A serum obtained by immunization with diphtheria bacilli agglutinated diphtheria bacilli in great dilution (1:10,000). It agglutinated pseudodiphtheria bacilli and other bacteria in dilution corresponding to normal horse serum (1:5—1:10). The two varieties of bacilli are therefore easily differentiated by means of this serum. Serum obtained by immunization with pseudodiphtheria bacilli agglutinated only bacteria from the same culture. There are many varieties of the pseudodiphtheria bacilli. [E.L.]

**Asepsis of the Clinical Thermometer.**—Devine<sup>5</sup> calls attention to the danger of carrying germs from one patient to another by means of the clinical thermometer. In a considerable research he has found little on this subject in the textbooks. In private practice each patient should have his own separate thermometer or the physician should carry his thermometer in a case containing a solution of mercuric chlorid, 1:5,000 to 1:2,000, in alcohol. In hospital practice the thermometers should be kept with rigid care in an antiseptic solution when not in use. [A.B.C.]

**Typhoid Bacilli in Diseases of the Respiratory System During Typhoid Fever, and Their Appearance in the Sputum.**—Glaser<sup>6</sup> states that although typhoid bacilli

have been found a number of times in the sputum of pneumonic patients, he does not consider them the etiologic factors in the disease. Pneumococci are also present in all instances, and usually in much larger numbers than typhoid bacilli. He reports a case presenting the symptoms of both diseases in a typical manner, and in which the diagnosis was confirmed by autopsy. Pneumococci were present in the consolidated lung in enormous numbers, typhoid bacilli as isolated rods; the latter's presence in the lung is evidently accidental and a part of the general blood infection. In another case, during the fourth week pneumonia developed; the sputum contained large numbers of typhoid bacilli. From a pleural effusion which followed, the bacilli were also isolated. In this case was the pneumonia due to the pneumococci and not to the typhoid bacilli? The hemorrhagic character of the sputum serves to differentiate the pneumonia of typhoid fever from ordinary pneumonia, but a hemorrhagic sputum during typhoid fever does not necessarily indicate pneumonia; hemorrhagic infarction is also quite common, and may present the same kind of sputum. He relates in detail a case to show the difficulty of differentiating between pneumonia and hemorrhagic infarction. [E.L.]

**On the Protective Action of the Omentum.**—De Renzi<sup>1</sup> communicates the result of experiments which he has practised together with M. Boeri, and which prove that the omentum plays an important role in maintaining the activity of the circulation of the abdominal organs, particularly that of the spleen. [C.S.D.]

**Tuberculosis of the Thyroid Gland.**—But few such cases have been reported, and although some of them were claimed to be primary this is difficult to prove; the only one which came to autopsy had in addition to a large thyroid focus isolated miliary nodules of the lungs. Clairmont<sup>2</sup> reports the case of a child of 2 years, otherwise healthy, which developed in the course of three weeks a quickly growing mass in the region of the thyroid gland. On account of intense dyspnea an operation was performed, and a tumor removed containing in its interior cheesy foci. The microscope showed it to be tuberculous. Six months later, on account of a fistula and a recurrence, a second operation had to be performed. This mass also showed tuberculous granulation tissue. As since then the child has apparently completely recovered and no other tuberculous focus is discoverable, the author considers this an instance of primary disease. The diagnosis is impossible without the microscope; the treatment is operative, and on account of the dyspnea must usually be performed very quickly. [E.L.]

**Antipyresis in Children.**—Saunders<sup>3</sup> states that the urgency of antipyresis depends on concomitant symptoms and not on the height of the mercury alone, it being very questionable if even moderate temperatures in comparatively mild diseases should be disregarded if there is evidence of suffering. The combined method of drugs preceded by hydrotherapeutic measures is not sufficiently employed. The coal-tar products may be used with safety in many cases, as early in scarlet fever, influenza, etc. The combination of phenacetin and camphor is found advantageous. Attention is called to the value of pilocarpin in diphtheria and scarlet fever. In pneumonia veratrum viride is the safest antipyretic, those who decry it being the ones who have used it least. Veratrum is also one of the best remedies for the relief of headache in the first week of typhoid fever. [A.G.E.]

**Treatment of Diabetes.**—Eichhorst<sup>4</sup> places no confidence in the medicinal treatment of diabetes, expecting results only from the use of a suitable diet. He has not been successful with salol, antipyrin, or other drugs, and has found the improvement following a season at Carlsbad or Neuenahr, not to be due to the water, but rather to the strict diet prescribed in these places. He discusses the diet necessary for diabetics, dwelling on the substitution of saccharin or dulcin for sugar, of graham bread for ordinary bread, and the fact that fatty substances must make up the caloric value of a diabetic diet. He prefers the slow withdrawal of carbohydrates and

<sup>3</sup> Pediatrics, January, 1903.

<sup>4</sup> Therapeutische Monatshefte, 1902, Vol. xvi, p. 443.

sugar, and their substitution with animal diet; he warns against their complete withdrawal in cases in which a considerable loss in weight results. As a beverage he prescribes pure spring water, to which small quantities of lactic or citric acid may be added, or alkaline and carbonated mineral waters. Alcoholic liquids of all kinds, especially those containing much sugar and carbohydrates, are to be avoided. He uses milk and cream in spite of their milksugar. Coffee and tea are to be used only in diluted form. The scale is a very important factor in the treatment of diabetics; by its means the daily amount of food, as well as the weight of the patient may be carefully noted. The urine must act as control, especially when bread is again given to the patient; 25 grams (400 grains) of bread should be started with, and this increased 10 grams (160 grains) each day, until a daily quantity of 100 grams (3½ ounces) is reached. As soon as sugar reappears, or symptoms of itching, neuralgia, cramps in calves, etc., show themselves, strict diet must again be taken up. [E.L.]

**Care of Human Glanders.**—Gabrielides and Remlinger<sup>1</sup> report a death from lymphangitis and multiple abscesses, which proved upon examination to have been the result of infection with the bacillus of glanders. The studies which they made of the blood indicate that the agglutination reaction is possibly applicable to the diagnosis of glanders in human beings. [C.S.D.]

**Syphilitic Tumor of the Stomach.**—Einhorn<sup>2</sup> reports the case of a man of 42, who for seven years had complained of digestive disturbances. He suddenly began to complain of gastric pain, which gradually became worse. Abdominal examination shows an irregular tumor of the epigastrium, apparently connected with the stomach. Test-meal gave increased amount of free hydrochloric acid. On account of this, the long duration of the illness, the slight emaciation, the well preserved motility and a history of syphilis, he made a diagnosis of gumma and placed the man upon mixed treatment. After six weeks the patient had entirely recovered and the mass had disappeared. [E.L.]

**Variola and Varicella.**—Swoboda<sup>3</sup> says there exists a grave variety of varicella—varicella varioliformis. He concludes that in varicella, as in variola, there are all forms and gradations, so that in a sporadic case, or at the beginning of a smallpox epidemic, a differential diagnosis may be impossible. The dualists, therefore, are wrong in stating that the two diseases may be separated on morphologic and clinical grounds. Etiology only remains true to us in case the originally infecting case can be traced. The fact that a varioliform varicella exists is also of theoretic importance; it does away with the objection to vaccination, which has been based on the claim that an individual can contract variola after having been successfully vaccinated, or having had variola, in as much as we have to do in most of such cases with the varioliform variety of varicella. He reports a number of cases in support of his theory. [E.L.]

## GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### REVIEW OF LITERATURE

**Modifications and Improvements in Operations on the Biliary Passages.**—Mayo Robson<sup>4</sup> says no medicament has yet been discovered which will dissolve gallstones, though general medical treatment may give relief in catarrh of the bile passages associated with cholelithiasis. Cholecystotomy is generally recognized as the operation aimed at in the treatment of affections of the gallbladder and bile ducts, but it is impossible to say before the operation what particular plan the operator will have to adopt on reaching the seat of the trouble. Many operations are, therefore, in a sense exploratory. With jaundiced patients the author now employs heroic doses of calcium chlorid, 2 gm. (30 gr.) doses by the mouth, or 4 gm. (60 gr.) doses by the rectum, three times a day for two or three

days preceding and following the operation. His incision was formerly vertical through the linea semilunaris. He now makes an incision through the middle of and parallel to the right rectus, separating its fibers and incising the posterior sheath with the peritoneum. If the gallbladder is distended and there is no jaundice, a simple incision of three inches is sufficient, but when necessary to explore the hepatic, common, or the deeper parts of the cystic duct, he prolongs the incision upward in the interval between the ensiform and the right costal margin as high as possible. It will be found by lifting the lower border of the liver in bulk the whole of the gallbladder, the cystic and common ducts are brought near to the surface, and enough traction can be made on the gallbladder by an assistant to hold the liver in this position while the operator proceeds with such manipulation of the passages as is requisite. By this incision and the lifting up of the liver border, instead of the gallbladder and cystic duct making a considerable angle with the common duct, an almost straight passage is formed from the fundus of the gallbladder to the entrance of the bile duct into the duodenum, and the whole is under the eye of the operator. He considers this incision a vast improvement over any other he has used. As a rule cholecystotomy is performed and a tubular drain is inserted, the tube being brought out through the dressing and its distal end passed into a sterile bottle beside the patient, which serves as a receptacle for excessive biliary discharge and prevents oft-repeated change of dressings. Cholecystectomy is preferred under certain favorable conditions, and essentially where the gallbladder is septic and its presence is a menace to the life of the patient. The author states that in the common duct cholelithiasis, especially where there is a small floating gallstone, it is common to find the head of the pancreas enlarged and hard, the result of chronic pancreatitis. This strongly simulates cancer, but subsides on removal of the stone. The chief lessons he wishes to teach are that we should operate early, before serious complications have ensued, and in operating we should do thorough, expeditious and careful work. [A.B.C.]

**The Packing of Bone Cavities.**—A. von Mosetig-Moorhof<sup>1</sup> presented a communication at the December, 1902, meeting of the Imperial-Royal Society of Vienna on the results of his experience in packing bone, in cases of necrosis or of osseous suppuration. The mixture used by the speaker for replacing the lost bone is composed of 60 parts of powdered iodoform, 40 parts of spermaceti and 4 parts of oil of sesamum. This mixture is sterilized at 100° C. for one hour and a quarter, and cooled with stirring. It becomes liquid at from 40° to 45° C. In practice, the diseased portion of the bone having been thoroughly removed after detachment from the periosteum, the cavity formed is washed with a 1% formalin solution and dried with sterilized gauze and with jets of hot air. The cavity is then filled with the above mixture heated to 50° C. which solidifies in the course of a few minutes. A number of cases were exhibited in which this proceeding has been followed with entire success and perfect cure. A. Fraenkel, in commenting on the above communication, remarked that the essential element is the total removal of diseased tissue and perfect asepsis. He has employed with success thoroughly sterilized silicious earth. [C.S.D.]

**Review of 720 Gallstone Laparotomies with Consideration of 90 Cases of Drainage of the Hepatic Duct.**—Kehr<sup>2</sup> reports the results of 720 laparotomies for gallstones which he has performed during a period of 12 years. He states that stones in the biliary passages do not produce pain until infection is added, when the resulting exudate dislodges the stone into other parts of the ducts, producing the symptoms of biliary colic. Jaundice is present in but 10% to 20% of cases when stones are lodged in the gallbladder or cystic duct; in 66% when they are lodged in the common duct. Enlargement of the liver is rare, and enlargement of the gallbladder disappears as soon as the chronic stage of the disease is reached. Spontaneous escape of a stone into the intestinal tract gives rise to a fistula, which often acts as a guide to an ascending cholangitis. A cure through medical measures is never

<sup>1</sup> La Semaine Médicale, December 17, 1902.

<sup>2</sup> Münchener medicinische Wochenschrift, October 14, 21 and 28, 1902.

effected. He advises operation in cases of cholecystitis, not helped by rest, in cases in which the stones do not leave the cystic or the common ducts, in chronic occlusion of the duct, and in acute purulent cholecystitis, for operation is less dangerous than expectant treatment. Usually he only drains the abscess, leaving the removal of stones to a secondary operation. He warns against waiting too long for operation. The operations performed most frequently by him are cystostomy and cystectomy. Of late he performs the latter especially often. The two comprise 542 operations in his series of 720. Numerous operations had to be performed for complications—63 gastroenterostomies, 30 closures of fistulas between gallbladder and intestine, 25 pyloroplasties, etc. Pancreatic palpation has shown the pancreas diseased in 34% of cases. He lost but 19 patients, or 31% of 535 pure gallstone laparotomies, combining with these 185 others in which a combination of operations was performed at the same time. An advantage of cystectomy, especially when combined with drainage of the hepatic duct, is that the stones are so thoroughly removed that there is little chance of a recurrence. [E.L.]

**Cholecystectomy.**—Moynihan<sup>1</sup> states that cholecystectomy was first performed July 15, 1882, by Langenbuch. It is indicated in injuries of the gallbladder, rupture, stab, or bullet wounds; in gangrene of the gallbladder; phlegmonous cholecystitis; membranous cholecystitis; chronic cystitis with dense thickening of the walls of the bladder and cystic duct; in chronic cholecystitis when the gallbladder is shriveled, puckered, and universally adherent; in hydrops or empyema due to blocking of the cystic duct by stone, stricture-growth, or in inflammatory products; in cases of fistula between the gallbladder or cystic duct on the one hand and the stomach, duodenum or colon on the other; in multiple lacerations of the gallbladder or cystic duct; in primary carcinoma of the gallbladder. The operation is described at length. He recites six cases in which the operation was performed, each being an example of one of the above enumerated conditions which warrant this operation. [A.B.C.]

**Complete Destruction of the Third Left Frontal Convolution: With Recovery.**—Berthomier<sup>2</sup> (Moulins) reports the case of a man of 66, who in June, 1900, suffered from an extensive fracture of the cranium together with almost complete destruction of the frontal lobe. Notwithstanding the extent and gravity of the lesions the patient recovered. The man became lefthanded, and notwithstanding the destruction of the convolution of Broca, he presented no trouble as to speech. [C.S.D.]

**How Shall We Anesthetize?**—Witzel<sup>3</sup> prefers ether to chloroform, since the latter is a depressant to the heart, and ether is a stimulant. Of the various methods in use for producing narcosis, he recommends the drop method. It requires more practice than the other methods, but is exceedingly satisfactory. By this means the patient inhales no more ether than is absolutely necessary, and the amount of ether used is kept at a minimum. Two individuals are required for the etherization, the physician holding the pulse in one hand and etherizing with the other, his assistant holding the mask over the forcibly retracted head. A hypodermic of morphin given from 45 minutes to one hour before anesthesia will, in most cases, prevent the primary stage of excitation. To prevent complications of the respiratory tract, he thoroughly disinfects the mouth and the air passages before the anesthetic is begun. He places the patient with his head very low and his neck strongly retracted. This forced reclination prevents oral fluids from entering the air passages, and permits the throwing off of tracheal secretions. He ventilates the air passages after the operation by means of systematic respiratory movements. The author insists upon everything being done methodically, and therefore all preparations are made beforehand, and anything the etherizer may be in need of is placed close to his hand on a table. Nausea and vomiting are very rare occurrences after this method. He condemns the combination of morphin and hyoscin with the anesthetic. [E.L.]

**Surgical Treatment of Acute Osteomyelitis.**—In a boy

of 9, with a severe osteomyelitis of two weeks' duration, Cumston<sup>1</sup> resected the lower half of the tibia, leaving the periosteum intact. In nine weeks the tibia appeared to be perfectly solid. A plaster dressing was then applied and the patient allowed to go about on crutches. Seen nine months after operation the boy was found to be in perfect health, with a leg to all appearances normal and quite as strong as its fellow. Cumston says that amputation or disarticulation should be resorted to only exceptionally, where there is complete pathologic change in the bone accompanied by destruction of the periosteum and more or less complete necrotic change in the soft parts. Subperiosteal resection is especially indicated in childhood and adolescence, but in certain cases is successful in the adult. [A.G.E.]

**Hydatid Cyst of the Pleura.**—Ransom and Willis<sup>2</sup> report the case. The patient was a woman of 43. She had been in ill health for two years, her illness having begun with symptoms that suggested gastric ulcer. On examination of the chest it was found to be normal, except for an area of absolute dullness at the left apex in front, extending from the clavicle to the third intercostal space. She was put under treatment, and expectoration, which before had been rather profuse, ceased after a month. She was sent to the country and gained much in weight. After several months she again began spitting large quantities of phlegm, the area of dullness persisted. Nothing in the sputum indicated any of the common pulmonary diseases. Hydatid cyst was suspected. An incision was made four inches in length, the center of which corresponded with the second intercostal space in the midclavicular line. The pectoral and intercostal muscles were separated and the pleura exposed. An exploring needle was thrust into the dull area and clear fluid was withdrawn. The opening was enlarged and much fluid evacuated. The cavity was a hydatid cyst of the pleura with no apparent communication with the lung, the latter being displaced merely by pressure of the cyst. A drainage tube was inserted, and after a few days the entire cyst wall came away. It was as large as the human urinary bladder. The patient made a good recovery, though a later operation for the removal of the second and third ribs to permit collapse of the chest wall became necessary. [A.B.C.]

**Tracheotomy Followed by Direct Insufflation as a Treatment to Prevent Death in the Course of Chloroform Anesthesia.**—Thiery<sup>3</sup> holds that artificial respiration and rhythmic traction of the tongue is insufficient for successfully combating accidents following the use of chloroform. On the contrary he finds that tracheotomy followed by direct insufflation gives excellent results in cases of apparent death. [C.S.D.]

**Cholecystotomy for Stone in the Common Duct.**—Ross<sup>4</sup> records the case. The patient was a woman of 57 years who had had attacks of biliary colic since 40 years of age, after the birth of her last child. The attacks occurred irregularly until four years ago. They then became more frequent, and during the past 12 months they had been so severe that life was considered in danger and even at her advanced age operation justified. The operation was performed under chloroform anesthesia, the gallbladder was found distended with bile, which was withdrawn by means of a cannula, and the viscus opened. A single stone which weighed over two drams was found in the common duct and removed. Nothing further being found the wound was closed with drainage, and the patient made an uninterrupted recovery. [A.B.C.]

**Diagnosis by Means of the Cystoscope.**—By means of the cystoscope Halban<sup>5</sup> diagnosed a renal calculus which had come from the right kidney; the corresponding ureteral orifice was edematous, lacerated and eroded. After some days the orifice was almost normal. In another patient he saw a diverticulum of the bladder wall entering into the composition of an inguinal hernia. This diverticulum could be seen to disappear by external pressure. In a third case following gonorrhoeal urethritis a mass developed in the floor of the bladder near the vesical orifice. It closed off the urethra making catheterization necessary. The cystoscope made the diagnosis

and suggested the treatment. In a fourth case coils of intestine could be seen through the posterior wall of the bladder. At each peristaltic wave the bladder wall could be seen to move with the intestinal loop. A diagnosis of adhesions to vesical peritoneum was made. [E.L.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Menstrual Epilepsy.**—The case reported by Fry<sup>1</sup> was that of a young married woman who had not been pregnant, and who had epileptic attacks at each menstrual period. At first the attack preceded each flow, but later occurred about the ninth day after its cessation. The left ovary was enlarged, tender, and adherent. It was removed, but the epilepsy persisted. Four months later the remaining appendages and the entire uterus was removed. Four light convulsions occurred during the two following months, but none have occurred now for 14 months. Nervous twitchings have also disappeared, and the patient is in the enjoyment of full health. [A.G.E.]

**The First Stage of Labor in Relation to Uterine Rupture.**—E. H. Tweedy<sup>2</sup> defines the beginning of the first stage of labor as the moment when the contraction of the uterine body is accompanied by a relaxation of the circular fibers in the cervix. Uterine contractions alone, the presence of blood-stained mucus, or a patulous canal are frequently present before labor begins. Uterine polarity results from an overstretched condition of the nerves of the lower segment causing paresis of the circular fibers. The cervix being fully dilated does not necessarily imply a sufficiently open os to permit the passage of the fetus. What is usually described as rigidity of the os is simply expansion to its utmost limit, the first stage of labor necessarily ending with a tear. The anterior lip is not easily incarcerated between the pubes and descending fetus. Its elongation is due to the retraction of the posterior cervical lip and the consequent dragging upward of the os which cannot sufficiently dilate. Such an os will in primiparas almost certainly rupture and the laceration cannot be immediately sutured, not only on account of the edema of the anterior lip, but because the posterior lip is taken up and there is nothing to which to stretch it. In multiparas on account of deposition of fibrous tissue the os may neither dilate nor tear, the rupture occurring in the lower uterine segment and vaginal vault, being preceded by none of the usual premonitory symptoms. [H.M.]

**Endometritis.**—Herman Boldt<sup>3</sup> discusses at length endometritis. The local treatment giving the promptest relief from bleeding in cases of chronic endometritis is undoubtedly to be found in the judicious use of the curet. About 60% of the women are relieved from atypic bleeding for a variable time by cureting. The general condition of the patient in all instances requires careful supervision. Good food, proper exercise, baths, and douches are all important adjuvants. After the endometritis has become chronic, it should be treated with intrauterine applications of one of the usual remedies. A 10% solution of carbolic acid is to be preferred. Frequent intrauterine irrigations with large quantities of a mild antiseptic solution will render good results. [F.C.H.]

**Disadvantages of Ventrofixation.**—Gradenwitz,<sup>4</sup> in discussing this subject, makes this summary of his conclusions: Ventrofixation by attachment to ligament stumps after removal of adnexal tumors is unjustifiable. Although retroflexion or inclination of uterus exists, still ventrofixation remains superfluous since the stumps are not ligated together but fastened with separate ligatures. Ventrofixation by attachment to the base of the ligaments without operation on the adnexa is not advisable because it promises the danger of forming pockets, and better results will be obtained through the Alexander-Adams operation. Ventrofixation by attachment to the anterior wall of the fundus is the most certain method of heal-

ing retroflexion but is not advisable, because of the danger of metritis, abdominal hernia, and disturbance of pregnancy and labor. In the stretching of the ligaments there comes danger of ileus. The Alexander-Adams operation may serve as a substitute after a previous posterior colpotomy; and occasionally after the climacteric, vaginofixation. He adds we must thank Kreutzmann, since as an eloquent monitor he opened the battle against ventrofixation. [W.K.]

**Treatment of Placenta Prævia.**—Fry<sup>1</sup> reports four cases, supplementing a series of 14 previously reported. The mother has been saved in every instance. Bipolar version and slow extraction were employed in 11 of the 18 cases. There is no argument for cesarean section in view of these results. Fry makes it a rule to examine under anesthesia every patient who bleeds during pregnancy. The uterus is emptied as soon as placenta prævia is recognized. When version by any method has been done, the secret of success is to deliver very slowly. Haste is not necessary, as the plugging of the cervical canal by the child prevents hemorrhage. [A.G.E.]

**The Control of Hemorrhage in the Removal of Pelvic Tumors.**—Herman Pearce<sup>2</sup> believes that the best way to control hemorrhage in the removal of pelvic tumors in the female is to search out and control the vessels that are the source of the hemorrhage as early as may be in the operation. When the tumor is parovarian and its growth takes it between the layers of the broad ligaments, in all broad ligament cysts, in intraligamentous fibroids of large blood supply and intimate connection with the surrounding tissues, and in extrauterine pregnancy with intraligamentous rupture, it is better to tie off the superficial blood supply at all points along the pelvic side, and then instead of tying again on the uterine side go to the healthy side including the uterus and healthy adnexa in the occlusion, and do a panhysterectomy from the opposite (healthy) side, coming upon the deep blood supply of the growth from below and behind. The electrothermo clamp is a valuable instrument. Ligatures is the best method for controlling bleeding vessels. Suitably prepared chromicized catgut is preferred to silk or any of the other ligature materials. [F.C.H.]

**Primary Abdominal Pregnancy in an Angle of the Omentum.**—Witthauer<sup>3</sup> reports a case of extrauterine pregnancy, in which an angle of the omentum appears to have been the primary site of the pregnancy. When the abdomen was opened an ovarian cyst about the size of a hen's egg, with the intact and unchanged right tube, was removed. The left adnexa was normal and the uterus not much enlarged. The cause of the hemorrhage was found in a hematoma situated at an angle in the right side of the pelvis. This was removed with the attached portion of the omentum, and when subjected to examination proved to be an extrauterine pregnancy. As there was neither in the tube removed nor elsewhere any signs of any previous connection with the ovum, the writer is convinced that a wandering of the ovum from the left ovary to this point in the pelvis had taken place and that this was a clear case of primary abdominal pregnancy in an angle of the omentum. He believes that such cases occur more frequently than hitherto supposed and are the true cause of unexplained cases of retro-uterine hematocele and hemorrhage. [W.K.]

**The Röntgen Ray in Gynecology.**—Eden V. Delphey<sup>4</sup> enumerates the various conditions under which the Röntgen ray may be used in and above the pelvis; but the main use of the Röntgen ray in gynecology is in the treatment of malignant neoplasms. Whenever the diagnosis is made sufficiently early, the tumor and often all the pelvic reproductive organs should be removed by surgical means so as to get entirely beyond the malignant growth and prevent recurrence. When this can be done the protuberant portion, if of the cervix, should be removed, and the rest subjected to the influence of the Röntgen ray. Quite a number of cases of carcinomas have been very much improved and epitheliomas have apparently been entirely cured by this means. As certain death is otherwise the only outlook, the patient should be given the benefit of the chance. [F.C.H.]

**TREATMENT**

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

**REVIEW OF LITERATURE**

**Treatment of Phosphaturia by Calcium Sulfate.**—

Etterlen<sup>1</sup> has obtained good results from the administration of chemically pure calcium sulfate in phosphaturia. It is given in cachets, in the dose of from 1.5 to 2 grams (22 to 30 grains) daily, mixed with an equal quantity of magnesium carbonate. If desirable, Contrexéville water may be substituted, as it contains 1.22 grams (19 grains) of calcium sulfate to each liter (quart). This treatment produced marked improvement in over 30 patients having phosphaturia. [L.F.A.]

**The Therapeutic Value of Bismutose.**—Bismutose is an odorless, tasteless, fine yellowish-white powder, containing 22% metallic bismuth. It is but slightly soluble, thus diminishing its toxicity, increasing its astringency and emollient properties, as it can act over greater surfaces. It is useful in all inflammations of the stomach and intestines, in hyperacidity, dyspepsia, and probably gastric ulcers. Starck<sup>2</sup> has employed it in 41 different cases with good success, his results being quicker than in other bismuth salts. It may be administered by rectum in cases of obstinate vomiting. The dose for a child varies from 6 to 10 grams (90 to 150 grs.) daily. [E.L.]

**Medicinal Treatment of Acute Nonsuppurative Otitis Media.**—Mahu<sup>3</sup> directs that children suffering from acute nonsuppurative otitis media be kept indoors and that they be given a purgative. Every two hours the temporal and mastoid region and the ear should be covered with a compress dipped in a solution of sodium bicarbonate, 60 parts to the 1,000, as hot as can be borne by the back of the hand. The whole may then be covered by a piece of oiled silk and held in place by a bandage. Before applying the compress, a few drops of the above solution may be dropped into the auditory canal, or the following solution may be substituted:

Cocain hydrochlorate . . . . .	0.1 gram (1½ grains)
Resorcin . . . . .	0.75 gram (12 grains)
Sterilized neutral glycerin . . . . .	10 cc. (2½ drams)

Three or four drops of this solution may be instilled at every second dressing. Three times a day the child should be placed on a bed with his head low and a few drops of the following placed in each nostril by means of a dropper:

Menthol . . . . .	0.6 gram (9 grains)
Sterilized oil of sweet almonds . . . . .	60 cc. (2 ounces)

The mouth and pharynx should be washed out every three hours with a quart of boiled water as hot as can be borne. This may be accomplished by means of a fountain syringe placed about two feet above the patient. At the end of two days, if the pain persists and the temperature is high, the ear should be examined and if the tympanum is red and bulging paracentesis should be performed.

**Santonin in the Treatment of the Lightning Pains of Locomotor Ataxia.**—Combemale and Chaber<sup>4</sup> have confirmed the findings of Wegro relative to the value of santonin in the treatment of the pains of locomotor ataxia. In the dose of 0.2 gram (3 grains) daily it rapidly calms these pains and prevents the occurrence of a series of attacks. The same result is obtained from smaller doses, 0.06 to 0.13 gram (1 to 2 grains) daily, but they must be continued for several days, and gastric crises may occur in the meantime. The subcutaneous injection of 0.04 gram (⅔ of a grain) of mercuric benzoate has also been used successfully in controlling the pains of this disease. [L.F.A.]

**Treatment of Laryngeal Tuberculosis.**—Two symptoms especially torment the patient with laryngeal tuberculosis:<sup>5</sup> hoarseness and dysphagia. Hoarseness may be combated by the application of hot compresses to the neck. These should be changed every half hour during the day, and at night should be replaced by a cotton bandage. The patient may take hot drinks, to which small doses of dionin may be added if the

cough is troublesome. The air of the room may be kept moist by steam impregnated with compound tincture of benzoin. Sprays containing menthol, 0.5 gram to 30 cc. (7½ grains to the ounce), or cocain hydrochlorate, 0.1 gram to 30 cc. (1½ grains to the ounce) may be used with advantage. The dysphagia may be combated by applications of the following collutory a short time before each meal:

Carbolic acid . . . . .	5.0 grams (75 grains)
Cocain hydrochlorate . . . . .	10.0 grams (2½ drams)
Glycerin . . . . .	60.0 grams (2 ounces)
Cherry-laurel water . . . . .	40.0 grams (10 drams)
Not to be taken internally. [L.F.A.]	

[This advice is reproduced but not commended. As a rule hot moist inhalations aggravate laryngeal tuberculosis. For local application orthoform, suprarenal extract, guaiacol, menthol, and iodoform in various combinations are generally superior to cocain. Anesthesin, too, promises well, but in my hands has thus far been disappointing. s.s.c.]

**A Local Application in Whoopingcough.**—Guida<sup>1</sup> recommends painting the pharynx with the following solution of carbolic acid in whoopingcough:

Crystallized carbolic acid . . . . .	1 gram (15 grains)
Solution of cocain hydrochlorate 2% . . . . .	5 cc. (80 minims)
Glycerin . . . . .	15 cc. (4 drams)

This should be applied during the attacks of coughing. [L.F.A.]

**External Antiseptics in the Treatment of Eczema.**—Gaucher<sup>2</sup> believes that in eczema the so-called antiseptics act less as antiseptics than as astringents. Among these are boric acid, calomel, salicylic acid, the naphthols, silver nitrate and corrosive sublimate. Boric acid and calomel are usually incorporated with vaselin in the proportion of 3 grams to 30 cc. (45 grains to the ounce) in the treatment of pustular eczema. Salicylic acid is equally useful. Gaucher considers fresh lard superior to either vaselin or lanolin as the base for this drug in the proportion of one part of salicylic acid to 25 parts of lard. Betanaphтол produces the same effects but is more irritating than salicylic acid and is usually employed in the proportion of one part to 50 of lard. Silver nitrate, recommended by Alibert, can be used in chronic eczema only over limited areas in 1% to 3% solutions. Corrosive sublimate is used as a lotion in the strength of 1 to 200, when the skin is indurated and thickened without ulceration. [L.F.A.]

**Treatment of Pericarditis with Effusion.**—Carrière<sup>3</sup> directs that (1) revulsion be practised; a blister may be applied and repeated if necessary; (2) diuresis should be favored by the administration of from 2 to 3 quarts of milk daily. If there is diarrhea 0.1 gram (1½ grains) of pancreatin may be added to each portion. If there is hyperacidity 1 gram (15 grains) of sodium bicarbonate may be given with each portion of milk. The patient should also be given:

Theobromin . . . . .	0.5 gram (7½ grains)
Powdered squill . . . . .	0.1 gram (1½ grains)
For one cachet.	

Four of these should be taken during the first and second days and eight during the third day. In children this combination must be used with caution and in much smaller dose; (3) the heart must be sustained; (4) if the condition is grave, with a tendency to collapse, the following potion should be given in 24 hours:

Ammonium acetate . . . . .	4 to 10 grams (1 to 2½ drams)
Tincture of canella . . . . .	4 grams (1 dram)
Todd's potion . . . . .	150 grams (5 ounces)

(5) the predominating symptoms should be combated; (6) paracentesis should be performed (a) if the effusion occurs rapidly, if the signs of compression appear; (b) if the pulse is small or irregular; (c) if there is a tendency to syncope or cyanosis; (d) if there is skodaic resonance posteriorly; (e) if there is edema of the wall; (f) if the fever is irregular or continues high, if the color is bluish. There are no counterindications save the existence of advanced tuberculosis. In performing paracentesis the instruments and seat of operation must be aseptic; the puncture must be made as low as possible in the area of dulness, preferably about ⅓ of an inch above the inferior limit and about 2 inches to the left of the sternum; the

needle should be forced directly backward, then parallel with the lower border of the heart, from right to left; evacuated very slowly and as completely as possible; the trocar withdrawn quickly and the part dressed antiseptically. If the liquid is purulent a nontoxic antiseptic liquid may be used. [L.F.A.]

**FORMULAS, ORIGINAL AND SELECTED.**

For fetid expectoration in chronic bronchitis or pulmonary tuberculosis:

- Ammonium ichthyolate . . . . . 3 gram (5 grs.)
- Eucalyptol . . . . . 2 drops
- Balsam of Peru . . . . . 3 gram (5 grs.)

Mix and encapsulate. Dose: One capsule three or four times daily. [s.s.c.]

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 20, 1903:

**SMALLPOX—UNITED STATES.**

**Changes in the Medical Corps of the U. S. Army for the week ended February 21, 1903:**

HARTUNG, HENRY, hospital steward, Fort Columbus, is transferred to Fort Myer, to relieve Hospital Steward Harry T. Brown. Steward Brown will proceed to Fort Greble to relieve Hospital Steward Henry B. Staley. Steward Staley will proceed to Fort Adams to relieve Hospital Steward Carl W. H. Westman. Steward Westman will proceed to Manila, P. I., for assignment to duty.

MILLER, ROBERT S., hospital steward, company of instruction, No. 2 hospital corps, Fort McDowell, is transferred to Frankford Arsenal, Philadelphia, Pa., to relieve Hospital Steward William Edwards. Steward Edwards will proceed to Manila, P. I., for assignment to duty.

DILLON, G. P., contract surgeon, is granted leave for two months, from about February 24.

**Changes in the Medical Corps of the U. S. Navy for the week ended February 21, 1903:**

HAWKE, J. A., medical director, retired, detached from Naval Hospital, Mare Island, Cal., and ordered home—February 13.

SIMONS, M. H., medical inspector, ordered to Washington, February 24, for examination for promotion, and thence to Naval Hospital, Mare Island, Cal.—February 13.

FITTS, H. B., surgeon, detached from the Naval Hospital, Sitka, Alaska, and ordered to the Pensacola—February 14.

NELSON, H. T., JR., acting assistant surgeon, ordered to Marine Barracks, Sitka, Alaska—February 14.

BERTOLETTE, D. N., medical inspector, detached from the New York and from duty as fleet surgeon of the Pacific Station, and ordered home to wait orders—February 18.

LEWIS, D. O., surgeon, detached from the Pensacola and ordered to the New York for duty as fleet surgeon of the Pacific Station—February 18.

GRIEVE, G. C., acting assistant surgeon, ordered to the Navy Yard, Boston, Mass.—February 18.

DYKES, J. R., acting assistant surgeon, ordered to the Franklin—February 18.

DABNEY, V., acting assistant surgeon, ordered to the Pensacola—February 18.

BLACKBURN, T. C., acting assistant surgeon, ordered to the Culgoa—February 19.

**Changes in the Public Health and Marine-Hospital Service for the week ended February 19, 1903:**

KALLOCH, P. C., surgeon, to proceed to Augusta, Me., for special temporary duty—February 14, 1903.

BROOKS, S. D., surgeon, to assume temporary charge of the Portland quarantine station during absence of Surgeon P. C. Kalloch—February 14, 1903.

FRANCIS, EDWARD, assistant surgeon, relieved from duty in the hygienic laboratory, and directed to proceed to Mexico and Durango, Mexico, for special temporary duty—February 13, 1903.

WARD, W. K., assistant surgeon, granted leave of absence for four days from February 13, 1903, under paragraph 191 of the Regulations.

BULLARD, J. T., acting assistant surgeon, granted leave of absence for thirty days from February 13, 1903—February 13, 1903.

HOLT, E. M., pharmacist, to proceed to Louisville, Ky., and report to Passed Assistant Surgeon G. B. Young, chairman of board of examiners, to determine his fitness for promotion to the grade of pharmacist of the second class—February 16, 1903.

MORRIS, G. A., pharmacist, granted leave of absence for seven days from February 11, 1903, under paragraph 210 of the Regulations.

*Promotion.*

GUITERAS, G. M., passed assistant surgeon, commissioned as surgeon to rank as such from December 13, 1902—February 11, 1903.

PUBLISHED WEEKLY AT 1321 WALNUT STREET, PHILADELPHIA, BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. V, No. 10.

MARCH 7, 1903.

\$5.00 YEARLY.

**"Science" and the Relative Value of the Sciences to Humanity.**—We would admit that none could be more grateful than are we for the grant of \$10,000 a year by the Carnegie Institution for the revival of the *Index Medicus*. However, a sign of the dominant feeling of the trustees as regards the value of medical and biologic science is sharply given in the rejection of the plea for a few thousand dollars, not annually, but once for all time, to fill the gap of four years in issuing the publication. A far more startling demonstration consists in the announcement that one-half of the entire income of the fund is to be devoted permanently each year to the single science of physics—\$150,000 annually to be spent by a fully-manned laboratory at Washington and \$100,000 to be distributed to investigators throughout the country. History got a single grant of \$5,000 last year. Literature, philology, art, anthropology, psychology—these are apparently held to be not one-two-hundred-and-fiftieth part as valuable to the nation and to civilization as is physics; biology, including medicine, hygiene and the scientific prevention of a hundred kinds of social and economic disease—these things do not seem of sufficient interest to the trustees. Why should not Mr. Carnegie make another attempt?

**The Diabetic Flour Swindle.**—According to a Massachusetts State Board of Health report, of thirteen samples of diabetic flour, or flour prepared for the use of diabetics and purporting to be free from starch, only three samples, the product of one manufacturer, were found to be free from starch; the other ten, or nearly 80% of the samples collected, were found not only to contain starch, but that in large quantities, seven being found with 60% or more of starch. These were in reality but little better than whole wheat flour, and were sold at prices varying from eleven to fifty cents per pound. There are probably few of the better informed of general physicians who would not say, "All the better for the patient, so far as his health is concerned," because bread that does not contain starch doubtless injures him more than the best-made, well-baked "crusty" wheat bread. There seems to be a deal of indefiniteness and a vast deal of difference of opinion among physicians as to these questions of bread and diet for diabetic patients. These differences do not show themselves so much in the textbooks, where there is

general uniformity of advice. But when it comes to getting his bread the poor diabetic finds that the physician knows little or nothing as to the chemic and digestive qualities of the breads he can buy. The matter is left without oversight to the bakers and commercial agents, precisely where it should not be left, and much to the perplexity of the patient. No wonder that the diabetic's health fails when he tries to digest some of the "bread" he is advised to get! After trying it he can but think, if he does not know that his disease is a modern one, that the origin of the scriptural injunction against giving a stone when bread is asked for arose from the experience of his poor ancient brethren in trying to live while conforming to the scientific diet-list of those days.

**A sharp distinction is needed as to glycosuria and diabetes,** but so little is it drawn that a very up-to-date cyclopedia, relying for its facts upon the textbooks, fails utterly to note it, and would have the patient, who has only a temporary and controllable glycosuria, frightened out of his wits by calling it diabetes and emphasizing the seriousness and hopelessness of his disease. There is every reason to believe that such a functional glycosuria is entirely a different condition from permanent diabetes, and should no more be confounded with it than should the athlete's albuminuria be classed with chronic interstitial or parenchymatous nephritis. This controllable, or passing glycosuria, although appearing in minor degrees, and even continuously throughout life, is not at all incompatible with what may be called health, with much normal work of any kind, and with long life. This is especially true if the patient does not become alarmed and does not indiscriminately indulge in "diabetic breads," and some of the other foods as expensive to his digestive system as to his purse.

**Reporting Causes of Death.**—The inaccuracies and indefiniteness of death-returns constantly vitiate the returns of vital statistics, and sometimes render them absolutely worthless. The Bureau of Vital Statistics of the Census Department, according to the *Sanitary Bulletin*, recommends greater definiteness and exactness, and specifically points out the following terms as needing explanation:

ABSCESS.—The cause of the abscess should be given, as

tuberculosis, traumatism, etc., and the *organ* or *part* of the body affected should be stated.

ACCIDENT.—Always state the *nature* of the accident, then the nature of the injury.

AMPUTATION.—See Surgical Operation.

ASCITES.—See Dropsy.

ASPHYXIA.—Give the *cause* of the asphyxia, whether *disease* or *external violence*, and if the latter state whether accidental, suicidal, etc., and the exact nature of the cause of death, as by illuminating gas, gas from stove, suffocation by gas, or deprivation of air in mine, etc. Similar terms are choking, strangulation, and suffocation, deaths from which causes should be always explicitly defined.

ASTHENIA.—What *disease* caused the asthenia?

CANCER.—Always state *organ* or *part* affected.

CHILDBIRTH.—If puerperal septicemia, this should be stated.

CHLOROFORM, ETHER, ETC.—See Surgical Operation.

CONGESTION.—This word without qualification should never be used in a certificate of death.

CONVULSIONS.—Give the *cause* of the convulsions, which are mere symptoms that may occur in many diseases. In females of childbearing age it should be ascertained whether they were of puerperal character.

DEBILITY.—Whether alone, or qualified as "general debility," "infantile debility," "senile debility," etc., this return is practically worthless. Give the *cause* of the debility, if known.

DENTITION.—Inquiry should always be made for the *disease*, as enteritis, etc., that caused the death of the teething infant.

DISEASE OF BRAIN, LUNGS, ETC.—When a mere statement of disease of a certain organ or part is given inquiry should always be made as to the *nature* of the disease. Many returns of this class are worthless on their face, as, for example, "liver complaint," "lung trouble," "kidney disease," etc., so far as exact diagnoses are concerned.

DROPSY.—The *cause* of the dropsy, a mere symptom of cardiac, hepatic, renal, or other organic disease, should be given.

ECLAMPSIA.—See Convulsions. The term "eclampsia" is likely to include cases of puerperal convulsions, hence special inquiry should be made in this respect.

EXHAUSTION.—A worthless term. What *disease* or *injury* caused the exhaustion?

FEVER.—What was the name of the fever?

FRACTURE.—What was the *cause* of the injury? Deaths should be classified under fractures only when there is no provision for classifying under the cause of the injury.

HEART FAILURE.—The use of this term is a stigma upon American statistics. It should never be accepted, but inquiry should be made whether some organic disease of the heart was intended, and if not, then for the disease that caused the "heart failure." Not infrequently diphtheria, puerperal septicemia, or other cause of death has been concealed by the ignorant or intentionally misleading use of this term.

HEMORRHAGE.—From what *organ* or *part* of the body did the hemorrhage occur? What was the *cause* of the hemorrhage? Inquire especially for puerperal hemorrhage, and in hemorrhage of the lungs (frequently reported as "hemorrhage" without qualification) always inquire as to whether the case was not a tuberculous one.

INANITION.—In some localities this term covers a multitude of imperfect diagnoses. What was the *cause* of the "inanition"? The *name* of the disease should be given that led to this condition.

INFANTILE.—This adjective adds no information in addition to the statement of age. *What disease caused death?*

INFLAMMATION.—Give the location of the inflammation and its cause, if known. Also ascertain whether acute or chronic.

MALASSIMILATION.—What *disease* caused the malassimilation?

MARASMUS.—What *disease* caused the marasmus (wasting)? This is a very unsatisfactory statement, as usually made, and is practically worthless for statistical purposes.

NATURAL CAUSES.—What was the *disease* causing death?

PERITONITIS.—Inquiry should be made for the *cause*, especially in deaths of females of childbearing age. Was the peritonitis puerperal, traumatic, etc.?

SEPTICEMIA.—Inquiry should be made for the cause, especially in deaths of females of childbearing age. Was the septicemia puerperal, traumatic, etc.?

SPASMS.—See Convulsions.

SPINAL DISEASE.—Was this a disease of the *spine* or of the *spinal cord*? What was the *nature* of the disease? If a tuberculous disease of the spine, that fact should be clearly stated.

STILLBORN (with age indicated).—A stillbirth is a child born dead. Returns are not infrequently received in which a definite age, in hours or days, is stated for a "stillborn" child. Ascertain in such a case whether the child was in fact dead at birth, in which event correct the statement of age to correspond; or, if the statement of age is found to be correct, then the child was not "stillborn," and some other cause should be substituted.

STRANGULATION.—See Asphyxia.

STRICTURE.—Stricture of *what*? It is usually of the urethra in males, but should be specified.

SUFFOCATION.—See Asphyxia.

SUICIDE.—What were the *means* used?

SURGICAL OPERATION.—What was the operation undertaken for? The *disease* or *injury* requiring a surgical operation should be stated. It may be assumed, as a rule, that the operation was required for some disease or injury, and that it was properly performed; hence, the operation in itself should not be assigned as the sole cause of death. A similar rule applies to deaths during the administration of anesthetics for surgical purposes.

TUMOR.—Was it a cancer? Whether a cancer or benign tumor, the *organ* or *part* of the body affected should always be stated.

TYPHOID PNEUMONIA.—Was this typhoid fever or pneumonia?

The Philadelphia Board of Health gives the following instructions to physicians:

Certificates will be returned for additional information, which give any of the following diseases, without explanation, as the sole cause of death:

Abortion, abscess, cellulitis, childbirth, convulsions, hemorrhage, gangrene, gastritis, erysipelas, meningitis, metritis, miscarriage, necrosis, peritonitis, phlebitis, pyemia, septicemia, tetanus. (Any one of these may be the result of an injury, and thus be a subject for investigation by the coroner. If it is not, the certificate should make that fact plain.)

No certificate giving "heart failure," "dropsy," or other mere symptom, as the sole cause of death, will be accepted, unless accompanied by a satisfactory written explanation.

In all cases of death from cancer or tumor, the physician must give the location of the same in order that it may be properly classified.

In all cases of stillbirth the physician must give the date of delivery in lieu of date of death, and must also give the surname of the child.

No certificate will be accepted which is mutilated, illegible, inaccurate, or any portion of which has been erased, interlined, corrected or altered, as all such changes impair its value as a public record.

**Some Fallacies of Natality Statistics.**—According to the frequently quoted figures of President Eliot, 28% of the surviving members of the Harvard classes, '72 to '77 inclusive, are unmarried, and those that are married have only two living children. The net result is a decrease of 28%. The interest in these figures seems to be based upon an absurd fear that this is really an indication of "race suicide," and that the educated classes must reproduce their kind or fearful consequences are to follow. But surely we now have thousands of educated men where were formerly tens, and hence the present

educated classes are not the children of the former educated classes. Then what is the object, evolutionary and social, of education in a democracy? To make a rigid caste system of the educated, or to bring the uneducated up into the condition of the educated? It would appear that a republican form of society should avoid any particular attempt at encouraging, and certainly any worry over the failure, of the educated to reproduce their kind, and be glad that the spreading of culture is such that the ignorant are progressively securing the benefits of education. It should not be forgotten that socialism and individualism have also a word to say as to the general utility of a too numerous educated or leisure class. The economic aspect is emphasized that such persons are largely directive and, to use a harsh phrase, parasitic, and must be fed and housed and supplied with leisure and luxury at the expense of the workers. One need not assent to this view to see that it has a cogency that in these days of trade-unions should not be forgotten. Lastly, it should be noticed that "education" is by no means confined to college learning. Many of our best educated men have not been, and still are not, college bred, and the fittest is by no means always the educated. It is a wellknown fact that those plants and animals most poorly adapted by nature and environment to protect their offspring produce the largest number, and the converse is equally true, applying not only to lower organisms but to mankind as well. The survival of the fittest and the wiping out of the unfit has the effect of overcoming apparent dangers attaching to a low birthrate among the physically, mentally, and morally competent members of society. What is needed is not an increase in the size of the family among the competent and well-to-do, but more intelligent and far-reaching efforts so to modify the conditions of the now submerged classes that they may become better off and competent to increase in numbers. While such increase will carry with it a corresponding restriction in the number of offspring, it will also mean the survival of a greater percentage of efficient and desirable citizens. Real race suicide is taking place among the ignorant, the diseased, the pauperized, the depraved, and the insane, despite their fecundity.

**Water as a Nutrient.**—Dr. John Uri Lloyd rightly contends that greater attention should be given to the role played by water as an integral part of food as a nutrient, in the same sense that carbon and nitrogen are nutrients when found in certain molecular combination. Physiologists and food analysts have been content to base their tables of food valuations upon the inorganic elements obtained by disruption of the molecules of plants and animals, but have disregarded the food value of the water itself; they have failed to recognize the combined water of organized water-bearing foods as an integral part of food. There is general recognition of the importance of water in the elimination of waste products, in facilitating the diffusion of gases, in regulating bodily temperature, and as a carrier of dissolved nutrient solids, but too little consideration has been given to the fact that carbon, nitrogen or hydrogen pure

and simple are not available as food, and cannot be assimilated as such; only when combined with water or by means of water do the elements become tissue-builders or heat-producers. There are abundant reasons for regarding water as an integral part of rather than as a mere carrier of food. It is the combined water that forms the real foundation of tissue pabulum, and it is to this vitalized or easily vitalized water-molecule that Professor Lloyd very happily calls attention.

"What knowledge is of most worth?" is the momentous question with which Herbert Spencer startled the pedagogic world over forty years ago, and in his famous "Essay on Education" he answers it as follows: "As vigorous health and its accompanying high spirits are larger elements of happiness than any other things whatsoever, the teaching how to maintain them is a teaching that should yield in moment to no other whatever." But so tardy has been the acknowledgment of this great truth that today on all sides we find chronic complaint, physical weakness, and overwhelming depression that proper instruction might have prevented. Recently in editorial comment on the belated but none the less worthy intention of the new Teachers' College in New York to prepare properly its matriculants to embody the plain teaching of health in their life work, a wellknown magazine<sup>1</sup> remarks that it may not be extravagant to say that this movement is of larger possible benefit than anything that has hitherto been done in education. It is not merely the rules of hygiene that are needed, nor the ordinary course in school physiology. Personal hygiene is applied physiology, but a proper understanding of certain elemental truths of human physiology must be acquired before they can be applied. Knowledge of the normal functions of the body and the simple methods of keeping them in healthy action is the one thing that no educated person should be excused from possessing; yet most of our children reach maturity without parental or scholastic instruction in the most elemental matters of health.

**The Teaching of Personal Hygiene.**—The ordinary instruction in physical education, physiology, dietetics, and exercise is not sufficient, and it is often faulty. It is not desirable to produce athletes, physical culture fanatics, or practitioners of new-fangled and erratic "systems" and "pathies"? What is needed is simple instruction by capable teachers in the proper care and use of the body, authoritatively based upon the best available modern anatomic, physiologic and hygienic data. We should not have "every man his own physician," as seems often the object in lectures, periodicals, and books relating to health; rather give every man fundamental knowledge that will enable him to understand and, if necessary, formulate the requisite rules of health, and to distinguish scientific medicine from quackery. Stripped of its superfluous technicalities this knowledge may be imparted to any one of average intelligence and education, and we strongly urge more literature and personal explanation in this direction

<sup>1</sup> World's Work, February, 1903.

from the American medical profession. The subject is much too important to be left entirely in the hands of lay teachers and writers.

**The Big and the Little Advertiser.**—The dominant ethical sentiment of the profession has determined that advertising is contemptible. And yet there are two classes of advertisers who go on their way apparently without punishment, sometimes, it would appear, without criticism. The first is the little sneak who, by secret methods or by his own hand, supplies the newspapers with notices that he has recovered his health, is going to Europe, or that he did such and such an operation on the great so and so. The little sneak advertiser claims that he cannot be honest and achieve success, and he quotes as his justifier the example of the big sneak, the great physician, who makes exactly the same use of the newspapers, and from exactly the same motives, but all the time pretending it is for scientific, professional, and altruistic reasons. The little advertiser knows that the big one, in his heart, cares no more for science, for the profession, or for the world, than does he, the little one. Hence the growth of the numbers of the small advertisers, who say they have no other way to get even with the superior advertising ability of the presidential and professorial advertiser. Now in this matter the profession is the great sufferer from the stupid cunning of both scamps, and therefore the great mass of physicians who despise both kinds of advertisers should devise some way to bring to both a consciousness of their crimes. Not by any means hoping for their reform—such men never reform—but only to make them less bumptious and less certain of their results. The great error they now make is in thinking they deceive anybody. Their ways are known to all of their colleagues, and our laughter and detestation are growing, but so long as their tricks bring them patients, membership and office in medical societies, so long are ethics, religion, and lasting fame scorned by them. We should show the advertisers, little and big, that we will have naught of them. The cure lies in our refusal of association, social and professional.

**The Trials and Humors of Prosthetic Charity.**—We have previously commented upon the oversight of the charitable to help the poor who have lost legs, arms, eyes, etc., by means of the many ingenious devices of the prosthetic artist. We have learned of a New York benevolent society which has done something in this way, but the results have not always been entirely encouraging. We have read somewhere of a battle between the patients of a hospital in which their crutches and artificial legs were almost the sole reliance of the fighters in place of "arms." The secretary of the association says that the last man for whom they bought an artificial leg was "so happy that he had to celebrate," and the celebration was so lively that his \$75.00 leg was soon in splinters. An artificial eye supplied to another who is called an old "professional man" (the word has more than one significance) also resulted in a condition of great "happiness" when he came to thank the secretary.

"One struggling widow who was keeping together a family of four or five children, placed her false teeth in a glass of water one night before retiring. The children had a little dog which, as illnourished as the rest of the family and having more appetite than sense, found the teeth in the night and chewed them up. The secretary smiled, but she bought the widow a new set of teeth.

"How could the woman eat if she had no teeth?' she inquired. 'And how could she work if she could not eat? There are people marked down on charity books today as incorrigibly lazy who got there through dyspepsia caused by bad teeth.'

"An artificial nose, for a man who had been deprived of that useful member through accident, and a \$50 flexible hand, not to be detected in a glove, for a girl, were among other odds and ends supplied."

The man without a hair on his head was out of work because of his appearance, and became so sensitive over the matter that he refused to go to the association rooms because he "would have to take off his hat to the ladies." But he sent his wife to state the facts in the case and petition for a wig. The wig was bought, the man got a job, and, happily, refrained from "celebrating." A girl in a store also "lost her job" because fever had left her without hair. "The association bought her a \$15.00 wig, and it proved so efficacious that she was married within six months." We know of one very careful and provident spinster who uses a crudely constructed "peg-leg" during the six common week days, but on Sunday she is happy in the use of a well constructed and artistic artificial leg—or, perhaps, under the circumstances, we should say limb. Despite all discouragements and "celebrations" the association finds that the handicap of lost arms, legs, eyes, etc., is so great for the poor that it keeps on with its really noble work, and on the whole believes it is of great service to them.

**The Situation at Ithaca.**—As Ithaca is a college town the epidemic of typhoid fever raging there has attracted attention all over the country, and has brought anxiety and sorrow to many widely scattered homes. The disease is unquestionably water-borne; and investigation has shown that the two watersheds that supply the town and the university have been indescribably contaminated with the offal and waste from hog-pens, barnyards, privies, cesspools, and vaults. Both the town, and the university authorities are aroused to their duty, which, in view of the condition for which they are responsible, they cannot shirk. In the students' infirmary everything is being done to give the best care to those stricken with the disease. While the majority seem to be genuine cases of typhoid fever, there have been some of paracolon infection; and these, like the cases of genuine typhoid, have caused some fatalities, the total number of deaths at this writing being nineteen. Although there has been quite an exodus of students, no real stampede has taken place owing to the manly conduct of the members of the senior class; and we are informed that there are still about 1,200 remaining. Several deaths have occurred among those students who were taken to their homes, at a greater or less distance from Ithaca, after having been attacked. Without wishing to refer particularly to these cases, we are of the opinion that typhoid fever patients do not stand trans-

portation very well. Several plans to improve the Ithaca water-supply are in contemplation, and the one that seems most likely to be adopted is the method of sand-filtration, toward defraying the expense of which Cornell University has offered to contribute \$150,000. In addition to this, it has been decided to cleanse the watersheds of the several creeks, regardless of cost. In this way the water will have been greatly purified before it reaches the filter. The lesson taught by the experience of Ithaca should be taken to heart by other cities, lest they, too, have to pay the fearful penalty for carelessness in sanitary matters.

## EDITORIAL ECHOES

**Imaginary Bright's Disease Produced by Quack Advertisements.**—The following clipping is taken from a recent daily paper:

### SUICIDE DUE TO CAUSELESS FEAR.

Andrew J. Teggin, an artist, whose pictures have been exhibited at the Academy of Design, took chloroform to-day and died soon afterward at the New York Hospital. Teggin's death was the end of five years' dread of Bright's disease. Though eminent specialists had assured him he had no symptoms of the disease, he persisted in believing that he was doomed to die from it, and this so worked on his mind that he killed himself rather than wait for the end he felt sure would come.

No statement of the case of the man's morbid psychology is mentioned, but the following passage published prominently in another portion of the same paper is highly suggestive:

### TEST YOUR KIDNEYS.

Let some morning urine stand for 24 hours in a glass or bottle. If then it is milky or cloudy or contains a reddish brick-dust sediment, or if particles or germs float about in it, your kidneys are diseased.

Could anything be more fiendishly deceptive? The fact that the "remedy" that this advertisement proclaims has been on the market for many years, and that, to our knowledge, this particular trap has been laid for some years, indicates that there must have been many victims. Imagine the horror that must fill the mind of the poor fellow who views a cloud of phosphates or bacteria, which can hardly fail to be present in the urine left in a "glass or bottle," as he appreciates that he is in the clutches of the dread Bright's disease; for does he not know that this is as surely fatal as is cancer or consumption? And if, because of winter's cold, no bacterial development occurs, and the urine remains clear, does he escape? Not if the advertiser knows it! For in that event there is provided the alternative of "a reddish brick-dust sediment" of uric acid coming down in the acid urine. What must be the sum total of the secret worry, the growing fear, the startling terror at every mention of the death of some one from Bright's disease, among the many who have been deluded by this advice? —[*Jour. Am. Med. Asso.*]

**Cigaret Premiums.**—In the United States House of Representatives the Committee on Ways and Means has reported favorably on a bill which imposes a penalty upon any manufacturer of tobacco who affixes to any package of tobacco, snuff, cigars, cigarettes, a mark, label, wrapper, or any other device which promises or offers a premium to the holder. It is intended to stop the issue of gifts to purchasers of these articles in quantity, and especially as applying to the youthful buyers of cigarettes. Previous to 1857 this practice had been carried on to an enormous extent, but the Dingley Act, which went into effect at that time, abolished this nefarious traffic, but since it remained in force only five years, sufficiently long to establish its great value, by the lapse of time it has ceased to be operative, and a revival of the old practice by the manufacturers of cigarettes is therefore apparent, hence the present bill.

## AMERICAN NEWS AND NOTES.

### GENERAL.

**Appropriations to Pay Doctors' Bills.**—A movement is on foot to have Congress pass a measure to provide for the payment of doctors' bills incurred by the Spanish war soldiers as the result of their services in Cuba. It is said that many of the men in service were compelled to pay out large sums for doctors' bills because the medical service of the Army was not adequate or else because the afflicted were too far removed from medical supplies.

**Inspection of Emigrants.**—It is asserted that because of United States Commissioner Williams' close application of the law as affecting emigrants, the directors of the Hamburg-American Steamship Company and the North German Lloyd Line have instructed their agents in Europe to accept no emigrants who are unable to pass the requirements of the authorities in New York. This is done out of self-preservation, so far as the companies are concerned, as the rejection of one out of every five of the emigrants and their deportation would consume the profits of the companies.

**Hospital Benefactions.**—PHILADELPHIA, PA.: The Medico-Chirurgical Hospital has received \$5,000 from the Baldwin Locomotive Works, and \$1,000 from William P. Henszey, a member of the firm. This sum will be added to the fund for the reconstruction of the main building of the institution, which was recently badly damaged by a boiler explosion. TARRYTOWN, N. Y.: According to the will of the late Mrs. Ellen Josephine Banker, of this place, the society of the New York Hospital will receive \$25,000 with which to build on the new grounds of the asylum in White Plains a pavilion for the accommodation of insane patients. CUMBERLAND, MD.: The Davis Memorial Hospital, which is being built by ex-Senator and Mrs. Davis, the parents of Mrs. Elkins, as a memorial to their son, who was drowned on a cruise off the coast of Africa, is nearing completion, and will cost in the neighborhood of \$100,000.

**Miscellaneous.**—NEW YORK CITY: Dr. Alvah H. Doty has been reappointed Health Officer of the Port of New York. Dr. Doty has held this office since January, 1895.—*Columbus Hospital*: The following appointments were made at the meeting of the medical board of the Columbus Hospital held on February 2: Dr. Frank Farquhar Ferguson was appointed consulting physician to the hospital; Dr. Frederick C. Keller attending physician, and Dr. Henry Hazen attending physician in children's diseases. WASHINGTON, D. C.: The Senate has passed a bill pensioning the widow of the late Major Walter Reed at the rate of \$125 a month. PHILADELPHIA: Dr. LeConte has been appointed to succeed Dr. John V. Shoemaker as Surgeon-General of the National Guard of Pennsylvania. TORONTO, CAN.: Dr. Goldwin Howland, a graduate of Toronto University, recently received the degree of M.R.C.P. in London, England. It is said that there are only six other Canadians holding this degree.

**An Example of English as Evolved by the United States Senate.**—When the bill to increase the pension of the widow of the late Walter Reed was under consideration in the Senate, the desire to express gracefully the recognition of the services rendered by the eminent surgeon led one of the Senators to propose that the following words be added to the bill: "In special recognition of the eminent services to mankind of said Walter Reed in the discovery of the cause and cure of yellow fever." This was about to be adopted when the suggestion was made that a better wording would be, "In the discovery of the means of preventing the transmission and propagation of yellow fever." This was considered to be more satisfactory, but when reduced to writing it appeared as follows: "In discovering the cause and method as well as the means of preventing the transmission and propagation of yellow fever." This wording was criticised, and the Senators interested in the bill now proceeded to write out a number of phrases and submit them to each other for approval. Their efforts culminated in the following production: "In discovering the cause and method of as well as the means of preventing the transmission and propagation of yellow fever." The numerous "ofs" sounding unmusical in the ears of one of the Senators, the now tired rhetoricians made another effort, and let the wording finally appear, "In special recognition of the eminent services of the said Walter Reed, in discovering the means of preventing as well as the cause and method of the transmission of the propagation of yellow fever." The result would seem to show that the more they tried to mend their English the more involved they made it.—[*N. Y. Times.*]

### EASTERN STATES.

**The Faulkner Hospital of Boston** has been opened to the inspection of the public and will be ready for the reception of patients on March 9. The building as it now stands cost about \$125,000 and is limited to 25 beds. Later it will be extended so that the accommodations will be doubled.

**Height of Buildings in Massachusetts Limited.**—The Supreme Court recently rendered a decision confirming the constitutionality of an act of the Massachusetts Legislature and upholding the right of that State to limit the height of skyscrapers in cities. The decision was based on the public use of light and air. The act as passed by the Massachusetts Legislature declares that buildings must not exceed 90 feet in height.

**Harvard Medical School.**—The proposed new medical buildings at Harvard will occupy a 26-acre lot, and the cost of the entire group is estimated at \$2,000,000, of which J. P. Morgan contributed one-half. Five of the new buildings will be used by the medical school, one by the dental school, and one will be a large power house. The five buildings will surround three sides of an open court, which is 520 feet by 215 feet, and the entrance will be through a gate on Longwood avenue.

**Smallpox in Massachusetts.**—For the first time since 1901 the State is practically free from the disease. There have been no cases reported outside of Boston for some time, and but 10 cases exist within that city. These are under quarantine. The *Boston Transcript* gives the history of the State's recent experience with the disease as follows: "It came into the Southern States in 1898, undoubtedly from the Spanish colonies, and worked north gradually until it hit Massachusetts in October, 1901. During the last three months of that year there were 778 cases and 97 deaths in the State; in 1902 there were 2,302 cases and 250 deaths, and thus far this year there have been 183 cases—no record of the deaths is obtainable. Quarantine and vaccination were the only agencies adopted by the health authorities to stop it; to these it gradually yielded, and it now appears to have lost its ground here entirely. Vaccination has been forced on the people in many communities where they showed disinclination to submit to it voluntarily, and smallpox hospitals have been established in nearly every town and city of any importance where there were no such hospitals before."

#### NEW YORK.

**The new Bronx Eye and Ear Infirmary** was formally opened to the public February 7, 1902. The incorporators are Dr. Charles H. McIlwaine, Dr. Everett M. Raynor, Mr. Charles H. Roberts, Mr. James C. McKenzie, and Mr. James Dalton. The dispensary service will be open daily except Sunday from 2 to 4 p.m.

**Influenza on the Increase.**—Compilation of the death records for the past week in New York City show an increase of 50% in the number of fatal cases of influenza over that of the preceding week. The total number of deaths from all causes was markedly diminished, but the increase from influenza was considered by the New York physicians as significant.

**Medical Inspector.**—A bill has been introduced into the New York Legislature which provides for the appointment of a trained medical inspector. If the bill becomes a law he will perform the duties now devolving upon the medical commissioner. The salary accompanying the position will be \$5,000 a year, and for this amount those in authority hope to secure the services of a trained alienist to visit the various insane hospitals of the city.

**Opium in State Prisons.**—The superintendent of Dannemora, after an investigation, has found that an attendant and a trustee in connection with the institution have been clandestinely supplying the convicts with opium. It is said that the practice has been going on for some time, and that only after rigid and thorough examination have the guilty parties been discovered. The attendant was promptly discharged, and vigorous measures will be adopted to prevent repetition of the offence.

**Psychopathic Hospital Bill.**—A bill suggested by the State Commission in Lunacy has been introduced into the New York Legislature for a psychopathic hospital in New York City. The proposed hospital will afford a place of detention for those who are suspected of being insane until such time as the proper official in charge shall make an examination and detail to the satisfaction of the court the mental condition of the person detained. If secured the hospital will be located on the East river opposite the Ward's Island institution.

**For Pure Drugs.**—A bill has been introduced into the New York Legislature to prohibit the sale of defective, stale, or otherwise deficient drugs, and to punish persons who make substitution of another drug for the one called for by a customer. The bill provides that drugs likely to deteriorate in time must be marked with the date of manufacture, and with a statement showing the quality, strength, and genuineness of the drug. A time limit must also be fixed after which the drug will be unfit for use. The bill was introduced at the instance of the Medicolegal Society of New York.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**Women Physicians in Philadelphia.**—There are at present 186 women physicians in this city. A number of these are said to make \$10,000 a year, while a large proportion average from \$2,000 to \$3,000 a year.

**Patent Medicine Advertisements.**—The Pennsylvania Legislature has passed a bill prohibiting the use of any person's picture or name as a testimonial for a patent medicine without securing the person's consent.

**For Sanitary Barber Shops.**—A meeting called by the International League of Barbers for the purpose of arousing public interest in the adoption of a bill by the Pennsylvania Legislature providing for better sanitary conditions in barber shops was held recently in Philadelphia. The proposed law regulates the practice of barbering, provides for the registration and licensing of barbers, and calls for the better education of those engaged in the work. It also provides for the appointment of a board of examiners, composed of five members, who have had at least 10 years active practice in the business. The movement has the cooperation of the International Union of Journeymen Barbers, which comprises nearly 10,000 persons.

#### SOUTHERN STATES.

**Columbian University.**—The new hospital and the new building for the department of medicine and dentistry of the Columbian University in Washington were formally opened February 28.

**New Ward for State Hospital for Insane.**—Plans are being prepared for a new epileptic ward for the State Hospital for the Insane at Springfield, Md. The building will be two stories high, and will accommodate about 100 persons. It is estimated the cost will be about \$25,000.

**New Naval Hospital.**—The amendment to the Naval Appropriation bill assigning the sum of \$125,000 for the erection and completion of new buildings for the accommodation of the United States Naval Hospital in Washington has been passed by the Senate. The buildings will be erected on the grounds belonging to the United States Naval Museum of Hygiene.

**Hospital Site Offered.**—A Baltimore woman has offered to the Commissioners of the District of Columbia a piece of property to be used for maintaining a Children's Hospital in Washington. The property, which is situated in the country nearer Washington than Baltimore, consists of over 40 acres of land and a large three-story house, which has room for 50 patients. The property was first offered to a Baltimore institution, but as that city is already well provided for in this respect with the Robert Garrett Hospital for Children at Mt. Airy, Md., the offer was not accepted.

**Sentenced to Penitentiary for Malpractice.**—Judge Stockbridge, of the Criminal Court of Baltimore, has sentenced Dr. W. B. Hawkins to 10 years in the penitentiary—the full limit of the law—for manslaughter in causing the death by criminal operation on November 15, 1901, of a female patient. The case had been tried a second time, the trial resulting in a vote of 11 members of the jury for conviction and 1 for acquittal. The accused was severely arraigned by the court, who said that there were no extenuating circumstances whatever, that aside from the nature of the crime itself the operation was performed in a most brutal and unscientific manner, so much so that no chance remained after the operation for the survival of the patient.

#### WESTERN STATES.

**Hospital Bill.**—Under a new ordinance which has been favorably recommended in the Chicago Councils, institutions for the care of the insane, inebriates, or similar persons are prohibited in all residence districts, unless the consent of the majority of the property owners in the block or on the opposite side of the street on which the building faces is obtained.

**Football Prohibited.**—A bill has been introduced in the Illinois Legislature prohibiting football in the State University and other institutions of learning supported wholly or in part by the State. The prohibition is made absolute and any breach of it is to be characterized as a misdemeanor, the maximum penalty being a fine of \$100. Not only are the students forbidden to play the college game, but presidents and faculties are forbidden to permit it.

**Patient's Consent Necessary Before Operation.**—Judge Tuley, of Chicago, has rendered a decision in the case of Mrs. Parmelia J. Davis against Dr. Edwin H. Pratt, granting to the plaintiff the sum of \$3,000 as damages for the operation of hysterectomy at the hands of Dr. Pratt without her consent. The doctor alleged that the patient had given her consent, but as she was suffering from occasional epileptic attacks at the time, and has since been adjudged insane, the fact was established, in the opinion of the court, that even though she consented, such consent was not sufficient in the eyes of the law, she being legally of unsound mind. Neither the sister nor the husband being present when this operation was performed is a strong circumstance tending to show that the doctor acted without the consent of the husband. One or the other would naturally have been present at the hospital at such a time. It is not claimed that the doctor performed the operation in an unskilful manner; no malpractice is charged. The absence of malice does not excuse an unauthorized trespass on the body of the plaintiff.

## FOREIGN NEWS AND NOTES

## GENERAL.

**Miscellaneous.**—Dr. A. S. F. Grünbaum has been appointed director of Cancer Research, for which Mr. Sutton Timmins, of Liverpool, recently gave a donation of \$50,000. The work as announced previously will be carried on in connection with the University College and the Royal Infirmary of Liverpool.

**Discovery of a Plant Which Drives Away Mosquitos.**—The prevalent notion which exists among the natives of West Africa that a certain species of plant which if placed in a room will drive away all mosquitos induced Captain H. D. Larymore, Resident of the Kobba Province, to make an investigation. He found that the natives living in Lokoja make use of this plant to protect themselves from the swarms of mosquitos. The plant has been identified by the experts at Kew as the *Ocimum viride*, Willd. It is a member of the order *Labiata* which grows from Senegambia southward to Angola. It grows wild but not abundantly. Specimens were obtained and planted in pots and boxes. Captain Larymore found that the presence of one of these plants in a room undoubtedly drove the mosquitos out, and that by placing three or four around his bed at night he was able to sleep unmolested without using a mosquito net.

## GREAT BRITAIN.

**Deaths Occurring in London Streets.**—It is asserted that about 4,000 persons are killed each year in the streets of London.

**Women Physicians.**—It is asserted that there are 247 women physicians in the United Kingdom; of these 82 are in London and its suburbs alone. In India there are 124 English medical graduates.

**Introduction of Yellow Fever Into Asia Feared.**—At a special meeting of the Epidemiological Society, held recently in London, the possibility of the construction of the Panama Canal introducing yellow fever into Asia was discussed. The speakers were unanimously of the opinion that the danger is most real and, therefore, it was demanded that pressure be brought to bear on Great Britain and the United States to give practical effect to the recent discoveries of the American Yellow Fever Commission toward preventing the spread of the disease among the over-crowded populations of Asia, where conditions are very favorable for its propagation. A committee was appointed whose duty it will be to draw the immediate attention of the governments to the matter and to begin an active propaganda to combat the danger. The society will correspond with kindred American societies with a view to obtaining their cooperation.

## CONTINENTAL EUROPE.

**Destruction of Rats.**—It is estimated that nearly 3,000,000 rats are killed in Paris each year.

**Medical diplomas** were granted to 1,350 young men in Germany last year. Ten years ago there were but 800 granted.

## OBITUARIES.

**W. E. B. Davis**, a leading surgeon of the Southern States, was instantly killed at Birmingham, Ala., by a passenger train February 24, aged 39. He was graduated from the Bellevue Hospital Medical College, New York City, in 1884. He was professor of gynecology and abdominal surgery in the Birmingham Medical College and was a prominent member of many local and national societies among which are the Southern Surgical and Gynecological Association, Tri-State Medical Association of Alabama, Georgia and Tennessee; American Association of Obstetricians and Gynecologists; American Medical Association, etc. He was honorary president of the section of abdominal surgery of the Pan-American Medical Congress in 1893 and vice-president of the Congress in 1896. He was also a Fellow of the British Gynecological Society. He gave many contributions to medical literature, his writings being chiefly upon abdominal surgery and surgery of the bile-ducts. He served as an editor on several medical publications.

**Theodore Gaillard Thomas**, of New York City, died at Thomasville, Ga., February 28, aged 72. He was graduated from the South Carolina Medical College, Charleston, in 1852. He was well known as a gynecologist, and several new operations were first suggested and employed by him. One was the removal of small ovarian tumors without abdominal section. The incubator for premature babies was his device. He was at one time one of the visiting physicians at Bellevue Hospital. He was surgeon at the Woman's Hospital and was a member of the New York County Medical Society.

**C. F. Ulrich**, of Wheeling, W. Va., acting assistant surgeon in the Marine-Hospital Service, died February 17, 1903. He was graduated from

the University of Louisville, Ky., in 1870. He was a member and ex-president of the Wheeling and Ohio County Medical Society; ex-president of the Medical Society of the State of Virginia and of the Board of Education. He was also a member of the American Academy of Medicine, American Public Health Association, and ex-surgeon of Holiday Post of the Grand Army of the Republic, and vice-president of the American Congress of Tuberculosis.

**Captain Franklin M. Kemp**, assistant surgeon in the United States Army, died at Neuva Caceres, P. I., February 23. He was graduated from the Long Island College Hospital in 1893. In 1895 he served as assistant surgeon in the National Home for Volunteer Soldiers in Dayton, Ohio, and in the following year was appointed first lieutenant and assistant surgeon in the United States Army. In 1898 he served with the exploring expedition in Alaska under Captain Eldridge and went to the Philippines in 1899.

**John Gerdine**, of Athens, Ga., February 18, aged 63. He was graduated from the medical department of the Tulane University, New Orleans, La., in 1861. He was president of the Clark County Medical Association and was at one time vice-president of the Georgia Medical Association. He was also a member of the American Medical Association and was medical examiner for several life insurance companies.

**A. L. Cressler**, of Wilkes-Barre, Pa., February 23, aged 75. He was graduated from the Jefferson Medical College, Philadelphia, in 1874. He was one of the charter members of the Luzerne County Medical Society and about twenty years ago was a member of the Pennsylvania Legislature.

**Benjamin T. Shimwell**, in Philadelphia, February 5, aged 51. He was graduated from the Jefferson Medical College, Philadelphia, in 1875. He was formerly professor of surgery in the Medico-Chirurgical College and was a member of the American Medical Association.

**Harry H. Hurst**, in Wilkingsburg, Pa., January 31, aged 28. He was graduated from the University of Pennsylvania, Philadelphia, in 1897. He was a member of the Pittsburg Pathological Society and former president of the Wilkingsburg Medical Club.

**Richard J. Gatling**, of New York City, February 27, aged 84. He was graduated from the Ohio Medical College in 1850, but he never practised medicine. He was the inventor of the Gatling gun and of a number of agricultural implements.

**Lieutenant-Colonel C. R. Maclean**, of Medford, Ont., February 16, aged 68. He was graduated from the University of New York in 1858 and from the Queen's University, Kingston, Ont., in 1859. He served as surgeon during the Civil war.

**James H. O'Toole**, in Charlestown, Mass., January 27. He was graduated from the Medical School of Maine, Bowdoin College, Brunswick, in 1830. He was a member of the Massachusetts Medical Society.

**Edward von Donhoff**, in New York City, February 7. He was a graduate of the University of Heidelberg, Germany, and was formerly professor of surgery in the Louisville (Ky.) Medical College.

**Samuel C. Hanford**, formerly of Brooklyn, died in Hempstead, N. Y., February 17, aged 81. He was graduated from the medical department of the New York University in 1845.

**Gustavus Bruhl**, in Cincinnati, February 16, aged 76. He was graduated from the University of Munich, Bavaria, in 1848, and was a member of the American Medical Association.

**Frank C. Hoegel**, in Allegheny, Pa., February 2, aged 27. He was graduated from the Western Pennsylvania Medical College, Pittsburg, in 1897.

**Benjamin Bevan**, of Pittston, Pa., February 20, aged 42. He was graduated from the New York College of Physicians and Surgeons in 1890.

**Alice H. Burdick**, of Passaic, N. J., February 19, aged 60. She was graduated from the Eclectic Medical College, New York City, in 1872.

**Vincent P. Kennedy**, in Litchfield, Minn., February 13, aged 79. He was graduated from the Rush Medical College, Chicago, in 1859.

**A. L. Vandewater**, of New York City, March 2, aged 58. He was graduated from the Bellevue Hospital Medical College in 1870.

**Charles C. Warden**, in Ottumwa, Iowa, February 14, aged 86. He was graduated from the Ohio Medical College, Cincinnati, in 1843.

**John M. McFarland**, in Rivera, Cal., February 13, aged 69. He was graduated from the Tulane University, New Orleans, in 1870.

**Ernest Gisborne Burke**, in Quincy, Mass., February 19, aged 30. He was graduated from the Harvard Medical School in 1897.

**Henry M. Ptolemy**, in Brighton, Mich., February 16, aged 47. He was graduated from the Detroit College of Medicine in 1889.

**Nelson B. Sisson**, in Porter, Ohio, January 28, aged 82. He was graduated from the University of Louisville (Ky.) in 1846.

**Wilbur A. Blauvelt**, of Newark, N. J., February 18, aged 27. He was graduated from the New York College in 1900.

**Alonzo D. Root**, in Crete, Neb., February 8, aged 66. He was graduated from the Cleveland Medical College in 1871.

**Lemuel G. Goode**, of Jersey City, N. J., February 17, aged 88.

**John C. Whaley**, of Osceola, Mo., February 3, aged 64.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## COMMENT ON PLAGUE MEMORANDUM.

BY

W. J. CALVERT, M.D.,  
of St. Louis, Mo.

Dr. Currie, in his "Review of the Plague Situation at San Francisco," published in *Public Health Reports* for January 30, 1903, gives a brief summary of the number and distribution of plague cases and notes the failure on the part of Chinese to report all their sick and dead, giving as a reason their fear of an autopsy and disinfection of rooms with sulfur. The startling statement that "possibly owing to contrary influences brought to bear against us by the agents of the State Board of Health we have been unable to secure their (Chinese) full confidence and cooperation" is made.

This summary is in every respect characteristic of plague and Chinese. Unfortunately a complete study of only a part of the question is made. The disease is studied from every side, but the Chinaman is left almost out of the question. At present the management of this race presents more difficulties than plague. His failure to cooperate has been noted in Hong Kong and elsewhere. Why so? An answer may be found in a study of the people. Chinamen, like the people of other nations, have certain national customs and religions which are dear to them and according to which they live. Consequently an insult to these customs and religions is an insult to the people. Briefly, among Chinese there are many factions, each with its leader and assistants, to whom the laymen look for guidance. He virtually dictates their policy on all questions save religion and old well-established national customs. To gain his confidence and cooperation is to gain that of the masses. Ordinarily, so long as no sacred right is trampled under foot no trouble from lay Chinamen need be anticipated, but if any of these rights are tampered with every Chinaman will resist in every possible way. There is no practice more repulsive to Chinese than autopsy work. It is against his religion, his national customs, and the masses will not cooperate with any board of officials who persist in this work. They may submit because they have to, they may approve of it because they know it will be done, but down in their hearts a bitter opposition is always present. It may be true that the State Board of Health opposes all or a part of the plague work in San Francisco, but it is probable that the autopsy work is, with the ignorance of the Chinese, sufficient to explain the present opposition.

As the Chinaman has demonstrated that he is not in sympathy with the present policy and is quietly blocking every move, why not stop for a moment to study him? He is human, he has a mind, he has an ambition to succeed and there is a way to gain his confidence and cooperation, without which nothing can be done. Why not omit autopsy work on Chinamen? It has been demonstrated that plague exists among them, so future autopsies can produce naught save opposition. It is much more important to know of plague from its onset than to find it after death and perform an autopsy. Why not teach the Chinese leaders every detail of plague; the reasons for and benefits to be derived from disinfection and the importance of knowing of every case of plague from its onset? They would transmit their knowledge to every lay Chinaman. If the leaders fully understand all, the masses can soon be taught. It must be remembered that these people are not educated as we are and one explanation may teach them nothing. Why not determine how much their religion influences their ideas of medicine? Why not demonstrate to them that all of their sacred rights are respected and that an attempt is being made to protect their race and property? This cannot be done so long as autopsies are made. In this way only can their confidence and cooperation be gained.

It is, indeed, sad to think that in this day of civilization we have in our Union a State which would tolerate a Board of Health capable of opposing in any way a measure to stamp out plague in one of our chief ports. If the quoted statement is not

true it should not have been made; if it is true there are laws in our land to bring the members of such a board to trial.

## A PLEA FOR MORE FREQUENT PRESCRIBING AND LESS DISPENSING OF DRUGS.

BY

FRANK VAN DER BOGERT, M.D.,  
of Schenectady, N. Y.

*To the Editor of American Medicine:*—I wish, if I may, to make through your columns a plea for more frequent prescribing and less dispensing of drugs by physicians. The evil resulting from this too frequent dispensing is, I think, especially apparent in smaller cities and towns, where the pharmacies of today are hardly more than candy and cigar stores, soda fountains and patent medicine shops. This is not altogether the fault of the pharmacist. So little prescribing is being done that the clerk whose duty it is to mix drugs is now spending his time in mixing drinks.

The pharmacist loses his cunning; it is impossible for him to keep his stock of drugs fresh, and when we physicians need active preparations it is next to impossible for us to find them.

## LABORATORY OF CRIMINOLOGY.

*To the Editor of American Medicine:*—My attention has been called to an editorial in your magazine of the date of February 14, in which you discuss an objection urged to the study of the relation of criminal propensities to physical signs, and urge, although not very explicitly, the point that a pupil possessing physical signs of degeneracy should be separated from his fellow pupils at school. You urge that it is an "injustice done to the great mass of the pupils by allowing them to be exposed to the moral contamination of pupils possessing the bodily signs of degeneration."—[Misquotation.—EDITOR.]

It seems to me that the criminal law for the past 200 years, as well as the better sentiment of the community for a much longer time, has been such that it would not permit a human being to be condemned simply for permanent disfigurement which he has inherited from his parents. It would hold him responsible only for his conduct, and not for the shape of his body. The good philanthropic mind of this age wishes by proper means to create a self-respect in the pupil and to give him a disposition to do good to his fellow-men. It would be regarded as a great piece of cruelty on the part of a commission appointed to inquire into criminality if said commission were to go among the well-behaved part of society and take an inventory of the height of the palate in the mouth, of the position and shape of the ears, and the form and shape of the skull. These permanent inheritances, if pronounced to be causally connected with crime, would destroy the self-respect of the pupil and would produce a suspicion in the minds of the community that would lead to misinterpretation of all his acts. It is hardly conceivable that the best disposed child could withstand this influence to evil. But what community would permit the teachers of the schools to hunt up signs of degeneracy and discuss them in the presence of the school? Would it not be fiendish to require among the duties of the teacher that he or she should be on the lookout for physical peculiarities which indicate degeneracy of some sort? Such fiendishness would, I doubt not, lead to cases of libel and to imprisonment, as actual criminals, of teachers who undertook to carry out such an injunction.

Nor would public opinion permit a modification of criminal law which instead of inquiring into the overt act of the criminal and adjudging him for what he has done should, on the contrary, proceed to examine his bodily configuration and condemn him for what he had inherited from his parents.

There has been a position in the Bureau of Education, not for the investigation of criminology in general, but for "the study of education as a preventive of crime and pauperism." It has been difficult to find a person to fill this place who is well acquainted with educational methods and their history and at the same time with an expert knowledge of anatomy and

physiology, together with competency to make statistical investigations. But in asking for the discontinuance of the office of specialist this difficulty was not considered so much as the liability of abuse which comes of urging on teachers a study of inherited bodily peculiarities.

WM. T. HARRIS.

[A more careful reading and accurate quotation of our editorial comment referred to by Mr. Harris would show that the foregoing letter is almost or entirely pointless. We have perfect sympathy with most of what Mr. Harris means to say in this letter, and surely with his essential contention. He confuses the matter by assumptions and non sequiturs, and gives his case away somewhat by "forcing the note." We might also have heartily endorsed the aim that lies behind the letter, and that has inspired many editorials in the newspapers of the country. We may be as fiercely opposed as he to placing the study of degenerates in the hands of those possibly atypical themselves. All that, however, has no bearing upon what we have urged in the editorial. A governmental laboratory for the study of criminology properly carried on, and under competent and conscientious men, would be of great service to the nation and to civilization. As to school children, Mr. Harris' criticism of this journal's expressed opinion is wide of the mark. We spoke of "a morally diseased or degenerate pupil who is teaching others bad habits and contaminating them with moral disease," etc. We said nothing as to the manner of conducting the examinations of degenerate school children, nor of what should be done with them, except to exclude them from the school. Are not children who are insane, feeble-minded, criminal, deaf and dumb, etc., now excluded? Recently came to our knowledge the case of a morally diseased and, as it proved, physically diseased school child, who so effectually taught a large proportion of the other pupils of a public school the art of sexual crimes that loathsome and nameless horrors resulted. The question we discussed had nothing to do with the appointment or retention of a head of the proposed bureau, nor with any of the "fiendish" methods we are mistakenly assumed to have advocated, and which we should detest as much as our critic. His words, indeed, could be twisted and used by the most outrageous socialist or demagog to advocate giving our public schools over to the control of the degenerates themselves. Do not let us throw the baby away with the bath. —EDITOR *American Medicine*.]

## TWO CASES OF TYPHOID FEVER WITH UNUSUAL COMPLICATIONS.

BY

F. ALAN G. MURRAY, M.D.,  
of Finzel, Md.

These cases occurred during the winter of 1901 and 1902, when typhoid was epidemic in this community. The patients were directly infected by drinking contaminated water.

**CASE I.**—Typhoid fever, complicated with round worms, double intestinal perforation, bedsores and erysipelas. Death occurred six months after exposure to the disease.

The patient was L. C., a female, aged 8, whom I was called to see November 10, 1901. Her pulse was 112 and temperature 103.5°. She had been sick about three days, complaining of headache, pain in the abdomen, weakness, loss of appetite, etc.

*Physical examination* showed a small-framed child, color pale, tongue coated, breath foul, heart and lungs normal, abdomen distended and tender, spleen not palpable. She had been passing worms for the last few days and I therefore gave her santonin and calomel. The case ran a typical course, with the occasional passage of some worms, until December 3, when at 11 a.m. the pulse was 132 and temperature 104°. During the night the patient had been seized with a severe pain in the abdomen, and has since been lying on her back with her knees drawn up and crying out with pain every few minutes. The abdomen is distended and very tender on pressure but not rigid, tenderness being most marked in the right iliac region. Expression of the face is anxious and drawn. Bowels moved five times since yesterday. I gave her 8 mg. (½ gr.) of morphia for the pain and ordered cold applications to the abdomen. From this time on until December 19, she remained in a desperate condition. Abdomen was distended and very tender, pulse ranging between 140 and 150, and temperature between 99° and 102°. Large pressure spots began to appear on her back, hips, ears and hands; these continued, became gangrenous and sloughed out. On December 21 her pulse was 140, temperature

99°, condition showed improvement. She is able to take more nourishment. Her abdomen is softer and less tender, and bowels are more regular.

My notes for January 10 state that the bedsores are clean and granulating well. There is a sore on the sacrum about two inches in diameter, and one above this about one inch in diameter. The ligaments of the spine are seen in this sore. There are also two sores on the left hip through which the head of the bone can be seen working. The other sores are small and nearly healed. On January 15, improvement continuing, I put her on a peptonate of manganese and iron. From this time until February 10 the bedsores gradually improved. On this day, however, the patient tried to walk by herself and fell on the floor, bruising the sores badly. The sores got rapidly worse, despite constant treatment, and about February 20 erysipelas developed, spreading over the lower part of the back and left hip. She died suddenly on the morning of March 5, 1902. A partial necropsy was made at 1 p.m., March 5. Rigor mortis was not complete. The body was warm and emaciated. Abdomen was not distended. On the back, over the sacrum and to the right above, were two deep gangrenous bedsores. On the left hip and exposing the head of the femur, was a large, deep sore; the skin around these sores was of a dusky red color and very much thickened. There was a foul-smelling sanious discharge from the sores. I opened the abdomen on the right side from the edge of the ribs down to the pubes. There were numerous recent and old adhesions between the intestines and the omentum, the appendix was bound down by adhesions crossing over it but was perfectly normal in appearance. On the ileum, about four inches above the cecum, were two large, puckered red scars, bound in adhesions. These were the only ulcerations in the intestines and they were still healing. These were the sites of the perforations that took place on December 3, 1901; and up to the time of her death the patient had attacks of pain in her abdomen when her bowels were constipated.

There was a small amount of straw-colored fluid in the abdominal cavity. The liver was much enlarged and very pale, extending across the abdomen into the left side. The left lobe was about the same size as the right. The spleen was not much enlarged, and there were no adhesions in the upper abdomen. No examination was made of the thoracic organs.

**CASE II.**—Typhoid fever complicated by Ludwig's angina; death from edema of the larynx. Charles C., aged 32, contracted the disease from his daughter, Case I.

On January 10 he complained of headache, dizziness, loss of appetite, had chilly sensations, felt weak and nervous. He had diarrhea a few days previous, and a chill three days ago. Temperature is 102° and pulse 80.

*Physical Examination.*—His face is flushed, eyes injected, tongue tremulous and coated. Heart and lungs are clear. Abdomen is soft, there are no rose-spots. Area of splenic dullness is not increased. Treatment consisted of the administration of acetanilid compound, soft diet and rest in bed. The case ran a mild typhoid course, the highest recorded temperature being 103.5°, until February 3, when a swelling developed on each side of the patient's neck. When seen on February 4, the temperature was 99.5° and pulse 100. There is a large swelling on each side of the neck under the sternomastoid muscle. This swelling does not extend up the angle of the jaws and is hard and painful on pressure. His voice is harsh and metallic and he has difficulty in swallowing; breathing is somewhat obstructed and labored. Neck is slightly swelled in front. The tonsils are neither reddened nor swollen. There is a profuse flow of watery saliva. The heart and lungs are clear, the abdomen and chest are covered with rose-spots. The edge of the spleen is palpable, and the abdomen is soft and flat. The patient died from suffocation at 6.30 a. m., February 5.

A partial postmortem examination was made at 8.30 a. m. Rigor mortis was not complete. The trachea was opened and the larynx examined. The mucous membrane was much congested, the vocal cords were swollen and edematous, passage almost closed. The abdomen was opened over the appendix, which was found very red and injected; lumen was patent and numerous small ulcers were noted all through the organs. The ileum contained numerous ulcerations. The stomach was full of a bright-yellow fluid. The abdominal cavity contained a quantity of straw-colored fluid. Further examination was not permitted by the relatives.

In Case I an operation for the perforation was out of the question on account of the miserable surroundings and lack of nursing. Such a procedure would have hastened the death of the patient, and as it turned out the perforation healed, death resulting from erysipelas caused by carelessness and neglect of the bedsores.

The second patient apparently had a mild case of typhoid and was doing well until the laryngeal trouble set in. The relatives had been told to watch the patient closely and send for me if any change for the worse occurred, as a tracheotomy would be necessary, but they did not send until morning and when I arrived the man was dead.

A case of Ludwig's angina complicating typhoid fever is reported by Drs. Robertson and Biedert in *American Medicine*, December 23, 1901.

## A SLATE PENCIL THREE AND ONE-HALF INCHES LONG LODGED IN A GIRL'S CHEEK FOR THREE WEEKS.

BY

STEWART LEROY McCURDY, M.D.,  
of Pittsburg, Pa.

Professor of Orthopedic and Clinical Surgery, West Penn Medical College; Professor of Anatomy, Oral and General Surgery, Pittsburg Dental College; Orthopedic Surgeon Presbyterian Hospital.

A girl, aged 7, presented herself at the oral clinic of the Pittsburg Dental College. She had a scar  $\frac{3}{4}$  inch external to the right side of the nose, on a line with the inferior margin of the ala. The wound had healed, but it was pink, showing its recent origin. There was a history of a fall down stairs, at which time the wound was produced. A doctor closed the wound with one stitch. After repair had taken place a lump was found in the tissues beneath and external to the wound. A dentist was next consulted, with the idea that the tumefaction had something to do with the teeth. The dentist was unable to make out the condition and referred it to the college clinic. Upon examination a distinct hard substance could be felt in front of the malar. It was movable. The finger in the mouth demonstrated that it had no connection with the maxilla. When pressure was made upon it the tissues in front of the ear moved as though some foreign substance had penetrated the tissues and passed backward. An exploratory incision was advised and accepted. The incision was made at the point of the original wound and the scalpel came in contact with a hard sub-

Fig. 1.—Adult skull, showing relative size of pencil and of skull.

stance. With a hemostat the object was grasped and a half of a wooden slate pencil was removed. A second effort removed the other half and the slate center unbroken. The moisture of the tissues had dissolved the glue used to hold the halves of the pencil together. The yellow paint on the outside of the pencil had also been dissolved. A portion of the pencil had been broken off, since the end near the wound was rough. The father was asked to search the house, and upon his return home the remainder was found in a dark corner of the stairs where the child landed. The wound was closed and it healed promptly without complication.

A study of the anatomic relationship of the missile, in the position where it had been for three weeks, might be of interest. The pencil shown in the illustration is  $3\frac{1}{2}$  inches long. As it penetrated the skin its point was deflected backward upon the anterior surface of the maxilla into the zygomatic fossa, underneath this arch toward the temporomandibular articulation, passing external to the coronoid process. It is quite gratifying that it did not injure the external maxillary artery, since the point of the pencil must have reached if it did not pass it.

**Diphtheria.**—A serious outbreak of diphtheria is reported from the Ochre river and Makinak districts. It appears that the disease has been in progress for some time and that several deaths occurred before its identity was recognized. Vigorous measures have been adopted to check its spread, and it is believed the condition is now under control.

## TRAUMATIC RUPTURE OF THE ABDOMINAL AORTA.

BY

JOHN GLENDON SHELDON, M.D.,  
of Telluride, Colo.

On October 28, 1902, I was called to make a postmortem examination of a man who had been instantly killed by being struck in the abdomen by a moving ore-car. The examination was as follows:

The body was that of a well developed and well nourished middle aged man. There were no evidences of trauma found on external examination of the body. The abdomen was slightly distended, but no evidences of injury or extravasation of blood could be determined. The left rectus muscle was somewhat torn, but showed no excess of fluid in the contused parts. The peritoneal cavity was filled with blood. Most of the blood was fluid, but a few clots were found in different parts of the cavity. The omentum was intact. The intestines showed nothing abnormal. The abdominal aorta was in its proper position, and showed no evidences of local dilation. There was a right-angled opening in the anterior surface of the aorta which measured about  $\frac{3}{4}$  inch in its entire length. This tear was situated about an inch above the bifurcation of the artery. The posterior parietal peritoneum and the mesentery were torn and were displaced and infiltrated with blood. The vascular system appeared normal. The heart and the large and small arteries showed no evidences of disease. No atheroma or thickenings were found in the aorta at any point. The vertebral column showed no evidences of disease or of deformity. The remainder of the examination showed nothing of importance. An irregular cicatrix was found in the upper part of the upper lobe of the right lung. The nervous system was not examined.

The history of the injury, reported to me by one who was present at the time the accident occurred, was as follows:

The edge of a moving loaded car struck the man fairly in the abdomen. The velocity of the car could not be determined, but it was thought to be moving as rapidly as an ordinary man could run. The man was not felled to the ground, but staggered a few feet. Gradually his legs weakened under him and he lay motionless on the ground about 20 seconds after being injured. Ten seconds later no evidences of life could be found by those who were with him.

The absence of signs of injury in the superficial structures of the body, might be due to the rapid and excessive anemia draining the system before the smaller vessels had time to bleed sufficiently to be noticeable. I have not seen or heard of a similar case. Neither have I been able to find reports of such cases in the literature.

## COMPRESSION OF THE AORTA IN POSTPARTUM HEMORRHAGE.

BY

LEO JACOBI, M.D.,  
of New York City.

*To the Editor of American Medicine:*—I desire to record the following case as bearing on the value of compressing the aorta in postpartum hemorrhage:

Mrs. W., aged 22, primipara, was confined on December 20. After a somewhat prolonged first stage, the pains becoming steadily feebler, further expectancy was deemed undesirable, and under superficial chloroform anesthesia the forceps were applied, and the head delivered from its occipitoanterior position with moderate difficulty. Bleeding was now rather profuse, and I therefore expelled the placenta by means of Credé's method. The uterus, however, refused to contract under the hand. Blood gushed forth, and literally in less time than it takes to tell it the woman was lying in a pool. The unnerving spectacle forcibly recalled to mind some recent discussions on the efficacy of aortic compression in this puerperal emergency. Easily finding the vessel, I pressed it against the spinal column. Bleeding ceased instantly. The effect was precisely like that of shutting off a faucet, or closing the clasp of a fountain syringe. The temptation to apply a crucial test was irresistible. Accordingly, I relaxed the pressure, only to witness a prompt return of hemorrhage, which again ceased upon renewing the compression. For fully a half-hour the aorta was thus held under continuous control of the left hand. Meanwhile, a hot lysol douche was given, and ergot in full doses administered. The uterus gradually recuperated and soon assumed a reassuring hardness. Thereafter nothing noteworthy occurred, the patient rapidly rallying from her acute anemia.

## POISONING FOLLOWING THE USE OF COCAIN IN LOCAL ANESTHESIA.

BY

FREDERIC GRIFFITH, M.D.,

of New York City.

Surgeon, Bellevue Dispensary; Fellow of the New York Academy of Medicine.

The employment of cocain as a local anesthetic in surgical procedures has not yet been limited in the hands of the painstaking surgeon. Careless use of this drug, however, will give a quick and potent systemic reaction, as in the following instance of my own:

K., male, aged 17, a packer by occupation, came to me to have enlarged glands of two years' growth removed from his neck. The "lumps" were hard and freely movable, and were deeply situated upon both sides of his neck beneath the body of the lower jaw, on a line with the first molar teeth. Separate times having been decided upon for the removal of the growths, that upon the right side was successfully removed, and proved to be of agglutinated, encapsulated, glandular tissue about the size of a horsechestnut. Cocain varying in strength of from  $\frac{1}{2}\%$  to  $\frac{1}{4}\%$ , dissolved in a weak, warmed soda solution, was employed as an anesthetic, with further tissue infiltration by means of plain soda solution; a total quantity of about half an ounce of fluid having been used containing one-half to one grain of cocain.

The patient, aside from being very nervous, for though constantly admitting throughout the progress of the operation that he felt no real pain, could hardly reconcile himself to the cutting. No systemic effects were apparent during or subsequent to this first operation. Nine days later, healing having progressed satisfactorily, I essayed to remove the gland upon the left side. Great difficulty was experienced in anchoring the growth during the dissection, as it was deeply placed beneath the platysma myoides muscle and while not large was very movable. A  $\frac{1}{4}$  stock, cocain solution, reduced by measuring syringefuls of weak, warmed soda solution to  $\frac{1}{2}\%$  was used as the working solution. The dissection was well started and I was having my patient open his mouth to press the gland from beneath the edge of the jaw by muscular action, when he asked for a mouthful of water, explaining that his "mouth felt dry." Before complying with his request I gave him a  $\frac{1}{4}$  grain morphin tablet by mouth. His pulse at this time was 72, full and velvety to the touch. Respiration was normal in action. Eyes were bright, pupils equal and normal. The countenance was slightly pallid. The patient became very alert and read my thoughts of his possible danger. Said he was "not going to faint or anything like that" that he "was all right" and sprang upright with great rapidity to prove his assertions. Quietly him I continued my work without the use of further injections of the cocain. Dryness of the mouth and throat gradually increased and I gave another  $\frac{1}{4}$  grain morphin tablet by mouth. In addition I loaded a hypodermic syringe with  $\frac{1}{4}$  grain of morphin sulfate to employ directly should occasion arise. Turning out the gland as quickly as possible after opening it, I cureted its contents of calcareous degenerated deposit but did not dissect the sac, relying upon a drain connecting with the lower part of the wound left open for the purpose. The dressing was completed with dry, fluffed gauze held in place by means of a gauze bandage. During the course of the next two hours the symptoms first increased then as rapidly passed away with no subsequent ill-effect. The dryness of the throat became marked, the cocain in this case partaking in its actions more of the nature of belladonna poisoning which has been observed according to Wood. Respirations increased in number somewhat and became labored. The pulse while not gaining over 10 or 20 beats at any time during the course of the drug's action became hard, jerky and irregular but recovered its normal characteristics rapidly. The patient's face first became pale then bluish, finally flushing and breaking out into slight perspiration.

Temperature was unaffected. The state of mind might be described as being that of one who was peculiarly alert to every outside impression.

The amount of cocain hydrochlorate used during the operation was according to my rough calculation between .16 and .19 gram ( $\frac{1}{2}$  and 3 grains). Enough and to spare to cause the most serious outcome. My fault lay in the continued use of the strong solution without having resorted to further infiltration dilution by means of the weak soda solution which is my usual custom when doing this work, and upon too great reliance of leakage during the course of the dissection.

Both chloral and opium in the form of morphin sulfate have been suggested as natural antidotes in cases of cocain poisoning. In several unrecorded instances in the surgical work of other operators I have seen the prompt effect produced by the latter drug.

## ATYPICAL VARIOLA.

BY

C. L. ANDERSON, M.D.,

of Santa Cruz, Cal.

It has been my fortune during a long and almost continuous practice of some 50 years to attend cases of variola almost every year. Lately I have had some experience that may be worth recording.

In a convent school of orphan girls of many nationalities—Spanish, Mexican, French, Irish, and German—all, however, American-born, numbering about 60, and ranking in ages from 5 to 16 years, I was informed by the Sister Superior that during one week about half the pupils appeared slightly ailing, somewhat like an influenza. They were allowed to remain in bed several days, using some domestic remedies, and it was deemed advisable by the Sisters to isolate the sick girls from the well ones. When I saw them they were busy in the playroom. Few complained of any discomfort. The darker skinned ones showed a perceptible eruption, while the fairer ones required a close examination of neck and scalp to discover any. As near as I could ascertain the eruption had been out from five to eight days. It was characteristic of varioloid, although none had ever been vaccinated, and its origin was unknown. However, a German family living near, consisting of eight or nine children and the mother (who had been vaccinated), were sick with a similar eruption.

Vaccination of all the pupils was advised, especially of those who had not suffered with the ailment. This was done to the number of 34, using vaccine that had been successful just previous in other cases. On the eighth day after vaccination the children were inspected. Only about three had "taken" satisfactorily. A revaccination was made, and among those were some who had recovered from the first eruption. One week later inspection was made, and all had "taken" either in the first inoculation or the second, and a few in both, except three or four, and particularly those previously rendered immune by the first eruption. It seems evident from this that vaccinia and this variola are antagonistic.

As to varicella, my experience is not so satisfactory. I am, however, assured by the experience a year or so ago of others in the Deaf and Dumb Institute at Berkeley, Cal., that varicella at first appeared among the 218 inmates, and that of 69 who had either variola or varicella all recovered, and that one was not a protection against the other. Vaccinia, however, is always more or less a protection against variola.

Our experience, then, on this side of the continent of the last few years shows a mongrel state of several genera of eruptive diseases, with a tendency, such as appears in all hybrid forms, to revert to the original, whether of the animal or vegetable kingdom.

We have them in this combination: variola, varicella, vaccinia, and probably one or more forms from Cuba or the Philippines, degenerate forms of what at one time was the most fatal and disgusting of contagious diseases—variola. As to the pathogenic germs, a satisfactory isolation, so far as I know, has not been accomplished, a modified condition seeming to be brought about. Not a death is reported in California from smallpox or any of its forms during the last three years. Among the inmates of the convent were some three or four girls who, so far as tested, were immune from vaccine. May it not be possible that these had the infection without the eruption, and were thus rendered immune? One or two more trials of vaccine may settle that point.

**Visiting Nurses' Association.**—The annual report of the Visiting Nurses' Association of Chicago calls the attention of the public to the need of following the example of other cities in adopting some organized plan to combat tuberculosis. The report states there were 226 new cases of tuberculosis coming under their observation last year and that 60 deaths were due to this disease. The State and city are urged to inaugurate a warfare against the spread of the disease. The whole number of patients cared for by the Association during the past year was 5,621, and 37,986 visits were made by the nurses, the greatest demand for their services being during the typhoid epidemic of August and September.

## THE TECHNIC OF THE OPERATION OF CELIOTOMY AS PRACTISED AT THE GYNECEAN HOSPITAL, WITH THE REPORT OF 93 CONSECUTIVE CELIOTOMIES WITHOUT A DEATH.

BY

HENRY D. BEYEA, M.D.,

of Philadelphia.

Associate Surgeon, Gynecean Hospital; Assistant Gynecologist, University Hospital; Instructor in Gynecology, University of Pennsylvania.

The operation of celiotomy for the relief of gynecologic diseases with the most favorable surroundings and by the well-trained abdominal surgeon has come to be looked upon at the present day as an operation associated with comparatively little danger to life. The published mortality of a long series of all kinds of cases by a number of the best operators throughout the civilized world is estimated at not more than 5%. The study of the etiology of the infectious diseases and traumatic infection by the bacteriologist; the development and better understanding of the principles of asepsis and antisepsis, the perfection of the technic of operation, and improvement of operative methods by the surgeon; and particularly the specialization of abdominal surgery and more accurate studies of the pathology and clinical significance of abdominal diseases during recent years, are the factors which have determined the advance in this class of surgery, the small mortality and the completeness of the restoration to health following it.

The indications for operation have increased, the opinion of the general practitioner that it is safer to allow the patient to suffer with, for instance, a myoma of the uterus, rather than risk the danger of operation is no longer justifiable, and more and more suffering women are being relieved.

Although the expert abdominal surgeon has attained a very high degree of perfection in rigidly practising aseptic and antiseptic technic, his mortality is small, and his influence in saving life is very marked, he rarely goes through a year's work without seeing one or two of his patients die from septic infection. The conscientious and painstaking operator never becomes accustomed to such most unfortunate accidents, nor can he rid himself of a strong feeling of blame in each instance; for it is very truly said that the surgeon's acts determine the fate of a flesh wound, and that septic infection, suppuration, and death from this cause are due to his technical faults of omission and commission. Therefore, most earnest, untiring, and unceasing efforts are daily being made by the conscientious surgeon toward the acquirement of a technic so absolute in the prevention of introduction and the destruction of pyogenic organisms that he may be enabled also to save these few who now die from septic infection, and relieve his mind of the constant worry, the fear of this danger, and the imposing of the fact that a life has been lost and children left motherless through his or his assistant's neglect of appreciation or application of an aseptic principle. For this reason the subject of the technic of the operation of celiotomy is ever new, and of sufficient interest to warrant the description of that practised by each individual operator who has made a careful study of the principles of asepsis and antisepsis and applied them in his practice. In this paper I wish, therefore, to describe in detail the technic of the operation of celiotomy as practised at the Gynecean Hospital, a hospital specially and only devoted to this class of surgery, and to make a short formulated report of 93 consecutive celiotomies performed without a death.

*The Preparation of the Patient.*—The patient who presents herself for the operation of celiotomy at this hospital, either as a charity and ward patient or one

entering a private room, when immediate operation is not demanded, is placed in bed and upon a preparatory treatment lasting from three days to a week. The objects of the preparatory treatment are rest, stimulation of the heart and circulatory system, examination of the blood and various secretions, and also to give the surgeon an opportunity to study the gynecologic disease, become familiar with the patient's general physical condition and her peculiarities. She is usually referred from a physician living outside the city; and if a poor working woman, is frequently weakened by her arduous duties, has traveled a long distance, is weary from the journey and a few days' rest is followed by a distinct improvement in her general physical condition, and she is better prepared for and more easily withstands the shock of operation. Many are nervous, disturbed, fearful of operation and unfamiliar with their new surroundings, and are made more content and willing to subject themselves to the operation by these precautions. A complete clinical and gynecologic history of the patient's previous and present illnesses is taken. Two careful systematic pelvic and abdominal examinations are made, and each recorded in a book kept for this purpose. The first examination is made a short time after the patient's admission to the hospital and before the bowels are open and a vaginal douche administered. The character of the vaginal discharge, any change or disease of the vaginal outlet, vagina, cervix, body of the uterus, tubes and ovaries and the various abdominal organs are carefully noted. The confidence of the patient has not been gained at this time, she resists the physician's manipulations, the abdominal walls are rigid, the rectum is found filled with feces, the examination is therefore difficult and although a diagnosis is determined, the definite opinion is reserved until the second examination. The second examination is made 24 hours preceding operation, following the same systematic plan. The disadvantages of the previous examination have now been removed, the abdomen is well relaxed and the pelvis empty, a very accurate diagnosis is made and the character of the operation definitely decided upon.

For these examinations the patient is placed upon an ordinary kitchen table having Edebohls' legholders attached. The legs are flexed on the thighs, the thighs upon the abdomen, the limbs widely separated and the buttocks drawn well down to the edge of the table. This Edebohls' position, we believe, gains the greatest possible degree of relaxation of the abdominal walls and allows the most satisfactory palpation of the pelvic organs. It is the duty of the attending nurse to see that the bladder has been emptied, immediately before the patient is placed upon the table. By this plan only (the making of two thorough pelvic and abdominal examinations under the conditions described) can a very accurate diagnosis be made, mistakes avoided, and the character of the operation definitely planned. Further, by this method it is scarcely ever necessary to delay operation, or disturb the system of the operating-room and its aseptic and antiseptic technic by an examination under ether.

The surgeon makes a physical examination of the chest, and if there is any question of doubt as to the presence of a disease of the heart or lungs, which would counterindicate operation, a specialist in internal medicine is called in, and assisted by his opinion, the further course of treatment is decided upon. Should the patient have bronchitis, operation is deferred until this is cured, and if this is not possible, she is placed on a treatment and asked to return to her home until all pulmonary symptoms have disappeared. A chemist and microscopic examination of the urine is made and recorded. Likewise a blood examination; the percentage of hemoglobin and a white and red cell count. Tincture of digitalis, .6 cc. (10 minims), and strychnia sulfate, 3 mg. ( $\frac{1}{70}$  grain), are given three times daily, and when there is an indi-

cation, a diuretic is administered. The bowels are opened daily. We would emphasize the importance of this preparatory treatment and precautions, as long experience has taught us that they avoid mistakes, lessen the danger of complications, make the convalescence easier, and distinctly influence the results.

The patient receives a daily bath and vaginal douche of one gallon of hot water night and morning. The special preparation, the sterilization of the abdominal surface, external genitals and the vagina, and the emptying of the gastrointestinal tract is begun 24 hours before operation. Four gram doses (1 dram) of Epsom salts dissolved in half a tumbler of water or soda water are administered every hour until the bowels begin to move freely. Five or six doses are usually sufficient. During the 24 hours preceding operation the diet consists of light, easily digested, concentrated nourishment, such as milk, buttermilk, soft boiled eggs, rare beef, soup, coffee, tea, and whisky if necessary. Unless the patient is very weak, no food is given on the morning of operation. If her condition does not warrant such abstinence, she is given a glass of milk, buttermilk, coffee, or a milk punch. Eighteen hours before operation she is given a warm bath from head to feet. The surface from the ensiform cartilage to the pubes is scrubbed with a nail-brush. The pubes and external genitals are shaved. Special care is devoted to the umbilicus and external genitals. After the bath the patient is dressed in a clean flannel undershirt and nightgown, her hair is plaited and she is placed in a clean bed. The nurse, who has prepared herself as described in the description of the personal asepsis, then washes or scrubs the abdominal surface from the ensiform cartilage to the pubes, and from flank to flank, and the upper third of the anterior aspect of the thighs, first with turpentine, second with green soap, third with sterile water, followed by a 1-1,000 mercuric chlorid solution. Then the abdomen is covered with a large sterile gauze dressing, which is allowed to remain in position until the next preparation. For the preparation of the external genitals and vagina, the patient is drawn down to the edge of the bed. The anus, the external genitals and the vagina are scrubbed with green soap. The vagina is washed throughout. The nurse does this by retracting the perineum with Sim's speculum, and scrubs the vagina, the fornices, and the vaginal cervix with cotton held in dressing forceps. She inserts her finger slightly into the cervical canal, and is very careful that the vaginal fornices and the folds of the external genitals are thoroughly cleansed. The scrubbing, which is very thoroughly practised and continued for 20 minutes, is followed by a vaginal douche of a gallon of hot water, or as much water as is necessary to completely rid the surface of soap. Then a douche of two quarts of mercuric chlorid solution (1-1,000) is given, and a light vaginal gauze tampon, wet with mercuric chlorid solution, is introduced as far as the cervix. The following morning, the morning of operation, the abdomen is again cleansed as before with turpentine, green soap, sterile water, followed by scrubbing with ether and alcohol, then mercuric chlorid solution and a wet gauze mercuric chlorid dressing is applied and held in place by a special form of dressing and binder. This dressing is not removed until the patient reaches the operating table. The patient is given another large hot douche of sterile water, followed by a mercuric chlorid douche, and a tampon of gauze is introduced as before. The vagina is prepared in every instance, even though the operation is to be confined to the abdominal route. The lower bowel is thoroughly emptied by an enema of soap and water three hours before operation. The patient is catheterized immediately before entering the operating-room. In the preparation of the abdominal surface and vagina, strict asepsis and antisepsis is practised; a sterile stiff-bristle surgeon's scrubbing brush is used, but although the scrubbing is long continued, care is taken not to irritate or excoriate the skin. The preparation is

always made by a nurse who is well advanced in her training, and who thoroughly understands the principles of asepsis and antisepsis, and in the selection of this nurse it is an imperative rule that she has in no way come in contact with a patient from whom there is even the possibility that pyogenic organisms might be carried.

*Preparation of Dressings, Towels, etc.*—The operating cloths, aprons, sheets, operating towels, and the operating clothing of the surgeon, assistants and nurses are sterilized by superheated steam in a Sprague sterilizer. The temperature of the sterilizer is maintained at 240° F. under 15 pounds pressure for two hours. All dressings, gauze sponges, gauze, drains, etc., are sterilized in the same sterilizer for two consecutive days and for two hours each day. Each material or article is enclosed in a muslin bag and marked. They are not tightly packed, so that all parts are exposed to the same degree of temperature. They are kept in the muslin bags in sterile glass jars between sterilizations, in a special room for this purpose, and after the last sterilization they are folded in a sterilized sheet and placed on a sterile glass table in the operating-room, from which position they are not disturbed until used.

Gauze sponges are employed, and are made of various sizes by sewing together (quilting) 18 layers of plain absorbent gauze. The edges are folded in and hemmed, to prevent the escape of loose threads into the peritoneal cavity. Seven of these sponges are employed at each operation, one 3 x 3 inches, two 10 x 7 inches and four 5 x 5 inches. This constitutes a set, and two such sets are prepared for each operation, although only one set is usually used. The number of sponges, always seven, is counted twice before sterilization, once in the presence of three nurses immediately before operation, and twice after the abdomen is ready to be or is closed. The absolute determination that every sponge has been removed from the abdominal cavity is the duty of the first, second, third nurse and the surgeon.

*Preparation of the Ligatures and Sutures.*—Four sizes of twisted silk are used—heavy silk (No. 5) for ligature of the large arteries; medium silk (No. 4) for suture of the cervix in hysterectomy and the ligature of the smaller vessels; a smaller size (No. 3) for various suturing in the abdomen; fine silk (No. 2) for the peritoneum and intestinal suture. These four sizes of silk are cut in lengths (18 inches long), and sufficient of each for an operation is placed loosely in packages made of two, then three layers of sterilized gauze and marked. The silk is sterilized by fractional sterilization in the Sprague sterilizer for 20 minutes, on two consecutive days immediately preceding operation. Silk-wormgut is used for suture of the abdominal incision in case the "through-and-through" or interrupted mass suture is employed. It is the heaviest and longest size, and is sterilized by boiling for five to seven minutes with the instruments at the time of operation. Catgut is employed for suture of the peritoneum and fascia of the recti muscles in closing the abdominal wound, and frequently as a ligature material and suture in the abdomen. The catgut is prepared by soaking in juniper oil for a week. The oil is then washed out with ether and the catgut is soaked in ether for 48 hours. It is then rolled on glass spools and is placed in a sterile glass jar containing pure alcohol. The gut is boiled in the alcohol for an hour at a time on several successive days. It is used directly from this jar and is always boiled in the alcohol for an hour before the operation. The alcohol is boiled by placing the glass jar in a vessel of hot water. Although this method of sterilization of catgut would not seem absolute, it has been the method employed for ten years in this hospital, and in no instance could the slightest infection be attributed to catgut. We would explain this by the fact that during these years it has been prepared and handled up to the time it reaches the surgeon by one nurse whose conscientious appreciation and application of asepsis cannot be questioned. An equally satis-

factory and assuredly sterile catgut is that prepared by the cumol-formalin method.

During the operation the silk is allowed to soak for a half hour in a 1-500 solution of mercuric chlorid made with sterile water and immediately before it reaches the surgeon is passed through boiling sterile water. The catgut is taken from the jar with forceps, catching the free end, in no way handling or exposing the spool, and is also passed through the mercuric chlorid solution.

The handling, preparation, and sterilization of every form of ligature and suture material, from the time it comes from the shops until it is handed to the operator during operation, is the duty of the one nurse referred to, the chief or first operating nurse. Further, at operation it is the only duty of this nurse to prepare ligatures, sutures, and dressings and handle them at the time of operation. She in no way comes in contact with any patient or possible infection. We would emphasize the importance of such a person in maintaining strict asepsis of these materials.

*The Water.*—The water used during operation for washing the wound, rinsing the sponges, the hands of the operator, assistants and nurses, making the potassium permanganate, oxalic acid, and mercuric chlorid solutions is drawn from a Kny-Sprague water sterilizer. It is carried to the operating-room in special sterilized and covered glass demijohns. The process of preparation is the distillation and the heating of the water by steam to 250° F. under 15 pounds pressure.

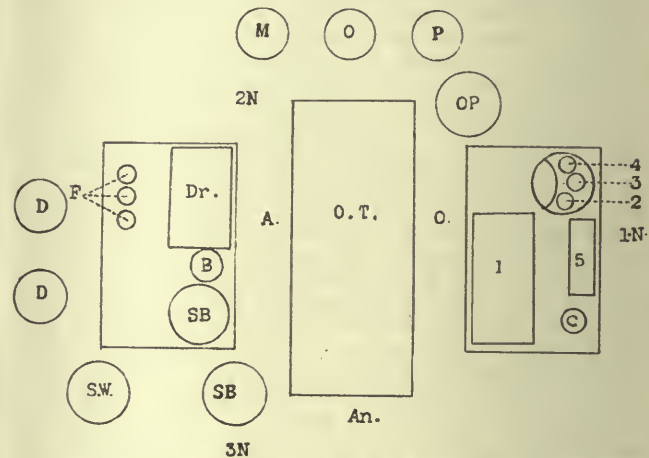

*Sterilization of Instruments.*—Instruments, glass and rubber drainage tubes, and any rubber appliance is sterilized by boiling for 30 minutes in a 1% solution of sodium carbonate. They are placed on a convenient tray and boiled in an instrument sterilizer heated by gas. The knife is boiled for seven minutes. Immediately before the operation the tray containing the instruments is carried to a sterilized tin receptacle containing a sterilized solution of the sodium carbonate. Appliances that are impaired by moist heat or steam are sterilized by thoroughly washing, scrubbing with green soap, rinsing, scalding with boiling hot water, and soaked in a solution of the mercuric chlorid (1-1,000). The same cleansing is practised after operation. Basins are sterilized by boiling for 30 minutes. No material that cannot be sterilized by boiling or steam is used a second time when it has been in any way in contact with an infected patient. As few instruments as possible are employed, 19 in all: one scalpel, two abdominal retractors, a needle-holder, two pairs of scissors (one curved on the flat and one straight), two pedicle needles, six small, two Tait and two Spencer Wells hemostatic forceps, and one dressing and one rat-tooth forceps.

*Apparatus.*—All apparatus, such as tables, etc., are prepared by thoroughly scrubbing with sapollo and water, scalding with boiling hot water, and washing with a solution of the mercuric chlorid (1-1,000). Glass top and iron frame tables and the Bolt operating-table are used.

*The Operating-room.*—The night preceding operation the walls, floors, and ceilings of the operating-room are flushed from top to bottom with a hose, mopped with a wet cloth and wiped throughout with a solution of mercuric chlorid (1-1,000). The room is then closed and not opened until the beginning of the immediate and final preparation of the apparatus. No one enters the operating-room after the primary cleansing, except those prepared to assist at the operation. When operation is performed upon a patient who has any infectious process or there is a possibility of this, a formalin gas sterilization is practised before the operating-room is used again. Likewise, any recovery or private room is disinfected in this way after being occupied by any patient having an infection.

*Operator, Assistant and Nurses.*—There are two assistants and three, sometimes four nurses in attendance at

each operation. The first assistant stands opposite the operator, and assists by sponging, holding a retractor or other instruments, or by following the surgeon's directions. He avoids introducing his hands into the wound or abdominal cavity as much as possible. The first nurse stands directly behind the operator, on the opposite side of the instrument table, and her sole duty is to care for the threading and handling of ligatures and sutures. The ligatures and sutures are placed in an earthen receptacle having five compartments and the surgeon is familiar with the size of silk to be found in each compartment. The aneurysm needle is threaded and similarly placed, always ready for immediate use. Each needle after it is used is returned to a certain receptacle. The second nurse assists in the final preparation of the abdomen and arranging of towels before the operation, oversees, constantly watches the strict maintenance of asepsis during operation, assists in the filling of vessels with sterile water, elevates and lowers the operating table. She is a nurse long experienced, thoroughly con-

scientious and her service is to be absolutely depended upon. The third nurse washes the sponges and hands them to the first assistant or operator. The second assistant administers the ether. He must of necessity be a trained anesthetizer. The operator, assistant, and nurses take a daily bath, and each morning of operation the hands, arms, shoulders, and axillae are scrubbed in the bath as though preparing for operation; the hair is also washed in this bath. Under no circumstances do they attend any patient suffering with an infectious or septic condition. If they have done so, they are not allowed to assist at an operation for from a week to 10 days, during which time they practise sterilization of the hands thoroughly once daily, not in the hospital, and when they assist again it is imperative that they wear rubber gloves. The attendance upon such patients or the dressing of any septic or suspiciously septic wound, if unavoidable is carried out with rubber gloves. Such duties are usually delegated to one person, who is in no way connected with the operative technic. The operator carries out the same precautions.

The operator, assistants, and nurses enter the operating-room some time, certainly a half hour, before the operation, dressed in sterile clothing, with sleeves rolled up almost to the axilla. Running hot filtered water in a sterile baby's bathtub (as hot as the hands will bear) is employed for preparing the hands and arms. Ivory soap is used, because it is penetrating and least apt to cause chapping. A stiff-bristle surgeon's brush, sterilized by boiling three minutes, is employed for

scrubbing the hands. The finger-nails are kept pared down as far as possible, so that no dirt can collect beneath the nails. The edges of the nails are kept round and smooth. The tissue covering the base of the nail is pushed back sufficiently to secure cleanliness and prevent excoriation. The hands and arms are scrubbed hard, energetically and continuously for 20 minutes, often longer, until the patient is etherized and placed upon the operating table. I believe there is a strong personal factor in the degree of cleanliness gained by this scrubbing. The soap is repeatedly washed off and renewed. The water is also constantly renewed and kept hot. Particular attention is paid to scrubbing beneath and about the finger-nails, about the wrists and folds of the hands, not escaping the surfaces between the fingers. The scrubbing is often continued until the skin is slightly macerated, like that of a washwoman. In the midst of the scrubbing, after 10 minutes, the surfaces beneath the nails and at the base of the nails are lightly gone over with a metal nail cleanser, which stirs up and makes more easy the separation of bacteria, that are so apt to be found here and are removed by renewing the scrubbing.

The hands and arms are then scrubbed free of soap, immersed for two minutes in a saturated solution of potassium permanganate, at a temperature of 110° F., then decolorized in a hot saturated solution of oxalic acid and then immersed and scrubbed in a hot solution of mercuric chlorid (1-1,000). A large sterilized gown is now put on the operator, the assistant, and each nurse, the sleeves being tied above the elbow. The hair is covered with a sterilized skull cap. The first assistant and the second nurse make the final preparation of the abdomen, removing the dressing, scrubbing the surface with ether, alcohol and a solution of mercuric chlorid. Sterile towels and sheets, and a large square of sterile gauze having a central slit or opening, are placed about and over the site of operation by the operator. The assistant and nurse then scrub and antisepticize their hands for a minute or two again, rinse them in sterile water, put on the sterile gown, the assistant also putting on rubber gloves, and the operation is begun, maintaining the same degree of asepsis throughout. Handling of tissue is avoided as much as possible. Metal retractors are used for separating the wound and forceps for the handling of tissue in suturing. During the course of operation the intestines are displaced upward, out of the pelvic cavity, and held in this position by the two large gauze sponges; isolating and exposing only the area of operation. The site of operation is constantly kept clean by sponging, and if necessary by irrigation. At the termination of the operation, just before the abdomen is closed, all blood and possibly remaining shreds of tissue are removed by irrigation with hot normal salt solution. A sufficient quantity of this is used to fill the pelvic cavity almost completely, and is then quickly soaked up in clean gauze sponges. This process is usually repeated twice, rarely three times, the two larger sponges being removed before the last irrigation, and a much larger quantity of the salt solution introduced. All bleeding is controlled, even small oozing areas, before irrigation is begun. As a test for bleeding, two perfectly clean sponges are placed in contact with the site of operation with the patient in the horizontal position, and allowed to remain one minute. Their appearance on being removed determines whether all bleeding points have been controlled. Before the last 2 cm. of the peritoneal incision is closed one liter of hot normal salt solution is introduced into the peritoneal cavity and allowed to remain there. As a rule it is necessary to elevate the patient to the Trendelenburg position in order to introduce the solution. The normal salt solution is prepared by having a standard solution (made by adding sodium chlorid to the distilled and boiled water and boiling this solution for an hour), a dram of which when added to a

liter flask of sterile water produces .6 of a 1% solution. The temperature of the solution should be about 110° F.

No door is opened or person allowed to leave the operating-room until the abdomen is closed, and the dressing and binder applied. In the rare cases in which a drainage-tube is introduced, it is cared for by the third nurse assisting at the operation, and strict asepsis is maintained during its care until it is removed. The dressing of the abdominal wound is composed of many layers of sterile gauze, covered by a large sterilized abdominal pad, held in position by a six-tailed abdominal flannel binder. This is placed and pinned in position by the first and second nurses. The first two layers, and thus many of the other layers of gauze are held over the wound by a sterile preparation of collodion, except when a drain has been introduced.

Rubber gloves, sterilized by boiling for 10 minutes, are always worn by the first assistant. They are worn by the operator and nurses in operations in which pus or any infected material is to be handled, and when for any reason there is the least suspicion of a previous patient having had infection. In putting on the rubber gloves they are caught by the edge of the gauntlet, filled with sterile mercuric chlorid (1-1,000) and the hand is easily and completely introduced without touching the outer surface of the glove. The gloves, if worn at the beginning of the operation, are never removed until the abdominal wound is completely closed. The medium weight and those having a roughened outer surface have been found the most satisfactory. The principal of the use of rubber gloves is to protect the hands of the operator and his assistants from infection, rather than to protect the patient. It is believed that the constant use of rubber gloves induces carelessness in the carrying out of the aseptic and antiseptic technic.

The most rigid discipline is practised in the operating-room. The personal asepsis and the asepsis of every detail of the technic are continually watched and criticised. The work is systematically divided among the assistants and nurses, and each attends strictly to his or her own duty and nothing else. The early presence of the assistants and nurses at the operation is insisted upon, the rule being that they must be in the operating-room a half hour before the beginning of the operation. No one is allowed to touch anything that has not been sterilized. It is the rule to consider no part of the technic "good enough," every assistant and nurse is made to feel seriously the responsibility of their position, and in their daily duties to be ever conscious of this responsibility and avoid personal infection.

The avoidance on the part of the operator, his assistant and nurses of coming in contact with infectious cases, the wearing of rubber gloves, and these with care when examining such cases, the assurance in this way that no pathogenic bacteria are being carried on the hands, we deem of the first importance in maintaining the best technic.

*The Treatment After Celiotomy.*—At the termination of the operation, the patient is immediately removed to a recovery room and placed in a bed covered with sterile sheets. Hot cans are placed about her and any necessary stimulation administered hypodermically. If there is profuse sweating a hypodermic of .6 mg. ( $\frac{1}{100}$  grain) of atropin is given. A special nurse is required for the first 24 hours, or until the bowels are opened and the patient considered "convalescent." The patient lies upon her back for the first four days. Unless the operation was a ventrosuspension she may be moved partly upon her side after this time by placing a pillow behind her for support. After the effect of the anesthetic has passed off the patient is made more comfortable by raising the knees over a pillow. If she complains of backache the pain is relieved somewhat by slipping a folded sheet beneath the small of the back. For 8 hours, until after the nausea of anesthesia has disappeared, thirst is relieved by moistening the tongue and lips with a cloth wet with cold water

or wrapped about a piece of ice. Nothing is administered by mouth for these 8 hours, then small quantities of hot water or soda water (1 dram) are given every half hour and gradually increased if it is retained by the stomach. Severe pain, nervousness and sleeplessness are relieved by a small dose of morphia, 8 mg. ( $\frac{1}{8}$  grain) administered hypodermically. In rare instances it is necessary to repeat the morphia. Each celiotomy patient is usually given one dose of morphia, even though there is no pain. It has been found to do no harm and affords great comfort. At the end of 12 hours purgation is begun by giving .63 gram ( $\frac{1}{8}$  grain) doses of calomel every hour until six doses are given, followed by 2 or 3 two-gram (31 grains) doses of Epsom salts. Three or four hours after the last dose of salts is taken, or earlier if the patient feels inclined to have a bowel movement, a soap and water enema, containing 4 cc. (1 dram) of turpentine is given. If this enema is not effectual it is repeated after three or four hours. Finally, if this one fails a high compound enema composed of 31 grams (1 ounce) of Epsom salts, 30 cc. (1 ounce) of glycerin, 8 cc. (2 drams) of turpentine, and 235 cc. (8 ounces) of warm water is given. The first or second enema, however, is nearly always sufficient to open the bowels. If the patient is uncomfortable and unable to pass flatus freely she is relieved by the introduction of a rectal tube. Vomiting caused by the anesthetic is usually much relieved by placing a large strong mustard plaster over the epigastrium for a few minutes.

For the first 24 hours the urine is drawn every 8 hours with a sterilized catheter and under antiseptic precautions. After this time the patient is encouraged by every means to pass her urine. Food is administered soon after the bowels are open (the patient is considered "convalescent"); usually at the end of 24 hours. Small quantities of milk, buttermilk, and milk and lime water, soup, soft boiled eggs, etc., are given frequently, and after 24 hours more she is allowed the ordinary soft diet of the hospital. The temperature usually remains about 100° F. during the first 48 hours and then quickly drops to normal. The maximum temperature is observed during and immediately after the purgation. The pulse remains below 100, but may in a successful case reach 120 or 130. Drainage-tubes or gauze drains are removed at the end of 24 hours, unless the bowel has been injured, when it remains for three days. A soft rubber tube replaces the drain for two days, being removed in sections to allow the tract to be obliterated from the bottom. A few hours after the bowels are opened the patient is returned to the ward. The first dressing is made and the sutures removed on the fourteenth day after operation. All patients are kept in bed for three weeks, allowed to sit up in bed for two days, then get out of bed and leave the hospital three or four days later, or as soon as they are sufficiently strong.

This aseptic and antiseptic technic and after-treatment is that employed in the usual case, but is of course subject to modifications in the complicated cases.

The following series of 93 consecutive celiotomies performed by me will serve in a sense to demonstrate the value of this technic. They were consecutive and unselected cases, patients of all classes coming to a gynecologic hospital. One patient was lost, but the death was the natural result of a far advanced sarcoma of the uterine parenchyma, involving all tissues to the pelvic bones, and the operation was a simple exploratory celiotomy. The fact that an operation was performed and an anesthetic given hastened the death a few days, but was in no way responsible for it. It has seemed therefore quite justifiable to exclude this one case from the statistics.

The celiotomies performed were as follow: Hysteromyomectomy, leaving the ovaries intact, 8 times; salpingoophorohysteromyomectomy, 13 times; salpingoophorohysterectomy, 2 times; hysterectomy, when both tubes and ovaries had previously been removed, 2 times; panhysterectomy, 1 time; bilateral salpingo-

oophorectomy, 2 times; unilateral salpingoophorectomy, 3 times; ventrosuspension and unilateral or bilateral salpingectomy, 3 times; ventrosuspension, with plastic operations on the tubes and ovaries, salpingostomy or elevation of the ovaries, 9 times; ventrosuspension with appendectomy, 6 times; ventrosuspension with plastic operations on the cervix, vagina, or both, 18 times; ventrosuspension alone, 6 times; appendectomy or abdominal drainage of an appendiceal abscess, 4 times; elevation of the ovaries, 1 time; elevation of the stomach, 3 times; gastrotomy, 1 time; cholecystotomy, 3 times; ventral hernia, 1 time; drainage of tuberculous peritonitis and tuberculous infected ovarian cyst, 1 time; exploratory celiotomy for abdominal fistula, 1 time.

Hysterectomy was practised for the following diseases: Myoma of the uterus, 21 times; inflammatory disease, 2 times; excessive metrorrhagia, 2 times; carcinoma of fundus of uterus, 1 time.

Salpingoophorectomy: For pyosalpinx and tubo-ovarian abscess, 1 time; papilloma of ovaries, 1 time; extrauterine pregnancy, 3 times; and multilocular glandular cystoma, 4 times.

Salpingectomy, salpingostomy, or elevation of the tubes and ovaries were performed for bilateral pyosalpinx, 4 times; hydrosalpinx or closed abdominal ostii, 6 times; bilateral tuberculosis of the tubes, 2 times; hematosalpinx, 1 time; and prolapse of the ovaries, 3 times.

Appendectomy for acute suppurative appendicitis or appendiceal abscess, 4 times; and chronic obliterating appendicitis, 6 times.

Elevation of the stomach for gastroptosis, 3 times; gastrotomy for gastric ulcer, 1 time.

The abdominal incision in every case, except five in which drainage was introduced, was closed by the layer method; the peritoneum with a continuous fine catgut suture, the fascia of the recti muscles with a larger size continuous catgut suture, and the skin with a fine silk intracutaneous suture. In the five cases in which drainage was necessary the incision was closed with the "through-and-through" silkwormgut suture, catgut being employed to suture the fascia. A gauze condom drain (the Mikulicz drain surrounded by a tube of rubber tissue) was used in all these cases. Drainage was instituted in one case when a rectoabdominal fistula had been closed after the removal of the fetal bones of an old extrauterine pregnancy; in two cases to drain an appendiceal abscess; in one case of tuberculous peritonitis; and in the remaining case where there was papilloma of the broad ligament, to destroy any remaining papillomatous tissue. Thus drainage was employed in about 5% of the cases; only in the two appendiceal cases actually as a drain.

In no instance, regardless of the character of the disease for which the patient was operated upon, was there infection or any suppuration of the abdominal incision, no hemorrhage in the tissue or other complication. No ventral hernia has been observed. One or both ovaries and more or less functioning uterine tissue was preserved, the operation described by me, in removing a myoma of the uterus in eight cases. Plastic operations, salpingectomy, salpingostomy or elevation of the ovaries, were practised to preserve the functions of ovulation, menstruation, and to allow the possibility of impregnation, in 13 cases. No patient thus operated upon has returned for operation. All are relieved of symptoms.

Intestinal injury was repaired in five cases and a rectoabdominal fistula in one case. A postoperative fecal fistula occurred, being present for three days, in the case of the rectoabdominal fistula.

All the patients recovered completely without complication, unless the case of exploratory celiotomy for advanced sarcoma of the uterine parenchyma be included. Adding this case there was one death in 94 consecutive celiotomies, a mortality of 1.06%.

## THE TREATMENT OF SUPPURATIVE INFLAMMATION OF THE KIDNEYS.

BY

FRANK WARNER, M.D.,

of Columbus, Ohio.

Professor of Operative and Clinical Surgery, Starling Medical College, Columbus, Ohio.

The causes of suppurative inflammation of the kidneys are so varied that the treatment which may be instituted for its relief is commensurate with its causes. Yet, numerous as are the causes of this disturbance, there is still a considerable sameness in the producing factor of all. First, a plain catarrhal inflammation; second, an infection. (a) This infection, from within, conveyed through the blood; (b) from without, infection carried into the bladder through the urethra, perhaps by a catheter, which may have been none too clean.

The most frequent cause, of course, is the presence of a renal calculus. This source of irritation begets first a simple catarrhal inflammation, which sooner or later takes on the suppurative variety of inflammation. However, this is not true in all cases, especially in recent cases of renal calculus. Yet, in the older cases there is an ulceration of tissue and a breaking down of some blood-vessels, as shown by the usual accompaniment of hematuria. Soon after this, if pus is not found in the urine, the case is pursuing an unusual course.

Pus in the urine, as a symptom, may mean a great many different things. It may mean an abscess in one or both kidneys, a pyonephrosis, an interstitial nephritis, or the suppurative trouble may be confined to the pelvis of the kidney alone, a pyelitis. Pyuria, however, more frequently means that the pus comes from the bladder rather than from the kidneys, and this is a very fortunate circumstance. Even though the pus is reasonably demonstrated to come from the kidneys, the patient may soon make a perfect recovery. A greater amount of hazard from an extensive involvement of the kidneys may ensue, even though in the beginning the pelvis of the kidney alone be involved in this suppurative trouble.

I have not found the settling of the question of the location of the diseased area which produces the suppurative in pyuria the simple one that many of our textbooks seem inclined to lead us to believe. It is true, if in the microscopic examination of the urine, we find associated with the pus an unusual number of large, flat, epithelial cells of the bladder wall, we may conclude at least that the bladder is involved in this suppurative inflammation even though the ureter and kidneys are escaping. Yet, should we infer that a purulent cystitis is that and nothing more, I am sure we should be led into frequent errors. If with pyuria we find the round-celled renal epithelium freely cast off, the likelihood of the disturbance being located in the pelvis of the kidney is very strong. If associated with the pus, the small spindle cells of the kidney present themselves, and especially if accompanied by renal casts, the case is not difficult to diagnose as one of interstitial nephritis. Without these casts, and having simply the small spindle cells to guide us, along with the presence of pus in the urine, we are still in the dark as to whether the trouble is in the kidney substance proper or whether the pus is yielded from some pathologic lesion in the ureter, for the appearance of the epithelial cells in the two regions present many similar peculiarities, confusing any but the most expert in microscopic manipulation. So many times in an examination of urine containing pus, epithelial cells from every part of the urinary tract are found, and not in excessive numbers the one kind over the other as to indicate the source of the chief disturbance. This would suggest to us the importance of not relying unduly on the microscope for our diagnosis of these suppurative disturbances of the urinary tract. While of the

greatest aid in helping us to formulate a conclusion if associated with the symptoms that pus formation has given rise to, without the clinical history we are going to fall far short of arriving at the truth if we fail to combine in each case laboratory results with case history. Take, for instance, one line of causes of suppurative inflammation involving a considerable area of the urinary tract, hypertrophied prostate, or strictured urethra. Sooner or later there is an infected bladder. From the purulent cystitis there may result an ascending inflammation taking in the pelvis of the kidneys, or even still higher into the kidney substance itself, forming a pyonephrosis. Falling short of the interstitial nephritis, we could certainly do nothing better to relieve the pyelitis than to relieve the strictured urethra or to overcome some of the cystitis due to the hypertrophied prostate, by frequent carefully administered aseptic irrigations of the bladder, and the regular catheterization of the bladder with a clean instrument. We must recall that one of the most frequent ways of producing a pyelitis or an interstitial nephritis is by a dirty catheter. It is difficult to persuade some of the laity of this proposition, yet every physician, after he has been in practice a few years, encounters such cases. If the hypertrophied prostate that is complicated with pyuria is handled with reasonable skill along the lines indicated, we shall soon see not only the bladder symptoms mitigating, but the ascending pyelitis will soon diminish or perhaps disappear, providing, of course, destructive changes have not already occurred in the kidneys. This, however, we cannot foretell without tentative trial. By this treatment we will have accomplished a twofold purpose: first, the bladder irritability will have been lessened and the chances of still further ascending pyelitis diminished; second, we will have demonstrated whether the possibility still exists of benefiting the patient by one of the more radical operations for the relief of the symptoms due to a hypertrophied prostate. If we cannot secure a material diminution of the pyuria by irrigation and catheterization, we will not accomplish good by a radical operation upon the prostate. If the case is of long standing and the infected area is not greatly benefited by the means just stated, the presumption is that the kidneys are involved in a pyonephrosis that will not yield or even be favorably influenced by an operation upon the prostate, however much good the operation may have done in the first place. At the same time that we are making this local treatment to the bladder from which the ascending pyelitis developed, we can accomplish some good by rendering the urinary tract as sterile as possible, by administration of some such therapeutic agent as salol, sodium benzoate, etc., and the free drinking of water to flush out the urinary tract.

To illustrate the development of a case of pyuria by direct infection, there comes to mind one of a typical case following typhoid fever and which may follow any of the infective fevers.

A male of 50 had typhoid fever. At the end of six weeks, when all seemed to be progressing well toward convalescence, the patient developed irregular chills, followed by sharp rises of temperature. There was very little to attract the attention in the direction of the kidneys. It is true there was some slight pain in the back, but hardly of a kind or degree to suggest the kidneys as a cause. In making a systematic inquiry as to the various secretions, the information was elicited that the quantity of urine was decidedly increased; that the patient urinated not only several times in the course of the night but a considerable quantity at each urination. Of course this at once suggested the idea of an examination of the urine. The faintest traces of albumin were found, but the sediment gave greater information. The microscope revealed pus in the urine. It not only revealed the presence of pus but the exfoliation of characteristic round-celled epithelium such as lines the pelvis of the kidney. There were present not more than the normal number of bladder epithelial cells. There were no bladder symptoms, such as vesical tenesmus, and no exfoliation of bladder epithelium, but as there was present the characteristic renal symptom of a pyelitis such as frequently follows the infective fevers, the diagnosis was regarded as made. The

urinary tract was kept in as aseptic a condition as was possible by the administration of salol. Large draughts of water were encouraged that the kidneys might be daily flushed to carry away the debris. Indeed, it seems a provision of nature that the polyuria which is associated with pyelitis is an effort of the kidneys to free themselves of the accumulating pus and inflammatory debris.

Despite the ease with which the suppurating surface was located in this case of pyuria, sometimes I have not found it so simple a matter. Morrow makes the suggestion of washing out the bladder and collecting a sample of urine within 10 or 15 minutes after that. He argues that if the pus comes from the kidneys you will get it in this way; if from the bladder, the thorough irrigation will have washed the pus so completely away as to give a urine free from pus for the time being. Personally I prefer to leave the catheter in after the irrigation and collect the sample in that way. I believe the chances of error are much less in following this custom. With a calculus in the kidney the element of pain is usually such a factor in aiding us to make our diagnosis that the presence of pus in the urine is only a confirmatory symptom. Yet I have seen all the symptoms of renal calculus present with a pyelitis and yet all symptoms subside.

For instance, here is a case that presented all the symptoms of renal calculus of the right kidney:

The patient had an intermittent hematuria, intense pain at times over the right kidney, radiating down the ureter, the pain being aggravated by motion; there was occasional vesical tenesmus and pus in the urine. It was demonstrated by the separator that this pus did not come from the bladder but from the right kidney. The patient was greatly run down preceding the disturbance of the kidney. Rest in bed and a tonic treatment brought about a complete subsidence of all symptoms and the trouble disappeared.

The trouble was evidently a simple suppurative inflammation involving the pelvis of the right kidney. This condition had been made more possible by the preceding ill health. The correction of the ill health had rendered it more probable of getting rid of the pyelitis before there was extension of the suppurative inflammation into the kidney itself. The high grade of pain in this case was evidently due to the inflammatory disturbance present; such a high grade of pain in a simple pyelitis being quite contrary to my experience, denoting rather the presence of a calculus, or as I have sometimes seen oxalic acid crystals produce this pain during their passage down the ureter. It seems to me this case should suggest to us the fact that as in all cases of pyelitis the health is greatly impaired, a tonic, reconstructive course of treatment should not be lost sight of while attempting to render the urinary tract as sterile as possible.

The symptoms that characterize a pyelitis due to tuberculosis of the kidney and those that are the result of a renal calculus have not always been distinctive in my cases. It is true that the element of pain is usually greater with stone. But the vesical intolerance, the fever, the emaciation, the polyuria may be very similar in the two cases. Purdy thinks blood is found in the urine at an earlier period with stone than in tuberculosis of the kidney. This has not been a distinction that has guided me in a differentiation of the two troubles. The Röntgen ray is valuable as a point of differentiation in some cases, but the Röntgen ray does not show all forms of calculi. The emaciation, as a rule, is greater in tuberculous cases, especially at an early stage. But after a prolonged suppurative disturbance about the kidneys, the eventuating hectic, resulting from whatever cause, leads to an emaciation that makes the latter symptom one of doubtful utility.

When a suppurative disturbance has continued so long as this, operative treatment is imperatively demanded. If a stone is found, remove it. If a tuberculous mass which is confined to the seat of its usual place of earliest implantation, near the pelvis of the kidney, break the mass down and treat it by drainage through the lumbar

incision. If the kidney seems so extensively involved as to render the cure from a mere nephrotomy ineffective, then we had best run no further chances by prolonging the destructive disturbance, but at once resort to a nephrectomy; provided, of course, that we are previously satisfied that the trouble is confined to the one side, and that two kidneys are in existence. If in the course of the operation a pyonephrosis is located and we are content to treat the disturbance by drainage alone, we should satisfy ourselves that the ureter does not contain a calculus which has been the original cause of the trouble in the kidney.

To attempt to discuss all phases of the treatment of suppurative inflammation of the kidneys would be quite out of the limits of a paper of this character, but I am convinced in having examined many specimens of urine in cases of slight alteration of the normal urinary flow, that there are quite a few of these cases which are the result of a very mild grade of pyelitis, and that many of the patients are promptly cured by timely administration of urinary antiseptics, especially if these are backed by a judicious tonic course of treatment.

## DIRECT FIXATION IN FRACTURES.\*

BY

GEORGE W. GUTHRIE, M.D.,

of Wilkesbarre, Pa.

Surgeon of the Wilkesbarre City Hospital; Consulting Surgeon to the Pittston Hospital; Ex-President Medical Society, State of Pennsylvania, etc.

The classic method of treating simple fractures by manipulation, coaptation of fragments, and the application of retentive dressings, generally gives good results. The same may be said of the treatment of compound fractures, provided a condition of asepsis be secured and maintained during the process of repair. A number of circumstances, however, even in simple fractures, militate against good results: for example, muscular action, interfering with good coaptation; the interposition of soft parts, muscles, fascia, and the like, and probably also blood-clots and lymph. To this may be added great obliquity in the line of fracture, and great irregularity in the fractured surfaces, as sometimes occur in cases of fractured patella. To overcome these obstacles, many surgeons advocate cutting down on the seat of injury and reducing the fracture by direct fixation. Direct fixation may be defined as a process by which the fragments of bone are accurately adjusted and securely fastened, in order that bony union may be obtained and deformity prevented.

W. Arbuthnot Lane,<sup>1</sup> of England, says: "In simple fractures the surgeon failing to secure accurate apposition, as determined by the radiograph, should cut down on the site of fracture and restore the bones to their original condition and hold them by wiring or by nails."

Dr. W. W. Grant,<sup>2</sup> of Denver, believes "the only way to maintain more certainly the accurate coaptation of fragments in certain oblique and joint fractures is to immobilize them by silver wire, screw, nails, or clamp, but only under the most approved aseptic conditions. In the absence of infection the results must be better. This department of surgery has not met the courage and skill that has been manifest in other fields, and it is too important not to receive the serious attention it deserves." Again he says,<sup>3</sup> "nothing short of operation by wiring, nailing, or fixation by some such contrivance will enable the surgeon to adjust thoroughly and fix the fragments."

The *New York Medical Record*<sup>4</sup> says editorially: "We may say, therefore, that in cases in which ordinary means of reduction fail, we must consider the advisability of making an incision and thus reaching the seat of difficulty. . . . The general rule may, therefore,

\* Read before Luzerne County Medical Society, November 5, 1902.

be laid down that in fractures, simple or compound, when reduction is impossible by ordinary means we must consider the application of bone or ivory supports in the shape of collars, nails, or screws to maintain the ends of the bone in their proper relation."

Dr. Estes in his address on surgery before the State Medical Society at Lancaster in 1898, said that "explorations by incision and adjustments of fragments by sight are not only justifiable, but in many instances absolutely essential for proper treatment. An accumulating array of instances has shown these incisions do not augment the danger when the operation is done with proper aseptic precautions, and that they markedly improve the results of treatment. The open method of treating fractures in proper cases is now not only the safe method but the proper and imperative method of handling many fractures."

In the management of compound fractures the same rule as to the necessity of fixation of fragments holds good, for closed fractures become compound fractures when they are treated by the method of open incision. In the care and treatment of ununited fractures, or pseudarthroses, the method of incision, resection of the ends of the bone and fixation of fragments by some of

Radiograph taken five weeks after injury.

the various methods, has the almost general support of the profession.

**Methods of Fixation.**—Many schemes have been proposed by the profession to carry out the purposes of fixation. Some of them are very ancient. Senn<sup>5</sup> says that Lapeyode and Siere, of Toulouse, are supposed to have been the first to use silver wire for this purpose in 1775. Both Agnew and Holmes say that fixation by wiring was first suggested by Horeau in 1805. In 1845 Dieffenbach advocated drilling several holes through the ends of fragments and the insertion of ivory pegs, but this was rather for the purpose of exciting inflammatory action and the deposit of bony callus than for fixation; the pegs were subsequently removed. With the same object in view Pancoast, in 1857, drilled through both fragments, pinning them together, and left the drill in position, removing it after bony union had been secured.

Among the modern methods of fixation the principal are: suturing; the use of ivory nails, cylinders or clamps; also intraosseous splints, and ferrules of bone, as recommended by Senn; and fixation by metallic clamps or plates, spikes, screws, or nails. A very general assent has been accorded by the profession to the use of catgut and kangaroo tendon for suturing soft structures: periosteum, torn ligaments, muscles and fascia. Senn also uses catgut to hold in place the fragments that have become separated in compound fractures, both of long bones and the skull. He carefully disinfects the separated

fragments by a warm 2.5% solution of carbolic acid, or a weak mercuric chlorid solution, places them in warm salt solution, reimplants them in their normal location and secures them by heavy catgut sutures and ligatures. His results have been most gratifying.

The whole trend of modern surgery is in the direction of the absorbable suture. Edebohls and Noble use catgut exclusively in their abdominal work. Kelly uses silk only in his four cardinal sutures for the ovarian and uterine arteries. Halsted, however, still uses silk in abdominal work, and buried silver wire in hernia. Silver is the only unabsorbable material that is worthy of the confidence of the profession in buried sutures. The investigations of Halsted and Welch demonstrate that silver has germicidal properties which render it serviceable in this work, and also as a first layer in dressings for raw surfaces. It is very easily encapsulated and very seldom gives trouble in bony structures. In three cases in which I have used silver wire for suturing the patella good results were obtained, but one of the patients returned at the end of six months with a suppurating sinus, caused by the silver wire breaking through its capsule, making its removal necessary.

The use of ivory and bone in the form of cylinders or intramedullary splints, clamps, and ferrules, has received considerable attention from some members of the profession, but they serve to show the ingenuity of the originators rather than any practical value they may possess. Their use has not become general, and probably never will. The use of metallic clamps or plates, spikes, screws or nails, has received considerable attention.

Several writers describe a clamp, made on the principle of the "iron dog" that sawyers and woodchoppers use to hold the log in position, called by one writer Gussenbauer's clamp, by another Brun's double metallic nail, one prong of which is driven into each of the fragments and allowed to remain until after union is effected, when it is removed. On the same principle Langenbeck screwed or drove a steel screw into each fragment and connected them by an iron bar. Parkhill's method of fixation, as described by Bryant, is a modification of Langenbeck's. Estes<sup>6</sup> describes a nickeled steel plate which he has been using to maintain coaptation in compound fractures for years. This plate, which is perforated with six holes, is laid across the fracture and holes drilled into the bone to correspond with those in the plate. The plate is then fixed by ivory pegs, which protrude from the wound. The plate is removed in three or four weeks by breaking off the pegs and withdrawing the plate through a small incision. In a recent letter, Dr. Estes says: "The little plate has given me great satisfaction and has been quite successful in St. Luke's Hospital." Wharton and Curtis describe a similar device in which the plate is made of silver and is secured by silver screws, entered flush with the plate and permitted to remain permanently unless suppuration ensues. Steinbach<sup>7</sup> reports four cases of fractured tibia in which he used silver plate after this method and in which he got good results. He removed the plate under local anesthesia. Several kinds of such plates have been devised and recommended, made of different materials and secured by various devices. If a good aseptic condition has been secured and the fixation devices be made of silver, whether it be wire or screws or nails, or plates secured by screws, suppuration may not ensue.

What has just been said will apply with equal force to spikes and screws or nails. In resections of the large joints, as the knee, one or two nails or pins of steel, or some other metal, are a great help in maintaining apposition and immobility; but unless they be of silver they should protrude from the wound so as to be removed after a reasonable time. This method is given by Leech<sup>8</sup> and accredited to Annandale.

Current medical literature contains the reports of a goodly number of successful cases in which nailing has been resorted to. Bryant says that operative treatment in fractures of the femoral head was first suggested by

Photograph taken six months after injury—flexed position.

Langenbeck and successfully carried out by Koenig. I quote from "Bryant's Operative Surgery:"

Koenig operated in a case of recent fracture, making a small incision over the outer side of the trochanter major, drilled a hole through it with a metal drill in the direction of the head of the bone, applied extension to the limb to the extent necessary to overcome the deformity, and then drove a long steel nail through the canal in the trochanter into the head of the bone and left it there. The limb was then immobilized and extended for six weeks. There is no record of the ultimate shortening, but good union and free motion of the joint were obtained.

Cheyne, in a case of recent fracture, exposed the fragments through a longitudinal incision made over the anterior aspect of the joint, exposed the fracture, made extension and internal rotation of the limb, and with the fingers in the wound manipulated the fragments into place; then a small longitudinal incision was made over the outer side of the trochanter major and two canals drilled through the fragments at a distance of  $\frac{1}{2}$  inch apart. Ivory pegs were then driven through the holes made by the drill and the limb immobilized. Good union and motion were obtained, but there is no record of measurements of the limb.

Gillette reports three cases of ununited fracture of the neck of the femur operated upon in the following manner: A horseshoe incision with its convexity downward was made, beginning an inch below and an inch posterior to the anterior spine of the ilium, carrying it down two inches below the trochanter major and bringing it up to the buttocks to about the center of the gluteus maximus muscle. The skin and the two layers of fascia were dissected up *en masse*. A chain saw was then passed between the posterior border of the tensor vaginae femoris and the gluteus medius, hugging the neck of the femur and the base of the trochanter major; it was brought out between the posterior surface of the gluteus medius and the anterior surface of the gluteus maximus; the trochanter major and its muscular attachments were sawed off, turned back, thus exposing the capsule of the joint. Then, by making a longitudinal incision into the capsule the fracture could be easily seen. The surfaces of the fractured ends were denuded and a bone peg driven through the neck of the femur, thus holding the fractured ends together. The capsule was stitched with catgut, the trochanter major restored and nailed in place with a small bone peg, the skin closed, and the limb immobilized. There was union and good motion obtained in all the cases, with shortening of from 1 inch to  $1\frac{1}{2}$  inches.

Curtis, in a case of ununited fracture of the neck of the femur of three months' standing, exposed the fracture through an anterior incision, passed a drill into the callus and between the fragments to cause irritation, applied extension to the limb and reduced the deformity, after which a drill was passed through the trochanter major from the outer side, transfixing the fragments; the handle of the drill was then removed and the drill itself left *in situ*. The anterior wound was closed and the limb immobilized. The extension was maintained for six weeks, at

the end of which time the drill could be easily removed. Good union and a useful limb were obtained, with three-quarters of an inch shortening.

At the meeting of the Medical Society of the State of Pennsylvania, in Philadelphia, September, 1901, Dr. Charles E. Thomson, of Scranton, reported a case as follows:

The patient, a man of 62, was injured by a fall of rock in August, 1899. He was bedridden three months, no diagnosis having been made. He then came under Dr. Thompson's care. A diagnosis of intracapsular fracture was made by radiographs. Operation recommended by Gillette, of St. Paul, was done December 12, 1899. A horseshoe incision was made around the trochanter major down to the periosteum. The flap being elevated, a second flap, including periosteum and a section of bone, about one-third of the shaft in thickness,  $2\frac{1}{2}$  inches below the trochanter was made and turned up. The fracture was found comminuted. Several pieces of bone were removed, the fractured ends adjusted, and a solid silver nail,  $\frac{1}{8}$  inch in diameter and  $2\frac{1}{2}$  inches long, was driven through the neck and into the head of the femur. The nail held the fragments firmly together, the wound was closed with catgut sutures, and the entire extremity and body encased in a plaster-of-paris dressing extending from axilla to the tip of the toes. No fever followed, the initial dressing was removed at the end of two weeks. At the end of five weeks the dressings were removed and the patient allowed to move about. He left the hospital on crutches. Seven months after the operation he complained of pain. A sinus had appeared at the seat of the incision, and this was followed later by an accumulation of pus in the gluteal region, which was evacuated under cocaine, a slight sinus persisting. Improvement continued for 18 months, when he walked without cane or crutch. He had 90° of free, painless motion. Shortly after he was found dead in bed.<sup>7</sup>

Dr. Thomson also reported at the Saratoga meeting of the American Medical Association the following:

On February 7, M. M., aged 60, a miner by occupation, fell on the ice, striking his hip. He was carried home, and put to bed for three days, afterward being allowed to sit in a chair, where he spent three months. He could not put weight on the limb for 18 months, and had constant pain in the hip. He walked bent almost double, with both hands on his cane, on which he carried the greater part of his weight, dragging his right limb. There was a shortening of one-half inch, and marked eversion of the limb. On manipulation a distinct movement could be made out between head and trochanter. On examination the patient appeared much beyond 60, and showed signs of senile degeneration; general muscular atrophy, arcus senilis, and atheromatous arteries. August 28, 1901, under complete chloroform anesthesia, a horseshoe-shaped incision was made around the great trochanter down through the muscles to the periosteum. In this case no bone flap was made; the capsular ligament was opened and the free motility of the head ascertained. We deemed this step necessary because the skiagraph showed what we feared was ankylosis of head in the acetabulum. I then drove two solid silver nails,  $\frac{1}{8}$  inch in diameter and 2 inches and 3 inches long, respectively, through

Straight position—photograph taken six months after injury.

the great trochanter, neck, and into the head of the bone. Only the long nail reached the head. It was not necessary to use the drill before driving the nails. The capsular ligament was closed with catgut sutures, external wounds with silk-wormgut without drainage, an aseptic dressing applied, and the entire limb and body encased in a plaster-of-paris spica. The patient did not suffer from the operation. He was allowed to turn over in bed. There was no elevation of temperature. The wound was dressed through a fenestrum in the spica at the

end of the third week, when the stitches were removed. Primary union was complete. The patient was removed from the hospital at the end of six weeks, and the spica taken off at the end of nine weeks, when the union appeared firm and there was 45° of free motion in the hip. Three months after the operation he could bear over half the weight of his body on the limb, and could walk upright. There was one inch shortening. Nine months after the operation the limb was straight, motion normal, shortening one inch, and he can bear the entire weight of the body on the limb without pain. He walks with a cane, but can walk very well without it. There is no pain except on direct pressure over the seat of operation.

Dr. Reed Burns, of Scranton, writes me under date of October 10, 1902: "I have nailed one fracture of the neck of the femur in a girl 10 years of age, four months or more after it occurred. I found the neck had been almost entirely absorbed; still the result has been quite satisfactory."

Dr. Leonard F. Hatch,<sup>10</sup> of Lynn, Mass., is strongly in favor of the treatment of fractures by a new method, the principle of which is to convert all compound fractures into simple ones, and when necessary to make simple fractures first compound and then simple again. He gives reports of 15 fractures treated after these principles, six compound and nine closed, or simple fractures, four of the long bones and five of the patella, all of which healed without pus and gave perfect results. He insists upon the most rigid antiseptic precautions, free incision in closed fractures, and he enlarges the wound in compound fractures when necessary, washes out thoroughly all clots and debris, removes all shreds of soft tissue and loose pieces of bone that interfere with perfect coaptation, ties all bleeding points carefully, replaces the periosteum when it is separated, accurately adjusts the fragments, using no means of direct fixation in long bones, and closes the wound with catgut sutures without drainage. Splints are applied and bandaged firmly. Dressings are removed on the seventh or eighth day and plaster cast or ambulatory splint is applied. In fractured patella he resorted to direct fixation after the method recommended by Butcher. He claims that this method of treating fractures is attended with less pain and swelling than the other methods; that it shortens the time of recovery by at least a week; that it prevents deformity and nonunion. He also strongly commends and advocates the ambulatory treatment.

The following case appears somewhat unique:

On December 4, 1901, I was called in consultation with Dr. Nathaniel Ross, of this city, to see W. T. at his home. The following history was given: The patient, aged 17, a pattern maker's apprentice, was injured about two hours before by his right elbow coming in contact with a band saw. The saw had cut through a cotton shirt and a heavy undershirt, and the elbow-joint was gaping open, a wound four inches long extending across the posterior aspect. A fragment of the olecranon three-quarters of an inch long was completely severed and retracted by the triceps tendon, and the trochlear surface of the humerus scratched by the saw teeth. The wound was thoroughly cleansed and irrigated with mercuric chlorid solution, about 1:3,000. The retracted fragment was brought down and nailed to the shaft of the ulna by driving a wire nail, called in the shops a cast steel wire brad 1½ inch, No. 16, entering about one-third of an inch from the margin of the fragment and penetrating the shaft about three-quarters of an inch. The soft parts were closed with interrupted silk sutures, the upper flap punctured so that the nail protruded slightly, a skein of catgut was left in the inner angle of the wound for drainage, and sterile gauze dressings applied. The limb was placed in a straight anterior splint from shoulder to wrist. The most perfect antiseptic precautions possible were observed throughout. The wound healed without suppuration, and the sutures were removed at the end of a week. The nail was withdrawn January 11, 1902. On the same day the accompanying x-ray picture was taken by Dr. Ahlborn, of this city. Passive movements were begun on this date and a Stromeyer splint applied, the angle of which was changed slightly every day. The accompanying photographs were taken in June, one showing the limb in a straight position, the other with the forearm flexed on the arm beyond a right angle. The patient has perfect motion of the elbow-joint, and an entire absence of deformity; in short, a perfect restoration of function.

It will be observed by consulting the radiograph, which was taken after the expiration of the fifth week, that there is little or no callus to be detected, thus con-

firming the statement of Senn that "accurate coaptation and fixation of fragments is conducive to ideal callus production," while we all know that imperfect coaptation and faulty immobilization conduce to excessive callus formation, which is most unfortunate in joint fractures. Indeed, the accurate union in this case and freedom from callus encourages the belief that osseous wounds may heal per primam very much like wounds in the soft parts.

This gratifying result warrants the conclusion that in order to secure a condition of very satisfactory asepsis it is not necessary to have at our command all the paraphernalia of the modern operating-room. Here the operating-room was the kitchen, but a very neat kitchen, in a comparatively new house; the table, a common kitchen table; the sterilizer, the range; with a tin pan in which the instruments, the nail and even the metal tack-hammer were boiled, and which served as an instrument tray during the operation. The operator should also be emboldened to attempt more surgery in the homes of patients, for with the common-sense means at our hands for disinfecting and sterilizing, to which may be added the use of rubber gloves, it is not always necessary to incur the inconvenience and suffering of rushing patients off to a hospital in order to get clean surgery, or to secure good results.

## ANEURYSM OF THE DESCENDING AORTA DIS-PLACING THE HEART.

BY

CHARLES F. BEESON, PH.G., M.D.,

of Fierro, New Mexico.

Surgeon for Colorado Fuel and Iron Company and Phelps, Dodge & Co.

CASE.—W. R., aged 48, is single and a miner by occupation. He has always done hard work, and has dissipated considerably in most every way. He has had the ordinary diseases of childhood, also erysipelas, malaria and yellow fever. He contracted syphilis 27 years ago.

I first saw this man in April, 1900, at which time he complained of pain in the back between the shoulder-blades. He had had this pain off and on for the past year. He described it as a dull ache. Examination showed dullness at about the seventh, eighth and ninth ribs posterior and to the left. There was no pulsation in this area. Heart impulse was visible over a wide area, the whole left chest, anterior, shook from the impulse. Apex beat was plainly felt three inches below and in the nipple line. The area of heart dullness was increased, it seemed as if the whole heart was bumping against the chest wall. The first sound at the apex was loud and strong. The second sound continued as a loud murmur, ending with the first sound, heard best over the mitral area and transmitted toward the apex. No murmurs were heard at the base. The heart seemed very close to the chest wall. The condition was very puzzling, and in my notes at that time a provisional diagnosis of mitral stenosis was made, little dreaming that an aneurysm was immediately behind the heart, crowding it to the wall and pressing the mitral area, producing a temporary stenosis. After a few days' rest in bed the heart quieted down considerably, the murmur still continued but was not so loud.

My patient improved rapidly and left camp in a few days, disappearing from view.

On September 4, 1901, just 17 months from the time of his disappearance, I was called to a tent and there recognized my old patient. He had aged 10 years since I last saw him, had become gray, emaciated, pale and haggard, careworn and weak. He complained of shortness of breath, pain in the back and around the heart and palpitation of the heart. He had smothering spells, was losing weight, could not swallow solid food and liquids went part way down, then stopped, and after a few moments either passed on or came up.

Upon examination an impulse could be seen in the fifth interspace internal to the nipple line on the left side, or in what is ordinarily considered the normal heart impulse area.

Palpation revealed a heaving impulse at this point and by

careful attention a distinct expansile sensation could be made out; the impulse was synchronous with the radial pulse. With the stethoscope the impulse could be heard, but there were no murmurs and no heart sounds in the left side of chest; dulness was pronounced in the region of impulse. At the right border of the sternum at about the fifth rib the heart sounds could be distinctly heard; no murmurs could be made out, although the valve areas could be easily placed. Further examination revealed an area of dulness extending from the right to the left nipple and between the fourth and sixth ribs, and extending downward and to the right to a hand's breadth below the right

A, Aorta. B, Heart. C, Left and larger portion of aneurysm. D, Cartilaginous portion of aneurysm which was attached to sixth rib anterior.

costal margin and in the epigastrium. No pulsation of the abdominal aorta nor of the femorals could be felt; the radial pulses were synchronous and of good quality, rate being about 80 per minute; artery was tortuous but no hard. Tracheal tugging was negative. A slight cough was present but not of a metallic character; there was no hoarseness.

A diagnosis of an aneurysm of the descending aorta below the bifurcation of the trachea and displacing the heart to the right was readily made.

Rest in bed, Tuffnell diet, and large doses of potassium iodid were instituted. Improvement began immediately and in 26 days the pains and pulsation had disappeared, dulness alone in normal heart area remained. The heart remained on the right side; the patient felt strong enough to go to work and so disappeared from view. He would not allow further treatment nor would he go to a hospital. I learned afterward that he was dissipating considerably.

On February 8, 1902, I was called to see my old patient, who had been drinking heavily and was supposed to be dying. I found him suffering intensely, he could scarcely breathe, and had severe pains and soreness over the chest and abdomen. He showed plainly the effects of deficient aeration. Heart impulse could be seen, felt, and heard at the tip of the ensiform cartilage. The left chest was partially filled with fluid. No pulsations could be seen or felt, and no murmurs heard. The liver dulness extended to the left and below the umbilicus.

On the following day the left chest was found to be filled with fluid which upon aspiration showed pure blood. The patient grew steadily worse, and slowly died on February 17, just 9 days from the time the leakage began. The postmortem findings were as follow:

*Necropsy*, 9 hours after death. The apparent age is about 60. Rigor mortis was well marked. Abdomen distended, and the intercostal spaces of left chest obliterated.

On opening the chest the left pleural cavity was found filled with blood. Some old clots were present. Mediastinum was displaced to the right, and there was no blood in it. The upper lobe of the left lung was lying in a blood mass, and had the

appearance, shape, and consistency of an enlarged soft spleen. Lower lobe was collapsed by compression of its mass against the chest wall. The right lung was edematous, and had numerous pleural adhesions.

The heart was lying to the right of the sternum with the left border at the right edge of the sternum vertically placed with the apex at the tip of the ensiform cartilage. It was slightly enlarged, especially at the base, and the muscle was flabby. The aortic opening was dilated, and the aorta sacculated with adherent clots and a nodular form of arteriosclerosis. The aortic valves were incompetent, with small tears near their bases. The mitral valve was negative. Springing from the descending aorta, just below the arch, was a large aneurysm the size of an adult head, attached behind to the seventh, eighth, ninth, and tenth dorsal vertebrae, which were eroded on their left sides and in front to the sixth rib, just internal to the nipple line, by a cartilaginous hardness. This attached portion was the original pulsating tumor, which came up behind the heart and displaced it. Another and larger portion spread to the left, passing between the lobes of the left lung, pressing the lower lobe against the chest wall and collapsing the upper lobe by shutting off its bronchus.

The aneurysm was also firmly attached to the pericardium, left pleura, and diaphragm. The esophagus was firmly pressed to the aneurysm by its envelopments. Its upper end being sacculated, explaining the symptom, dysphagia; its lumen was patulous, it was not eroded.

The thoracic duct could be traced to the aneurysm, but was there obliterated. The left vagus was also apparently destroyed as it passed the aneurysm. The aneurysm had not ruptured but was leaking; it was well filled with clots, but in places there was none.

The diaphragm was depressed and its curvature obliterated. The liver was enlarged, pushed forward, downward, and to the left, extending below the umbilicus. The surface was granular, hard, and resisted cutting. The cut surface shows characteristic nutmeg liver. The stomach and other abdominal contents were considerably disarranged.

An interesting question might be brought up in connection with this case: Was the diastolic murmur heard at the apex in the beginning due to pressure of the aneurysm against the heart, or was it Flint's murmur, or an aortic regurgitation?

The absence of a murmur at the aortic orifice and the facts that no murmur could be heard after the heart had slipped to the right and that the mitral valves were found negative at the necropsy lead me to the opinion that the murmur was produced by the squeezing of the heart between the aneurysm and the chest wall.

I believe I am strengthened in this opinion by a case of Dr. Osler's, mentioned in his textbook, third edition, p. 724, in which he intimates that possibly a presystolic murmur was produced by a greatly enlarged spleen with dropsy pushing the heart strongly upward.

## COMMUNICATED INSANITY OR PSYCHIC INFECTION.

BY

J. W. WHERRY, M.D.,

of Clarinda, Iowa.

Assistant Physician Clarinda State Hospital.

That an individual may imbibe ideas from another, incorporate them into his own mentality, believe in them implicitly, and conduct himself in accordance with this belief, is a fact within the observation and knowledge of all. That he may imbibe ideas contrary to former methods of thinking, that under the stress of sufficient personal influence he may even adopt beliefs directly opposed and contrary to all previous convictions and which necessitate a complete reconstruction of his entire mental fabric, is not such a common event, but occurs with a sufficient frequency to establish its possibility. A man previously steeped in sin, a frequenter of evil places, a brother of vice, at variance with society and waging war against the church, attends a religious revival. He comes to scoff, and night after night the pleadings and importunities of the faithful are laughed to scorn. But the ceremonies are impressive, the very atmosphere is surcharged with religious enthusiasm, every word uttered and every note sung is saturated with the essence of this new truth, until suddenly, and without any unusually apparent external cause he makes a complete mental surrender. It is not a matter of reason. It is not a matter of judgment. In one moment he has abandoned all the theories, beliefs, and opinions of years and adopted, without hesitation, new theories, new opinions, and new beliefs simply at the

A, Aneurysm. B, Heart.

instance and suggestion of others. The change is so extraordinary, so wonderful, so miraculous that he can ascribe it to nothing short of Divinity itself, and in many instances the psychic metamorphosis is so complete as to stand the test of years.

Again, take a man who is modest, retiring, and unassuming; a model husband, a good neighbor, and a faithful friend. He is kind, considerate, and charitable to a marked degree. His judgment is sound and practical, and has proved a sheet anchor to many friends in times of stress and storm. One day he casually joins a crowd on the street and listens to an impassioned orator, whose words come hissing from a hot and seething brain, and the wild and fanciful theories which fall from his lips seem monstrous in the extreme. He wonders that the crowd remains to hear. Later he wonders that he remains himself. But the eloquence of the speaker is fascinating; his statements are alluring and his arguments appeal to some primal elements in the man the existence of which had never before been suspected. As he listens he becomes more and more convinced. Fantastic and even dangerous theories now appear to be dressed in the garb of truth, and he imbibes, absorbs, and adopts until he finally becomes one of a furious mob, flinging defiance at the laws of both God and man.

It is unnecessary to dwell on a phenomenon so frequently observed, so easily recognized, and so universally believed to be true. Knowledge is acquired. Information must come from others. Relying so much on others for what we know, and realizing our helplessness without their aid, we feel some delicacy, or at least some hesitation, in refusing proffered aid, simply because the theories advanced are a little shady or seamy. Having once adopted them, they eventually become a part and parcel of ourselves, and sometimes, like deformed or misshapen children, receive unusual care and attention. Consequently, from great anxiety to know more we occasionally accept what is not exactly true, and are allured by striking and novel theories painted in false but glaring colors. More than this, owing to our great faith in some particular teacher, or writer, or friend, may we not unknowingly accept ideas that are absolutely false, and that in after years may impair mental integrity and form the basis of that dark and tangled thread which runs through so many judgments? The followers of all great leaders have experienced this in a measure. The disciples of dowieism and christian science and various other fads have demonstrated it beyond the shadow of a doubt; if they have stopped short of believing that the moon is made of green cheese, it is only because the heads of their respective organizations did not teach it. The proneness of the human mind to adopt vagaries is doubtless due to several causes. There is a psychic reaching out for something which this life does not supply; a mental craving for the mystic, the unreal; a burning desire to explore the mysteries of a recently discovered country, called New Thought, and, like people who tour everybody's country but their own, these travelers in the world of New Thought are those who know little or nothing about Old Thought. Common, ordinary, practical, methodic ways of thinking are too much for them, and they reach out for something easy and flighty and expressed by the "thusness of the which." Last, but not least, there is the personality of the originator standing behind the idea, and, when the association is direct and intimate, this counts for much.

These peculiar fads, however, are regarded as legitimate, or at least are tolerated, but while their promoters and followers have never perhaps had any direct or important dealings with the commissioners of insanity as by law provided, yet I doubt very much if any outside their ranks look upon them as models of sanity.

Granting then that we do sometimes accept theories and opinions of more or less questionable sanity and incorporate them into the working formulas of our lives,

the object of this paper is to ask whether or not it is possible for one to unconsciously absorb and finally adopt the *insane* delusions of another? Can an insane individual communicate his insanity, in the same form, with the same delusions, the same hallucinations, and the same general manifestations, to another? The following case in point will serve as an illustration.

On April 22, 1895, two sisters, twins, aged 40, were brought before the commissioners of insanity of their county, adjudged insane and admitted to this hospital. They are designated on our records as Nos. 1,481 and 1,482, and the history of each is as follows:

*No. 1,481.*—The patient, a white female, aged 40, was born in Indiana. She is a Protestant and is single. She has had a common school education and is a book agent by occupation. This is her first attack, the duration before admission being about 18 months. Special history accompanying the papers of admission was as follows: This lady became insane about 18 months ago. The Lord tells her not to eat for a certain length of time. Symptoms are on the increase. There is no adequate external cause for mental trouble. At times she refuses to eat.

*No. 1,482.*—The patient, a white female, aged 40, was born in Indiana. She is a Protestant and is single. She has had a common school education and is a book agent by occupation. This is her first attack, the duration before admission being about 18 months. Special history accompanying the admission papers was as follows: This lady became insane about 18 months ago. The Lord tells her not to eat for a certain time and then tells her what to eat. She has been very religious for some time. She refuses to eat for 14 or 15 days and then will eat for a time. There is no adequate external cause for mental trouble. These sisters are still in the hospital and the following is an abstract of their history subsequent to admission.

*No. 1,481.*—This is a case of chronic mania, with delusions of a distinctly religious type. She holds communications with the Lord and receives instructions from Him regarding her daily conduct. In this way she is told when to eat and what to eat. She receives warnings of attempts to poison her by the introduction of poisonous materials into her food. She secludes herself in the toilet-room and preaches at the open window, in a loud, declamatory style, to the world at large. She is resistive to the limit of physical strength but is cowed by superior numbers. She mistakes her ward physician for a former superintendent and charges him with various crimes and misdemeanors. She believes there is a conspiracy on foot to murder her, though she gives no reason why, but has unlimited confidence in the Lord and her own physical strength to prevent it. She is much concerned about her sister's welfare; this is about the only natural thing noticeable in her conduct. For a time she was allowed to visit her sister in another ward at frequent intervals, but her influence on her sister was so bad that the visits were discontinued. She is at all times very disorderly and disagreeable.

*No. 1,482.*—This is a case of chronic mania with religious delusions and marked impressions with a religious coloring. She is on her knees, praying in a loud voice, the greater part of the time. She receives communications from the Lord regarding her food and general conduct, and it is noticed that this delusion, which abates at times, is much stronger and more dominant after a visit from her sister in another ward. She secludes herself, when permitted, in a room where she can see her sister at the window in the ward above and there drinks in the words of exhortation with eagerness. She has no strength of character and when permanently kept away from her sister seems to recognize a lack of support, is less assertive, and there is evidence of a tendency on the part of her delusions to dissipate and re-form into several delusions, illy-defined and variable, except that the religious element permeates the whole. She is becoming extremely filthy in her habits and has no care of her person. She is disposed to disrobe and requires almost constant care and attention. She anoints her hair with saliva and smears the same material over her face. She is extremely disorderly.

This, in brief, is the history of these two patients, who for purposes of comparison may be designated A and B. Though we have no definite recorded history to that effect, it is evident that all through life patient A has had a marked influence over B. A has a firmness and stability of character which is in strong contrast to the weakness, unsteadiness and vacillating mentality of the other. Even after their admission here A occupied the position of counselor and adviser to B whenever an opportunity offered. A's delusions were fixed, unchangeable, and never wavered from their first inception. B's delusions were more unstable and variable, especially in intensity; at times, in danger of being altogether submerged beneath a sullen, surly, dogged obstinacy,

but after a visit from her sister coming out strong and vigorous as though they had again felt and responded to the touch of a master hand.

The sisters lived a secluded life, except when occupied at their vocations, and had no interest in nor feeling or affection for anybody but each other. In this seclusion they reacted on each other in a varying degree. The stronger character of A dominated and molded the mental life of B, while the latter evidently looked to her sister for guidance and direction; believed in her implicitly and relied upon her with a faith that was childlike in its purity.

What else than the dominating leadership of the one and the childlike trust and simplicity of the other could account for the facts as we find them? The same religious delusion entertained by both, varying only in its intensity. A believed that her food was poisoned at times, refused to eat, and moral suasion being ineffectual was fed mechanically. B entertained the same belief; strong after a visit with her sister, weak after a period of separation, and would refuse to eat, but could always be prevailed upon to take food. A desirous of gaining access to an open window where she could exhort her sister, and B equally desirous to stand at an open window where she could receive the admonitions of A, and consequently be strengthened in faith.

Heredity may have prepared the soil in both, but heredity, which cannot even transmit disease, surely could not dictate years in advance that when these brains did succumb it would be manifested by the same form of mental alienation, with the same delusions and similar resultant manifestations. These cases resemble each other too closely for that. Was the hereditary influence in this instance exaggerated beyond anything hitherto recognized, by virtue of their being twins? I think not. But let us see. Here is another case also on the records of this institution.

On June 16, 1899, two sisters, one aged 32 and one 28, were admitted to this institution, and the similarity between these two cases and the twins previously mentioned is very striking. They are designated on our records as Nos. 2,590 and 2,591, and their history before admission is as follows:

No. 2,590.—The patient, a white female, aged 32, was born in Iowa. She is single and a school teacher by occupation. She has had a common school education. This is her first attack, and was caused by worry over family affairs. Her form of disease is delusional melancholia. The duration of disease before admission is unknown.

Special history accompanying the papers of admission: The first symptoms were manifested some years ago. She is deranged on the subject of religion, and has an idea that she has been wronged. She has threatened to injure others.

No. 2,591.—The patient, a white female, aged 28, was born in Iowa. She is single and a school teacher by occupation. She has had a common school education. This is her first attack. The cause is unknown. Her form of disease is delusional melancholia. Duration of disease before admission was three months.

Special history accompanying the papers of admission: Derangement is manifested on the subject of religion, and she imagines that family wrongs exist. She has threatened to injure others.

The following subsequent history is gleaned from our records:

No. 2,590.—This patient has been very much under the influence of morbid thoughts and feelings since her admission. She took a school in April, but, after teaching three weeks, concluded she was "crazy" and left the school. She imagines great wrongs have been committed against herself, and threatens vengeance against others. She is very emotional and restless, and has been quite irritable on several occasions. *She is very much concerned about her sister's condition, and inquires for her frequently.* After two months she began to improve, and made a good recovery, being discharged October 23, 1899.

No. 2,591.—This patient has marked delusions of persecution. She has been teaching, and thinks every one became set against her in the vicinity in which she taught. She is restless and disorderly about her clothing, and disposed to disrobe herself at all times unless prevented. She was kept in bed two days and then allowed to get up at her own request, but persists in returning to bed every little while unless prevented by the nurses. Says she is not ill, but goes to bed because she doesn't know what else to do. She is weak, careless, indolent,

and without energy. She believed that some of the family had been wronged, and retained her delusions of persecution for some three months, when she began to improve. She made a good recovery, and was discharged October 23, 1899.

These two cases are remarkable in many ways. Both were nearly the same age. Both were single. Both were teachers. Both had the same form of disease. Both had the same delusions. Both had the same desire to injure others. Both were admitted to the hospital on the same day. Both recovered at about the same time, and both were discharged from the institution on the same day. Then note the points of similarity between these cases and those of the twin sisters, and for purposes of comparison let me designate the last-mentioned cases as Y and Z. The insanity of Y preceded that of her sister by some years. She was the elder of the two, and was stronger and more dominating. Z was weak and vacillating; would lie on the bed for hours, if permitted, devoid of any strength of character, while energy and self-reliance were nil. Y had delusions of persecution, and believed some great wrong had been done *herself*, while Z had the same delusions but believed some injury had been done *some of the family* (evidently her sister). But while Z does not feel that *she* has been wronged particularly, yet she adopts the same ideas in regard to injuring others as her sister.

Surely much could not be claimed for heredity in this instance, for whatever impress was stamped upon the infant in its mother's womb both children could not have been stamped at the same time. Then, whence this great similarity? Other factors may have been at work, but in two such cases, so nearly identical that the history of one is practically a copy of the other, save in the origin and intensity of the disease, is it unreasonable to suppose the possibility of the insanity being communicated? Could heredity account for all this? I still think not. Fearing, however, that some may still be inclined to give heredity undue prominence I will refer briefly to one more illustration, a man and wife, who were both at one time inmates of this institution:

No. 2,379.—The patient, a male of 35, is married and is a farmer. He has had a common school education. The cause of insanity is religion. Duration of attack before admission was about five months. He has a strong hereditary tendency. The form of insanity is primary mental deterioration. He was admitted to the Independence Hospital May 28, 1898, and transferred to the Clarinda Hospital September 30, 1898.

His history subsequent to admission is briefly as follows: He is intensely religious and is dominated by delusions of a religious type. He alternates from periods of exaltation, accompanied by acts of violence when interfered with, to states of pronounced morbid depression, but the religious element runs through it all. He has many delusions and all are well defined. He has threatened suicide during periods of depression. Later his delusions became more simplified, and were finally merged into one concise statement, viz.: That he was Christ. He has made no improvement in any way, and on August 29, 1902, was transferred to the new hospital at Cherokee.

No. 2,352.—The patient, a female of 31, is married, being the wife of the patient whose history is given above. She is a housewife, and has had a common school education. The cause of insanity is religion and the influence of her husband. The duration of attack before admission was five months. There is no history of heredity. The form of insanity is given as primary mental deterioration. She was admitted to the Independence Hospital May 25, 1898, and transferred to the Clarinda Hospital September 30, 1898.

Her subsequent history is as follows: The patient is quite excitable, emotional, and devoid of proper will power or self-control. She has peculiar religious ideas, resembling those of her husband, but not clearly defined, and in attempting to give them expression she shows much mental confusion, sometimes approaching incoherence; while at the same time she has the appearance of one who is striving to recall impressions the details of which have escaped her memory. On other subjects she is clear and rational. Later the delusions became more and more evanescent, and finally disappeared. Whenever the question of her discharge was brought up, however, she begged to be allowed to remain here so that she might be near her husband. She was finally discharged recovered December 14, 1900, and, so far as known, has remained well.

The peculiarities of these two cases come out prominently in the history of each. One, the husband, having well-formed delusions of a religious nature; his wife

entertaining much the same delusions, but illy-defined. The husband having a strong hereditary history, namely, a mother insane and two cousins who committed suicide while insane. The wife had no hereditary history but was described as having no will power or self-control. The delusions of her husband growing stronger after separation and becoming more clearly defined; the wife's delusions, on the contrary, under the same circumstances become more wavering, uncertain, and finally disappearing. It may be mentioned here that the wife, even after recovery, failed to realize or recognize the extent of her husband's mental alienation.

The one fact which stands out conspicuously in the foregoing illustrations and which is so striking as to challenge attention is this: In each case the delusions communicated have been exclusively of a *religious* nature. Is there no significance in this? Is there any dissimilarity in the ease and facility with which different forms of delusions may be communicated to another? I am inclined to believe that in all the illimitable world of thought no delusions would be so readily accepted and adopted by another as those pertaining to religion. The human mind is peculiarly susceptible to the mysterious, and all sorts of religious vagaries find there a lodgment and a fruitful soil. Statements regarding things of which we know nothing are accepted with little caution. The essence of religion is not knowledge but faith, and faith is elastic and knows no limit. Knowledge teaches circumspection; faith teaches trust. Knowledge leads to wariness; faith to confidence. Knowledge says, doubt first; faith says, believe. The limit of belief depends on faith, and faith is measured by the confidential relations between teacher and pupil. Consequently it is easy for one whose belief in religion is already firm and sure to accept additional ground for a trial of faith, especially when the incentive comes from one whom she has always regarded as a model of virtue and a fountain of truth. From the sane and rational idea that in some general way the Lord will provide it is only a step to the belief that He will take an active, personal interest in our affairs and will guide and direct in all the multitudinous details of life. It only requires one step more to believe that He absolutely controls the individual's conduct and that every act, regardless of its quality, is performed under the direct supervision and at the instance of the Almighty.

A hurried reading of these cases may not be convincing, but even a brief study will, I am sure, impress the thoughtful man with the fact that such a remarkable array of symptomatic similarities must have its origin in something more than heredity. Taking a thousand cases in this hospital it would be difficult, if not impossible, to find two individuals who have never come in contact with each other, holding identically the same delusions and peculiarities of thought and feeling and giving expression to them in exactly the same way. Why this is so I do not know unless it is that insane minds differ from each other just as sane ones do and that a man retains his individuality whether insane or sane. The whole field of insanity has not yet been covered and many things remain unexplained. There are depths in each human mind that have never been sounded. There are rifts and crevices unexplored where unknown thoughts and feelings lie concealed. There are vast Siberian wilds, peopled with widely scattered fancies that came we know not when. And when least expected these strange and alien sentiments obtrude themselves on consciousness, demanding recognition. Whence came they? How did all these dangerous notions so opposed to all we had been taught and had been led to believe from our youth up gain access to this hitherto peaceful domain? With stringent laws against the introduction of elements so foreign to our natures in what way did these psychic anarchists secure a foothold? They came unconsciously, of course, or at least through ignorance of their real nature. They came stealthily in

times of stress and by virtue of unquestionable faith in some men and things. In unguarded moments, when caution and prudence and doubt, those sentinels on the outposts of mentality, have fallen asleep, queer, peculiar and misshapen concepts have crept in and stamped their lasting impress.

No sane man would voluntarily accept an insane delusion. To recognize it as such would be to reject it instinctively. But are all delusions recognizable as such? By experts, yes. By strangers, frequently. By relatives and intimate friends, seldom, unless their attention be called to their fallacy by others. We are so in the habit of taking our friends for granted that slight modifications of their usual methods of thinking, feeling and acting are likewise taken for granted, and if, in addition, we have had a lifelong training in accepting their every statement as law and gospel, these slight and scarcely perceptible deviations are gradually accepted as a matter of course; when, if the same proposition was presented in its completeness, fully rounded out and well defined, its fallacy would be recognized and the whole thing rejected as spurious.

The change from sanity to insanity is seldom sudden and complete. "It is the little rift within the lute" which daily widens. It is not so much a transformation as a new growth, the delusions developing gradually and the feelings and actions modifying themselves in accordance therewith. Or it may be that the feelings are the first to be implicated. Strange and unfamiliar sensations are experienced by the individual. They are new and unusual and grow in intensity. His knowledge of anatomy and physiology (limited or otherwise) affords no satisfactory explanation, and, as time goes by, the peculiarity of these sensations are thrust more and more forcibly into the field of consciousness and demand a reason for their existence. Being so extraordinary in their manifestations he must needs ascribe them to some mysterious cause, and in his frantic and misguided endeavor to find an explanation the delusion has its birth.

But whatever the form of development, the fact that these impressions can be communicated to another, under certain conditions, cannot be gainsaid; and that such cases do occur, and much more frequently, too, than is generally supposed, I likewise verily believe.

## BRIEFS ON PHYSICAL TRAINING.

BY

G. FRANK LYDSTON, M.D.,

of Chicago, Ill.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's Hospital.

No. 4.

### Athletic Overstrain.

Athletic overstrain occurs in two forms, which may be termed acute and chronic. The acute form is seen in two classes of individuals: 1. Individuals completely out of training who undertake the performance of feats which could be performed easily enough if they were in perfect condition, but which result in severe strain because of a lack of proper preparation. 2. Individuals who are in excellent training, but who undertake feats for which no system of preparation could properly prepare them; feats which are inordinate and absolutely inexcusable. As the athlete increases in age, this form of overstrain is very likely to occur. The strength of the individual is perhaps at its maximum at about middle life. The elasticity and recuperative power of the muscles, heart, and bloodvessels have, however, begun to decrease. This decrease is, it is true, imperceptible under ordinary circumstances, but the latent defect shows itself immediately the athlete subjects himself to severe and sustained muscular effort. The effect

upon the heart and bloodvessels is particularly disastrous.

Benjamin Ward Richardson, many years ago, called attention to the "white spot in the soldier's heart," due to severe and long-continued exertion. This condition of the heart we are now quite familiar with as one of the marked forms of myocarditis. Minor, but very serious, degrees of the same condition often occur as a consequence of athletic overstrain. In most instances hard training has been kept up for a prolonged period, and there exists a chronic overstrain, with consequent chronic changes in the heart. These come on very gradually, and may perhaps not manifest themselves until, some years later, the individual ceases his training. The effects may not become manifest until he becomes the victim of some acute or chronic disease. This condition of the heart explains why certain persons of fine muscular development and enormous physical strength die as a consequence of so-called heart failure, when all other indications seem to favor a speedy and complete recovery. A wornout heart fiber explains the death of many individuals who are apparently in perfect physical condition, and in whom absolutely no physical symptoms of disease of the heart can be found. The test of such a heart is not the stethoscope, but its behavior under the strain of exercise or disease.

Richardson said that he did not believe there was a professional or celebrated amateur athlete in all England who, at the age of 50, did not present symptoms of heart disease. Whether his statement be correct or not, this much I believe to be true, namely, that the proportion of athletes who, at the age of 50, present symptoms of cardiac disturbance is not a fair criterion of those who actually have damaged hearts. The constant hammering of the heart on the bloodvessels under the strain of excessive physical labor, especially when associated with a liberal diet of proteids, or, as is sometimes the case with athletes during the intervals of training, excesses in venery, tobacco, and alcohol, should be expected to work havoc with the walls of the bloodvessels. Endarteritis, with its attendant train of evils, is a frequent and natural result.

At certain times physical exercise which ordinarily is well tolerated, can be classified as overstrain. For example: In the individual who, soon after a full meal indulges in physical strain usually, if the act be repeated many times, gastric disturbance is produced. Atony of the gastric muscle, with consequent dilation, is a not infrequent result of vigorous exercise when the stomach is distended.

In the previous paper I mentioned incidentally the action of muscular exercise upon the liver. It has been my fortune to observe several cases in which slight hepatic enlargement, with some tenderness and marked disturbance of the functions of the organ, followed immediately upon athletic overstrain. In one instance the gentleman was training under my observation for an amateur championship boxing contest. At the end of this course of training he broke down, and was annoyed for several years by occasional attacks of albuminuria, associated with digestive disturbance, lumbar myalgia, and the condition of the liver above described. In another instance, a very powerful man broke down in a similar manner, and experienced considerable hepatic disturbance for some months. Still a third case worthy of mention: A gentleman who was not in perfect training entered a barge race. When the race, which was a closely contested one, was over, he was greatly prostrated. Beginning with the day of the race, he suffered for more than two years with hepatic torpor, tenderness and slight enlargement, associated with very annoying and very intractable digestive disturbance. This same subject, since ceasing training, has been the victim of very severe and almost unmanageable lithemia.

Many years ago I expressed the opinion that appendicitis was frequently traumatic. I based this view upon

my observation of the extreme frequency of appendicitis in athletes. The correctness of the view which I then expressed is well illustrated by the triteness of this phase of the etiology of appendicitis at the present time. The action of the psoas muscle in bruising the appendix and favoring infection, and the results of pressure of the abdominal muscles upon a distended large bowel are too well known to require comment.

By the chronic form of athletic overstrain I mean the results of hard, steady, systematic training for a prolonged period, when no sudden and violent demand is made upon the patient's strength and skill. The subject may gradually increase his exercise until immense demands are being made upon the resisting power of his heart, lungs, bloodvessels, and abdominal viscera, without realizing at any time that he has subjected himself to severe strain. The constant wear and tear of the muscular labor, with its attendant increased tissue metabolism and increased demands upon the eliminative areas, may give rise to very serious degenerative changes, which are none the less menacing to health and life because of the insidiousness with which they develop.

One of the most frequent and important evils of chronic athletic overstrain is renal disease. The strain thrown upon the kidney in severe and sustained muscular exercise is much greater than is ordinarily believed. Some years ago I conducted a series of experiments upon athletes in training, and found that severe muscular effort was in very many instances followed by more or less albuminuria. In some instances casts were present. Careful, prolonged observation of the class of individuals under consideration has convinced me that the severe strain upon the kidney, incidental to the excessive tissue metabolism and demand for eliminative renal action in athletes, is often responsible for organic renal disease. The disease is most likely to take the form described by Fothergill, as "vasorenal disease," in which interstitial nephritis, endarteritis, and a hypertrophied and, perhaps, dilated heart are conjoined.

Cardiac hypertrophy and dilation are obviously the most frequent of the serious results of athletic overstrain. Moderate cardiac hypertrophy in the well-trained athlete is a normal condition. Excessive training makes it abnormal. The cessation of training also makes it abnormal. When the amount of muscular exercise falls below that which is necessary to maintain the powerful heart action, the integrity of the cardiac muscle soon becomes impaired. The disused voluntary muscles shrink down and cause no trouble, but the hypertrophied heart degenerates, and degeneracy here means serious impairment of its structure and function. *Pari passu* with its degeneration it may develop dilation. More or less fatty change in the heart may be found associated with myocarditis.

A very frequent result of injudicious physical training is emphysema. This is likely to be associated with a dilated heart. The dilation, as usual, follows hypertrophy. In instances of very young subjects, who are athletically indiscreet, chronic, or even acute, dilation, without preliminary hypertrophy, is not infrequent. Exercises involving the lifting or raising of weights, with the lungs distended and respiration temporarily suspended, are most frequently responsible for both the emphysema and the cardiac disturbance. It is wise to inform persons who train, of the dangers of performing violent muscular exercises while holding the breath after full inspiration.

An occasional result of athletic overstrain is aneurysm. This condition is the result of sudden muscular effort involving, as a rule, heavy lifting, or similar straining efforts. It rarely occurs in young subjects with healthy arteries, but develops most frequently in the mid-period of life, when the elasticity of the vessel walls has become impaired and has become replaced by the relatively brittle and inelastic quality of the vascular

tunics of middle life. If the individual has been unfortunate enough to have contracted syphilis, or has the gouty diathesis, or if, superadded to excessive and continuous muscular and circulatory overstrain the drinking habit exists, so much the greater the danger of aneurysm from sudden and violent strain. Continuous excessive athletics, associated with the conditions above mentioned, constitute a most potent predisposition to aneurysm.

The mechanical effects of athletic overstrain upon the kidney are worthy of consideration. It is remarked in this connection that displacement of the kidney in well-trained athletes is very rare. Systematic, long-continued muscular exercise so builds up the power of the abdominal muscles as to afford a distinct protection against renal displacement. Individuals who have not had systematic training, and who consequently are the unfortunate possessors of relaxed and atonic abdominal muscles, may produce renal displacement under sudden and violent strain. I have known it to occur in athletes who were considerably out of condition.

Hematuria from sudden violent strain, as in lifting or wrestling, is an occasional result of overstrain. I have seen several cases of quite obstinate hematuria produced in this way, and others in which it was difficult to dissociate the results of the muscular overstrain from possible direct traumatism of the kidney.

It is worthy of note in this connection that persons who have never indulged in muscular training often tolerate muscular labor much better than the athlete who is out of condition. The explanation of this is very simple. The athlete whose muscles are under perfect control has educated them in such a manner that their full power may be exerted at any moment. The response to his volition is almost as ready as when in full training. The inherent strength of the muscle and its resistancy to strain are very much reduced by being out of condition. When he undertakes to perform a muscular feat of any kind, he instinctively sets about it as though he had carefully prepared for the effort. This he does as a matter of habit. The result is inevitably overstrain. One of my friends not long ago sustained a fracture of a rib in wrestling with a man who was in no sense a match for him. A lack of condition and the relatively brittle bones of middle life were responsible for the accident.

An important feature of continued overtraining is that it may develop chronic general myasthenia. Acute myasthenia is of course frequent. I desire to call attention to the possibility of trauma of the bladder occurring from indulgence in athletic exercises when that viscus is distended with urine. Rupture has been known to occur, although I have never met cases of this kind. I have, however, seen a number of cases in which hematuria and more or less prolonged vesical atony were produced in this manner.

Hernia as a result of athletic overstrain is a very rare condition in individuals who have trained systematically for athletic work. Systematic, gradually increased training is one of the best prophylactic measures against hernia, even in individuals who are congenitally weak in the inguinal region. Sudden muscular strain in individuals unprepared for such efforts is, as is well known, a potent factor in the etiology of hernia. I desire to call attention at this point to the pernicious habit which is prevalent among athletes of wearing a tight belt about the waist during training exercises. The pressure of the belt and the counterpressure of the abdominal muscles bring severe strain to bear upon the viscera and inguinal rings; and in case of a congenital predisposition to hernia that condition is very likely to result from violent muscular effort.

Another point worthy of consideration is the fact that the abdominal muscles never attain a degree of development proportionate to those of the rest of the body when compelled to labor against the constriction of a tight belt. The muscles of the abdomen are, so to speak, placed in

a splint at a time when all the other muscles are having full play.

I desire to lay special stress upon the fact that indulgence by athletes in alcohol and tobacco is especially dangerous. In the first place, the effect of these stimulants upon the nervous system is to incite the subject to overexertion, and, in the second, it is well to remember that even the strongest heart and muscular system are likely to develop pathologic changes under the combined influence of a severe athletic regimen, alcohol and tobacco. Even slight indulgence should be tabooed. A single cigar or a glass of wine may determine the question of success or failure in contests when either strength or skill, or both, are demanded.

Competitive athletics as ordinarily understood should, in my estimation, be tabooed, for it is in that direction that the greatest danger of overstrain lies. Athletics for health, and with the idea of attaining the standard of perfection natural to the given subject, are perfectly safe and rational. Athletic training for prowess only is senseless as well as dangerous.

I am well aware that the desire for supremacy in athletics rises superior to all physiologic objections to competitive athletic contests. The whole story is most beautifully told by Barry Pain in his "Glass of Supreme Moments." There is infinite pathos in the picture of Lucas Morne, dying from heart strain after a closely-contested boat race. Death gives him at the last various glimpses in the "Glass of Supreme Moments," in which are depicted the periods of greatest ecstasy in the lives of his friends, including that of the athlete who had barely beaten him in what proved to be his death struggle. The supreme moment of his competitor's life was the desperate finish of the race in which he had beaten Morne.

Realizing the difficulties of the task, I still believe that the physician who approaches the subject with an intelligent grasp of the situation may do much to repress, or at least modify, the train of evils that follow in the wake of competitive athletics. Despite all that can be said against such athletics, they will doubtless continue to be popular so long as the innate savagery of man is enabled through circumstances of environment to struggle to the surface. The demand for competitive athletics of various kinds is largely the instinctive cry of the human animal for a "kill" of some kind.

It is not my intention to discuss exhaustively the favorable or unfavorable conditions under which competitive athletics may be practised. I will, however, incidentally say a word of warning against the prevalent idea that an athlete may continue capable of doing his best work until middle life, or past it. It must be remembered that "a man is as old as his arteries." This aphorism is especially pertinent as applied to the athlete. It is well to remember that the athlete's arteries are, with certain brilliant exceptions, older than those of the average healthy man. As has already been indicated, his muscular power may be at its maximum, although his resistancy and recuperative capacity and visceral integrity may fall far behind it in degree. The man who gets a great deal out of himself physically before the age of 30 is bound to "go back" after that period. Mr. Edward Hanlon, the famous oarsman, never said a truer word than when he stated that, in his opinion, no man should train for or enter competitive athletics after the age of 30. Such men as Sullivan and Fitzsimmons are notable exceptions, perhaps, yet each of these men is something of a physical freak. So far as both of these men are concerned, the pathetic story of their downfall merely emphasizes the truth of the foregoing statement. Who that has watched the career of some of our phenomenal athletes will not agree that with them the pitcher usually goes to the well once too often? The man who attains supremacy on borrowed energy—energy borrowed from his physiologic bank—is called upon to pay his notes sooner or later. He cannot do so and goes into physiologic bankruptcy.

## SPECIAL ARTICLES

## THE ILL HEALTH OF HERBERT SPENCER.

BY

GEORGE M. GOULD, M.D.,

of Philadelphia.

The following citations concerning the health of Herbert Spencer are from the article by Iles in the *World's Work* for February, 1903:

Spencer was born April 27, 1820.

A contributor to the *Leader*, writing of Spencer, at about the age of 30, says:

"Despite his vigorous look, he had even then misgivings about his health."

He had, as a young man, a strong bass voice of good timbre, and used to sing in part music until ill health forbade the exertion.

When he began the composition of "First Principles" in 1860, he adopted the practice of dictating to an amanuensis. He was spending the summer by the shore of a Scottish loch. His habit was to dictate for a quarter of an hour, then row for an equal period with the object of so stimulating the circulation of the blood as to carry him through another 15 minutes' dictation, and so on throughout the forenoon. Neither then nor afterward did he work in the afternoon.

Ten years later, at times when his health fell to a low ebb, he would go to a racket court in the north of London, play with the man in charge, and dictate in the intervals of the game. One of the most abstruse portions of his *Psychology*, the *Argument for Transfigured Realism*, was composed under these unpromising circumstances. His usual program as he wrote the volumes of the "Synthetic Philosophy" was to leave his house soon after 9 in the morning, and direct his steps to Kensington Gardens. There he walked until nearly 10 o'clock, his head slightly bent, his pace somewhat rapid, his mind evidently in meditation.

Ever since [1855] he has been a sufferer from insomnia, and for 18 months after the completion of his book [the *Psychology*] he could do nothing. Then in his impatience he one day resumed work, to discover, as George Sand and others in like case had done, that his strength gradually came back to him. He slowly regained vigor enough to accomplish a large amount of toil, but never with perfect security; it was always touch and go with him. At such times he threw up his work and hurried away to his native Derby, or to Brighton or Tunbridge Wells. There he went about killing time as best he could, feeling thoroughly bored and miserable. In three or four weeks he would return, apparently restored, and without an effort take up his work at the point where he had dropped it; in a moment the bow of Ulysses was bent as easily as ever. As time went on these relapses grew less frequent, and at the end of 15 years' work on the "Synthetic Philosophy" he found himself, in 1875, in much better health than when he began. In 1897 he underwent a serious collapse, followed two years later by a marvelous restoration, attributed to the use of meat cooked in a particular way. This rejuvenescence disposes him to believe that nervous troubles may be assuaged with advancing years.

He often went to the theaters and the opera, usually in company with friends. He set much store by his annual outing in Perthshire or Argyshire, where he fished for salmon with the thoroughness which went into everything that he did. His flies were always of his own design. Indoors, when in London, to get through the long, dull evenings when he had no engagements, he played whist at first and then billiards, at which his game was steady rather than brilliant. He often dined out, less from choice than for distraction from toil.

The magazine article of Iles has a full-page portrait of Spencer reading without spectacles, and entitled, "He reads without glasses at eighty-one." It has the stiff, retracted appearance of presbyopes reading within the easy limit of their near-point.

When Spencer visited America in 1882 his address to his friends at Delmonico's was a chapter from his gospel of relaxation and rest. This was drawn from personal experience. In early life he was told by his physician that his health would never improve while he worked so hard and lived alone in lodgings. From the sixties onward . . . his recreations became varied and of inestimable benefit. When lawn tennis was revived he took it up eagerly; he was always ready to join a picnic or excursion, when he was as active and sportful as the youngest.

He first dictated his correspondence, often rebelling at its onerous demands. Then he turned to his systematic work, soon rising to the full tide of dictation; usually he went on without a break till close on 1 o'clock, when he hurried away to luncheon. If his health was out of order he would stop abruptly at any moment and leave the house, saying that his head felt queer. When fairly well he would smoke half a cigar, finding that it promoted the flow of thought.

Considering the difficulty of his subjects, the solidity of the

matter and his finish of style and treatment, his rate of composition was not slow. On good mornings he would produce 1,000 words. This was reduced by the time occupied in revision, the arrangement of materials and relapses into ill health to a daily average for the year of 330 words. In 1879, when he was recovering from a serious illness, sitting under the trees of Kensington Gardens, he dictated his autobiography to an amanuensis.

Spencer has never been much of a reader; he was wont to say that if he were to read as much as other people he would know as little as they. He has never bought many books, nor borrowed from circulating libraries or other sources, and yet he has managed to accumulate enormous stores of knowledge. He read but little in the forenoon, and he dared not read at all in the evening through dread of insomnia, but for all that he seemed to miss nothing in print that bore on his work. Almost all his reading must have taken place at odd moments, just after breakfast, after luncheon, and in the afternoons regularly passed at the Athenæum Club. A little time went a long way with him—five minutes over an article, half an hour over a book, availed him as much as half an hour or half a day to another man. Much was communicated to him by friends of eminence in science, etc.

Naturally of a robust build, he preserved his bodily vigor till past 60; it was in 1884 that he became unable to take his accustomed long walks. In that year he began to drive to the Athenæum Club in the afternoons.

So far as we may draw conclusions from the interesting but, medically speaking, extremely vague suggestions of Mr. Iles, it is at once evident that the symptoms, and their causes, in Mr. Spencer's case are not essentially unlike those of the five already<sup>1</sup> studied. When published, the autobiography may bring more definiteness of detail, and could the case records of his physicians, if he has consulted any, be added, there would be still more certainty elicited in the diagnosis. Of especial service would be the report of the refraction and muscle-balance of his eyes, if such data could be obtained. The early "misgivings about his health," the ill health as a young man that interdicted the exertion of singing—of these we should like details. Unlike all the others Spencer early learned the wisdom of dictating to an amanuensis, and of breaking up his periods of literary work by alternations of rest, exercise, or amusement. These periods of work were sometimes so short in duration as 15 minutes. The intellectual labor itself, of course, could not and did not tire in so short a time. Like all the men whose clinical biographies I have studied,<sup>2</sup> Spencer used up his ability to do literary work in the few morning hours, and could not carry it on afternoons. He did not use his eyes in such labor evenings because if he did so he was afflicted with insomnia. There was the same necessity as in the others of "killing time," and of being "bored and miserable" in doing so. Only late in life was he unable to take the "long walks" which had been his necessary and saving custom during his life. These long walks, as in the other cases, demonstrate that no organic disease existed, and his 83 years, still well borne, is another proof that the lifelong "nervous troubles" were of a clearly functional nature, that the "always touch and go with him" was dependent upon a temporary, slight, subtle, and easily overlooked cause. In a few minutes "his head felt queer," with near use of the eyes, is one of the most definite hints Mr. Iles gives us, and almost all patients with severe eyestrain make the same complaint.

That Spencer has not been so great a sufferer as De Quincey, Carlyle, and the others mentioned, seems due to several wise habits early formed and always carried out during his life: 1. He dictated all his works. (It should not be forgotten that even in his dictation there was probably use of the eyes at near range, in the consultations of notes, references, etc. An average of 330 words a day is a very small result so far as amount of product is concerned.) 2. He availed himself of the literary labor of assistants hired for the purpose, or given by friends. 3. He learned, as few literary workers do, to gather his data from the books, etc., which he consulted, with a fraction of the ocular labor that is required by others. 4. He read little, and, plainly, not at all works of a light or popular nature. 5. He practised the art of rest and relaxation when he became "nervous" and "his head felt queer," even if 15 minutes' labor brought on these symptoms. Mr. Spencer's "rejuvenescence" in old age, and his belief that "nervous troubles may be assuaged with

<sup>1</sup> De Quincey, Darwin, Huxley, Carlyle, and Browning.

<sup>2</sup> See *Biographic Clinics*, P. Blakiston's Son & Co., 1903.

advancing years," are but the philosophy of the presbyope who has never heard of the relief that always comes to the eye-strain patient when accommodation effort has become impossible, or when presbyopia has been fully established.

In 1882 Mr. Youmans said of his friend, Mr. Spencer, that he broke down completely from overwork in 1855, and that since then he had not had a night of sound, refreshing sleep. "A victim of overwork" is another expression of Mr. Youmans. Again he says of him in 1882, "The distress of his life for 20 years has been insomnia." At this time Mr. Spencer was 62 years of age, and hence the beginning of this period of great sleeplessness began when he was about 42 years of age—precisely at the beginning of the presbyopic failure, when eye-strain is greatly increased. In 1855 Mr. Spencer was 35 years of age, at which time Youmans says he broke down from overwork. How much of a "victim of overwork" Mr. Spencer was at 35 and 42 appears plainly in Mr. Iles' article. His speech at Delmonico's was in reproof of our American overworking, and in praise of his own lifelong devotion to the doctrine and art of "rest and relaxation." Of all literary men that ever lived, Mr. Spencer was least accurately described as one who overworked. The explanation of Mr. Youmans is an echo of the old error that when the health of an intellectual man or writer fails, it is because of "overwork." The cerebral function of a philosophic or literary man is not more exhausting than that of a business man, engineer, or physician. Then there are millions of people in our strenuous world who "overwork" without insomnia or breaking down, and who work five or ten times as much as Spencer ever did. But they do not have compound myopic astigmatism, and they cannot "read without spectacles at the age of 81." Insomnia, neurasthenia, and breakdown are common results of eyestrain.

That Mr. Spencer is able to read without spectacles at his advanced age is a perfect proof that he is, and has been, myopic. There is nothing in the fact to be proud of, but rather to be sorry for. Such patients, if they have not suffered thereby from nervous or digestive disorders, have at least denied themselves one of the greatest pleasures in life, that of seeing the world. They do not know how anything a few feet away looks to normal eyes. But the two myopic eyes of a person are not once in a thousand instances alike in their refraction, nor are they without astigmatism. The symptoms from which Mr. Spencer has suffered, at least from early manhood, show that he has always had compound myopic astigmatism, probably anisometropic. There are thousands, even millions, of literary workers, bookkeepers, seamstresses, clerks, students, and professional persons, who are able to work for ten or more hours a day at near-range ocular labor without "queer feelings in the head," "nervousness," headache, insomnia, or digestive troubles. There are other thousands who are able to do so only by the use of spectacles or eyeglasses correcting the "error of refraction" of their eyes. Without such lenses they have some or many of the symptoms complained of by DeQuincey, Carlyle, Darwin, Huxley, Browning, and Spencer. Mr. Spencer has been compelled to adopt the devices described by Mr. Iles in order to obviate, poorly and temporarily, the cerebral and nervous disorders following the use of his eyes even for a few minutes. At any time during his life lenses properly correcting his ametropia would, I think, have enabled him to avoid wasting his superb intellect in boredom and "killing time," and would have permitted him an ability to read and work, as well as a freedom from nervous troubles, which would have been to himself the source of the greatest satisfaction, and wherefrom the world would have enormously profited.

**Sea Air in the Treatment of Tuberculosis.**—It is asserted that several physicians and a number of associations in Berlin will test the value of sea air on a number of patients suffering from tuberculosis. As ordinary steamers, owing to the noise, unpleasant smells, and want of proper accommodation, are unsuitable, it is proposed to build a large floating sanatorium, with roomy, open-air wards, medical supervision, and a complete equipment for scientifically testing the effects of the sea air. The cruising ground is to be the northeastern Atlantic, in the neighborhood of the Canary Islands. Should success attend the effort, further floating sanatoriums will be built. The voyages will last about six weeks.

10. A Further Study of the Influenza Bacillus. F. ELDRIDGE WYNEKOOP.
11. The Fly as a Carrier of Typhoid: An Inquiry Into the Part Played by the Common House Fly in the Recent Epidemic of Typhoid Fever in Chicago. ALICE HAMILTON.
12. Pneumonia: The New "Captain of the Men of Death." Its Increasing Prevalence and the Necessity of Methods for Its Restriction. ARTHUR R. REYNOLDS.

2, 3, 4.—See *American Medicine*, Vol. III, No. 25, p. 1059.

5, 7.—See *American Medicine*, Vol. III, No. 25, p. 1062.

6.—**The Clinical Application of Some Thyroid Gland Experiments.**—Breisacher briefly refers to his experiments in keeping dogs on a diet of milk or milk and eggs for a number of days before extirpation of the thyroid gland, and noting the subsequent influence of a milk, egg, boiled and raw meat and beef broth diet; 30% of those fed on milk or boiled meat remained entirely healthy, but died when put on raw meat or beef broth. All animals fed on raw meat from the beginning succumbed to the operation. These experiments have resulted abroad in the recommendation of a milk and vegetable diet in myxedema, cachexia strumipriva, and Basedow's disease. American clinicians, however, have paid little attention to the question of diet in these troubles. [H.M.]

8, 9.—See *American Medicine*, Vol. III, No. 25, p. 1061.

10.—**The Influenza Bacillus.**—Wynkoop calls attention to some atypical manifestations of this bacillus. During the past five years hundreds of cultures made from inflamed throat and nasal mucous membranes, eyes, etc., have been examined, and many local disorders found dependent on the influenza bacillus and not in pyogenic bacteria. Laryngitis, pharyngitis, and tonsillitis and apparent diphtheria are among these. The conjunctivitis caused is characterized by suddenness of onset, rapidity of development, and shortness of duration. The severer cases suggest blenorhea or conjunctival diphtheria. The symptoms disappear quickly under antiseptic treatment. [H.M.]

11.—**The Fly as a Carrier of Typhoid.**—Hamilton describes Chicago's water supply and sewage conditions, presenting maps and diagrams showing the distribution of the disease. She also reports the bacteriologic studies made in relation to the agency of flies. The concentration of the epidemic in the Nineteenth Ward from July to October, 1902, can not be explained by contamination of drinking water, or of food, or on the ground of ignorance and poverty of the inhabitants, for this ward does not differ in this respect from several other parts of the city. The sewers are too small, only 48% of the houses have sanitary plumbing, 7% of the remainder have defective plumbing, 22% water-closets with intermittent water supply, 11% have privies connected with the sewer but without water supply, and 12% have privies with no sewer connection. The streets in which the sanitary arrangements are worst had the largest number of cases. Flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of a typhoid patient were used to inoculate 18 tubes, and from five of these the typhoid bacillus was isolated. [H.M.]

12.—**Pneumonia: "Captain of the Men of Death."**—Reynolds gives many statistics showing its greatly increasing prevalence and reviews the suggestions of other writers in regard to individual prophylaxis and the placing of it on the list of notifiable diseases in regard to the importance of clean

streets and of thorough ventilation of places of public assembly and dwelling houses. Every precaution used in a case of diphtheria should be employed in a pneumonia case. [H.M.]

### Boston Medical and Surgical Journal.

February 26, 1903. [Vol. CXLVIII, No. 9.]

1. A Few Remarks on Blood-pressure. JAMES MARSH JACKSON.
2. Intestinal Obstruction Below the Ileocecal Junction. THOMAS H. MANLEY.
3. The Treatment of Hemorrhoids. JOHN O'CONNOR.
4. The Use of Cargile Membrane in the Nose in Order to Prevent Adhesions. HARRIS PEYTON MOSHER.
5. Gonorrhoeal Urethritis Without Symptoms. ARTHUR L. CHUTE.

1.—**Blood-pressure.**—Jackson has experimented for three years with Gaertner's machine and believes it sufficiently accurate for all practical purposes. In arteriosclerosis the readings of the latter were higher, the brachials being more affected by the disease than the smaller vessels of the finger, and he believes the Gaertner machine was nearer right. All records of blood-pressure should be accompanied by the name of the instrument used. He has found exophthalmic goiter cases (women) with a pressure of 120 to 160 not diminishing on improvement in symptoms. In five out of six cases of chronic nephritis with decapsulation of both kidneys there was rise of pressure even with marked improvement. In one the pressure rose from 125 at the time of operation to 210 at the end of two weeks. Pressure in a young healthy man ranges from 106 mm. to 130 mm. of mercury, but it is frequently as high as 150 in the perfectly sound. In young women it ranges from 90 to 110. Elderly persons have an elevated pressure due to arterial changes, and one should not be disturbed if it reaches 175. Low pressures are uncommon except in shock and collapse. Pressures of 200 are dangerous, of 250 very dangerous. He records that five patients in one year with pressures over 190 died of apoplexy. As an aid in diagnosis blood-pressure is fast taking an important place. [H.M.]

3.—**Treatment of Hemorrhoids.**—John O'Connor, of Beunos Ayres, gives his results in 150 operations for hemorrhoids, after Whitehead's method. In the whole series of cases there was no fatality. Five patients suffered from some after-contraction at the seat of operation, and six were annoyed by a "weeping bottom" as a sequel to operation. The latter result and the contractions occurred in his early cases, and are attributed by him to encroachment upon the skin-margin of the anus. He now never allows his circular incision to come nearer than one-sixth of an inch to the skin-margin. The average time consumed in the last 26 operations was 12½ minutes. The pile-bearing area being removed, the upper cut end of the mucous membrane tube is brought down and sutured to the lower cut margin by a continuous catgut suture loosely applied, all hemorrhage having previously been carefully controlled. Mr. Jacobson, in "The Operations of Surgery," devotes half a page to a criticism of the Whitehead operation. For this he is censured by the writer. A terse, unique description of the operation is given which should be read in the original. He condemns the usual practice of "stretching the sphincter." [A.B.C.]

4.—**Cargile Membrane to Prevent Adhesions in the Nose.**—Mosher has tried cargile membrane in operations within the nasal cavity to prevent postoperative adhesions. His results have been satisfactory. It here cannot be used in one flat layer as within the abdomen, but it is rolled or folded together and wedged between the opposing denuded surfaces. He has used it on turbinates after cauterizing, and on raw surfaces after the removal of spurs. It is considered appropriate for the following additional conditions also: On the septum after operation for the correction of deflection; a sleeve for a packing which has to be left in the nose some time; to hold down flaps of mucous membrane after the submucous dissection of cartilaginous spurs; as a guide and stimulant to the growth of epithelium to prevent the formation of a perforation, and in order to help toward the closure of perforations after refreshing their edges; and as a dressing for the cartilage of the septum whenever it is found to be exposed. [A.B.C.]

5.—**Gonorrhoeal Urethritis Without Symptoms.**—Chute

reports the case of a student who two years before the present trouble had chancroids. He knew of no other venereal trouble. He had had numerous exposures but was wholly unaware of any trouble until there was an onset of unilateral epididymitis. About this time a rash appeared on the body. The other epididymus was soon involved. There were no urethral symptoms for several days, when a slight discharge appeared. The finding of scales accounted for the rash, which disappeared after the use of sulfur ointment. Stained secretion from the urethra showed gonococci. The combination of symptoms as above recited had led another physician to make a diagnosis of syphilis. Another case, that of a youth of 18, is recited. Sixteen days after exposure and without any previous symptoms whatever he suffered from retention of urine. This was relieved and the prostate was found swollen, painful and tender. Expressed secretions showed the presence of gonococci. The author questions whether some strictures and other unaccounted for complications may not arise from an unrecognized attack of gonorrhoea. [A.B.C.]

### Medical Record.

February 28, 1903. [Vol. 63, No. 9.]

1. Remarks on Achylia Gastrica and Pernicious Anemia. MAX EINHORN.
2. Recent Researches on the Voice. E. W. SCRIPTURE.
3. Doctrine of Survivorship in Case of Two or More Deaths in a Common Disaster. THEODORE SUTRO.
4. The Etiology and Prevention of Senile Cataract. J. WILKINSON JERVEY.

1.—**Achylia Gastrica and Pernicious Anemia.**—Einhorn reports three new cases of achylia gastrica in which there was return to normal secretory activity and others in which there was abrupt development of achylia gastrica in pronounced hyperchlorhydria with return to normal secretion after the achylia had persisted for years. These cases cannot be compared with nervous dyspepsia in which a varying condition of secretion is present. In cases of carcinoma with achylia it is difficult to decide whether the cancer causes the achylia or not. Cases in which diagnosis of cancer is difficult are rare. He describes the clinical and pathologic findings in cases of pernicious anemia, his own observations speaking against the assumption that it is caused by atrophy of the stomach. In most cases of achylia gastrica a nearly normal condition of the blood is found. In one case in which total atrophy of the mucous membrane was found pernicious anemia did not exist during life. We occasionally observe gastric juice in pernicious anemia, sometimes even in increased amount. The two diseases sometimes occur together. These cases are, however, in the minority. [H.M.]

4.—**Etiology and Prevention of Senile Cataract.**—A case with paralysis of the sphincter papillæ and a clear lens on one side, with a normal iris and cataractous lens on the other side, has suggested to Jervey that senile cataract is caused by irritation of the capsule from the movements of an iris stiffened and roughened by the nutritional changes common in old age, and due to arteriosclerosis, rheumatism, gout, Bright's disease, diabetes, etc. Efforts to prove the development of permanent cataract by extraction or imbibition of water or abnormal ocular solutions have terminated unsatisfactorily. There is much evidence to support Schoen's views that all simple and senile cataracts commence as capsulitis. The effect of trituration of the lens capsule for the hastening of cataract falls in with this theory. The impossibility of obtaining full dilation in the majority of cases is accounted for by the thickening or stiffening of the iridian fibers, and not by atrophic conditions. By interrupting the iris and preventing its activity in cases in which opacification is beginning, the process may be arrested. Mydriatics would be necessary in younger persons, but in the senile are superfluous. Jervey advises the making of a minute nick in the pupillary border sufficient to break the continuity of the sphincter. This will result in partial dilation and cessation of hippus. If continued use of a weak atropin solution seems to assist in control of iridian movements, there is no objection to its use. Constitutional treatment and proper glasses are also important. The measures indicated must be used early. [H.M.]

1. A Critical Review of Some of the Recent Literature of Tuberculosis. (Second Paper.) JONATHAN WRIGHT.
2. Pulmonary Anesthesia. W. A. BRYAN.
3. A Case of Intussusception in a Baby Five Months Old. LOUIS FISCHER.
4. Pyemia and Exsection of Part of the Lower Jaw Following a Fracture Due to Tooth Extraction. J. A. HOFHEIMER.
5. The Prophylaxis of Appendicitis. H. ILLOWAY.

**1.—Recent Literature of Tuberculosis.**—Wright has made a critical review of some of the recent literature of tuberculosis. Koch, in a recent article, unsparingly reviews the vulnerable evidence, entirely circumstantial, of the actual transmission of bovine tuberculosis to man. He regards the fact not only as unproved, but as highly improbable. By his observations on dust in air currents drawn through moistened tubes, Saenger concludes that dust particles floating in the inspired air cannot penetrate very far into the bronchioles. Still further experiments lead him to assert that it is impossible that tubercle bacilli floating in the inspiratory air current should penetrate with this into the pulmonary alveoli. The author conceives that the tubercle bacillus is carried to the alveolar regions of the lungs only by blood or lymph vessels into which they enter either directly through the surface epithelium of the upper air tract or from lymph nodes and other foci of infection or lodgment. As to experiments with the inoculation of animals with human tubercle bacilli, the tendency in the very numerous articles which are appearing is to deny the absolute insusceptibility of animals to large doses, but at the same time to support the essential claims of Koch. As experimental observations multiply and are more carefully controlled, they are coming to be more in accord with clinical experience. The author calls attention to Massei's paper on tracheal hemorrhage, and to the observations of Donelan, and says it is possible that many so-called cases of early tuberculosis have been merely recoveries from tracheal hemorrhage occurring as a sequel of influenza. He is not in favor of artificial abortion in cases of tuberculous laryngitis complicated by pregnancy. He believes pregnancy more frequently retards than hastens the march of tuberculosis in women. The author refers to the statistics of Mircoli as quoted by Bronstein and Fränkel, covering 2,897 cases treated by serum therapy. Out of 250 cases of limited apyretic tuberculosis 95 were cured, 110 improved, 30 remained stationary, and in 15 the process ran its course. Of 932 phthisical patients with fever with circumscribed tuberculosis 168 were cured, 511 improved, 163 stationary, and 98 who grew worse. Bronchopneumonia without mixed infection: out of 655 patients there were 192 cured and 301 improved. The same complicated by the invasion of other bacteria, 332 cases, among which 31 were cured, 142 improved, 61 grew worse, and 98 remained stationary. Of 712 cases of bronchopneumonia with cavities, 281 improved, 290 grew worse, and the others remained without change. [C.A.O.]

**2.—Pulmonary Anesthesia.**—Bryan presents some useful facts concerning the administration of anesthetics, the action of patients under their influence, the signs that are of value to the anesthetist, and the means to be used in emergencies that may arise during anesthesia. The author also gives a report of some recent work with ethyl chlorid, which has been very satisfactory. [C.A.O.]

**3.—Intussusception.**—Fischer reports a case in a baby of 5 months. The most marked symptoms were pain, continued vomiting, abnormal distention of the abdomen, tympany and fecal impaction, the gut being so obstructed that no feces passed for more than ten days. There was absence of all inflammatory symptoms, such as rise of temperature, until two days before the death of the patient, when temperature rose to 101° F. and the pulse to 160. During the first two or three days not only was clear blood passed by the rectum, but large masses of jelly-like mucus, tinged with blood, were frequently expelled from the rectum until the end. The mass of gut could be felt in the rectum about 2½ inches from the anus, and a catheter could be passed outside the intussusception as well as inside it some 14 inches, without reaching the limit of the invagination. Operation was refused and the child died. [C.A.O.]

**4.—Pyemia Following Tooth Extraction.**—A case is

reported in detail by Hofheimer of a boy aged 9, whose lower jaw was fractured by a dentist while extracting a tooth. General pyemic infection with multiple abscesses followed. Several operations were necessary to drain these abscesses. A gradually increasing necrosis of the lower jaw posteriorly to the point of fracture also appeared, necessitating the removal of the ascending ramus; this was done by the intrabuccal method, thus avoiding a large, unseemly cicatrix on the face, and leaving but a slight deformity. [C.A.O.]

**5.—The prophylaxis of appendicitis** is discussed by Illoway. He holds that this disease is in the majority of instances provoked by constipation, either temporary or habitual, and that by removing this condition we will greatly obviate the risk of appendicitis. In constipation the residual matter accumulates in the cecum and distends it; the orifice leading into the appendix is thereby opened. Feces can now pass into this part, or rather are driven into it. Complete return into the cecum is prevented by fecal matter in the cecum. Bacteria enter and give rise to an inflammatory process, or concretions may form. To illustrate this point, cases are reported in which appendicitis has been cured by relieving the constipation. [C.A.O.]

## Medical News.

February 23, 1903. [Vol. 82, No. 9.]

1. A New Use for Thyroid Extract: A Cure, or at Least a Complete Control of Hemophilia Through Its Administration: Its Effect also on Another Form of Hemorrhage. EUGENE FULLER.
2. Cortical Hemianopsia and Sector Defects of the Visual Field. EDWARD JACKSON.
3. Ossiculectomy. EDWARD B. DENCH.
4. The Discrepancy Between Clinical Manifestations and Pathological Findings in Appendicitis. NATHAN JACOBSON.
5. The Treatment of Typhoid Fever. G. WYTHE COOK.
6. Aseptic Surgery on the Niger Delta. FREDERIC GRIFFITH.
7. Remarks Upon Adherent Pericardium. GEO. MONTAGUE SWIFT.
8. Hyoscin in the Treatment of Morphinism: Its Office and Value. GEORGE E. PETTEY.
9. The Scope of Vaginal Section. EGBERT H. GRANDIN.

**1.—Thyroid Extract in Hemophilia.**—Fuller reports that a Hebrew youth of 15, four of whose uncles and two of whose brothers had died from hemorrhage, a result of circumcision, was brought to him suffering from constant hematuria and swollen joints. The boy was much emaciated and anemic. The usual styptics afforded no relief, and it seemed death was imminent. As an experiment 5-grain doses of thyroid extract were given three times daily. After only a few doses the hemorrhage ceased, and within two weeks the swelling of the joints had subsided. Nine months after the initial treatment there had been no return of the hematuria, the boy had gained much in weight, and his health was better than ever before. Another was the case of a man of 55 who had been under treatment for nephritis for a year, the usual symptoms being present. Two months before the writer saw him he began suffering from hematuria, which persisted. Examination showed the hemorrhage came from the prostate. Perineal cystotomy and drainage failed to relieve the condition. Again 5-grain doses of thyroid extract given three times daily controlled the hemorrhage completely, though of course the nephritis persisted. The writer hopes the drug will be given a trial in other cases of hemophilia. [A.N.C.]

**2.—Cortical Hemianopsia and Sector Defects of the Visual Field.**—According to Jackson sector defects occur almost as frequently as complete lateral hemianopsia, generally remaining an enigma to the patient and too often to the physician also. In half-blindness the straight line of demarcation often shown in charts does not exist. The finding of irregularities in this line does not negative the idea of a hemianopic lesion, but supports it. An absolutely straight border may be taken as evidence of malingering. The significant thing is that in the two eyes the indentations and extensions of the blind area correspond to each other sufficiently to identify portions of the retina having connection with the same part of the visual center. Almost invariably the seeing field encroaches on the blind part at the region of the fixation point. The writer reports cases interesting from the definiteness of the lesions involving the visual cortex in the occipital lobe, giving additional support to the view that the upper portion of the cortex has to do with the lower parts of the fields. He also shows charts in

which the contraction of the field in tabetic atrophy and a sector defect in detachment of the retina simulate hemianopsia. While the part played by hemianopsia in the diagnosis of a given case is most frequently that of a localizing symptom, its recognition may throw the first light as to the real cause of obscure cerebral symptoms. [H.M.]

**3.—Ossiculectomy.**—Dench says this operation is indicated in three classes of cases: (1) chronic nonsuppurative otitis media, with intact membrana tympani, operation for improvement of function or relief of subjective noises, vertigo, etc.; (2) chronic suppurative otitis media; and (3) previous suppurative process which has resulted in the ossicular chain being bound down by adhesions with impairment of function. An exhaustive and highly instructive paper deals with these various conditions, the treatment indicated, together with descriptions of operations. Of 88 cases of chronic nonsuppurative otitis operated upon for the improvement of function, 76 were improved, 10 were unimproved, 1 grew worse after the operation, and in 1 the result was unknown. Of 92 cases operated upon for the relief of suppuration, 53 were cured, 25 improved, 2 unimproved, and in 12 the result was unknown. In most of the cases the hearing was improved, and in no instance was the hearing made worse. In 9 residual purulent cases, in which the 2 larger ossicles were removed for the improvement of hearing, 7 have been improved, 1 unimproved, and 1 case is still under treatment. Most of the cases of this character were operated upon by synechiotomy of the stapes. [A.B.C.]

**4.—Discrepancy Between Clinical Manifestations and Pathologic Findings in Appendicitis.**—Jacobson, of Syracuse, recites a number of cases illustrative of the paper's title. He then sums up the points he wishes to make emphatic: We must not depend too much upon finding the so-called classic symptoms of the disease; we are not to be misled by apparently mild constitutional manifestations; local signs are to be regarded as more significant, and can be relied upon to a greater degree than can constitutional manifestations; the persistence and the aggravation of any manifestation is to be viewed with alarm, and strongly suggests progression of the disease; the diagnosis of catarrhal appendicitis, because of the apparently mild symptoms presented, is often unwarranted; true conservatism, if by that we mean the conservation of life, is along surgical and not medical lines in every case of progressing appendicitis. Every case in which the diagnosis of appendicitis can with positiveness be made, demands surgical rather than medical care. [A.B.C.]

**6.—Aseptic Surgery in the Niger Delta.**—F. Griffith reports that a native was attacked with a machete and wounded as follows: Amputations of both cheeks; lacerations of scalp and forehead; shattering of the left shoulder, requiring an excision of the outer half of the clavicle to be made; incised wounds of both hands, flapping the palms; and penetrating, incised wounds of the abdomen, allowing the protrusion of intestines enough to fill a pint measure. Happening in the bush, this patient walked 10 miles before reaching assistance, and had completely recovered at the end of six weeks' time. The wounded condition of a woman is described, the weapon being the same. Wounds consisted of gashes of the hands, severed and shattered clavicle, slashes in the abdomen which opened the peritoneal cavity. The woman, a native, walked 10 miles to find medical aid. Appropriate treatment resulted in complete recovery. [A.B.C.]

**7.—Adherent Pericardium.**—Swift has found adherent pericardium a not unusual condition. The points for diagnosis are the great irregularity of heart action, the patient not appearing correspondingly ill; the indraw of the intercostal spaces with systole, the marked dyspnea and consequent apprehension, the great enlargement of the liver with or without ascites. In hospital cases the prognosis has been invariably bad. It may be good if the patient can have an abundance of nitrogenous food to supply the extraordinary heart demands, especially great in a growing child; and if the adhesions which have formed do not pinch too closely the nutritive vessels, inducing atrophy; and if one can arrest the rheumatic condition. [H.M.]

**8.—Hyoscin in Morphinism.**—Petty replies to the con-

demnation of the use of hyoscin by Crothers and Mathison. The effects of hyoscin are very little, if any, more lasting than those of other narcotics. Delirium, delusions, etc., from its use are of short duration. Instead of hyoscin and bromids causing dementia, each of these remedies has made a greater reputation in the treatment of insanity than any other two in the materia medica. After the use of hyoscin in morphinism the perfect recovery of all the mental faculties has been one of the most uniform and striking features. It not only occupies, but fills, when properly used, as important a place in the treatment of morphinism as does chloroform or ether in the practice of surgery. [H.M.]

**9.—The Scope of Vaginal Section.**—Grandin thinks that although experience may yield the deftness which will enable one to operate on any intrapelvic and many intraabdominal conditions through vaginal section, yet far too frequently these attempts at surgical legerdemain result in incomplete and faulty work and prolonged anesthesia with immediate or remote effect on kidney, heart, and lungs. These considerations outweigh the charges brought against the man who prefers to do his work through the abdominal incision, whereby not alone touch, but also sight, assists him in rapid work, in knowing work, and in complete work. The vaginal incision commends itself for diagnosis and for palliative treatment. It may also be used for curative purposes in certain conditions. As regards tumors, it may be used for their removal when they can enter the pelvic brim. If they cannot enter this brim, although it is possible to drag down and cut out gradually, this he calls not surgery but butchery, and they should be ruled out from the scope of vaginal section. The same remark applies to tumors surrounded by adhesions or complicated by pyosalpinx or ovarian abscesses. These conditions may alone be treated from above. Diseased appendages when readily accessible and only slightly adherent may be removed by vaginal section. In Grandin's view the symptomatology of uncomplicated uterine displacement is dependent on the amount of downward sagging of the organ, and not on the mere version, hence these cases do not fall within the scope of vaginal incision. The uterus must be drawn up and held up, and not merely fastened anteriorly to the vagina. The shortening of the round ligaments also can best be done by abdominal incision. [W.K.]

#### Philadelphia Medical Journal.

February 28, 1903. [Vol. XI, No. 9.]

1. Tropical Diseases: Sixth Lecture in a Course on Tropical Diseases, etc.; Abscess of the Liver. CHAS. F. KIEFFER.
2. Diseases of the Biliary Tracts. JOHN B. DEEVER.
3. Rupture of the Urethra; Pyosalpinx; Excision of Tumors of the Neck. THOMAS H. MANLEY.
4. Is Nephroptosis Hereditary? JOHN G. SHELDON.
5. A Case of Trigeminal Neuralgia Complicating Typhoid Fever. CHARLES J. ALDRICH.
6. The Toxemia of Pregnancy. WILLIAM H. WELLS.

**1.—Tropical Diseases.**—Kieffer discusses the treatment of abscess of the liver. In the treatment of this disease prophylaxis plays a very important role, the most important step of which is the prompt and energetic treatment of the amebic dysentery. At a recent meeting of the Egyptian Medical Congress, Kartoulis advocated the routine treatment of amebic dysentery with abundant lavage, twice daily, with a 0.5% aqueous solution of tannin; if such treatment is thoroughly instituted liver abscess need not follow amebic dysentery. He further claims that when liver abscess does occur, it is due to the improper treatment of the dysentery. Kieffer firmly believes this to be incorrect, that in a certain percentage of cases, no matter how thoroughly the dysentery is treated, even when the clinical cure is promptly obtained, abscess follows. Protargol has been used in the treatment of dysentery in injections of a 1% solution, with excellent results. Next to prophylaxis the most important part of the treatment is to relieve the chronic congestion of the liver. This is accomplished by the free exhibition of the saline sulfates, or active counterirritation applied over the surface of the organ. When these measures are unavailing and an abscess appears to be forming, hepatic phlebotomy is indicated. When pus has formed in the liver, the indication is for prompt and thorough evacuation just as in abscess elsewhere. Exploration of the liver for suspected pus must be thorough and searching,

and preferably under general anesthesia; always being prepared to complete the operation of evacuating the abscess cavity or cavities by any of the recognized procedures. The method with trocar and cannula is particularly applicable to deep-seated suppuration in the liver, especially when the pus is found posteriorly or in the dome. Kieffer believes that it is unwise to curet or irrigate the abscess cavity. If the sac is very large, making a counter opening is necessary, then washing the sac is safe. [F.C.H.]

**3.—Rupture of the Urethra; Pyosalpinx; Excision of Tumors of the Neck.**—Manley details the following cases: (1) Urinary extravasation into the perineum and scrotum, subsequent to a rupture of the urethra posterior to a stricture; (2) gonorrheal pyosalpinx in an unmarried woman of 27. The patient has passed through all the acute stages of pelvic peritonitis and there remains a large, tense, painful mass in her left groin, pressing well down behind the uterus. This was opened by way of the vagina; (3) female, 6 years of age, suppurating nodes in the submaxillary triangle of the right side of the neck. Manley is opposed to operating upon these latter cases until local and constitutional remedies have failed, because they never endanger life, and all the talk about their being the centers for the diffusion of sepsis is purely visionary; in most cases they tend toward spontaneous dispersion, and, except in an experienced hand, their operative removal is a highly perilous procedure. [F.C.H.]

**4.—Is Nephroptosis Hereditary?**—Sheldon believes that heredity is the most important factor in the etiology of floating kidney, and that an abnormally movable or a floating kidney never occurs unless the patient is congenitally predisposed to the condition. These opinions have been derived from the experiences and writings of students of the subject and from personal experiences. [F.C.H.]

**5.—A Case of Trigeminal Neuralgia Complicating Typhoid Fever.**—Aldrich reports a case of severe and persistent trigeminal neuralgia which developed in the convalescent period of a typical attack of typhoid fever, and which has continued for three years. In mapping out the area of pain it is strictly delimited to the distribution of the sensory portion of the third branch of the trigeminal. Whether this neuralgia is due to changes which took place in the nerve itself, due to nutritional disturbances or to toxic agents, or whether it is a pressure neuralgia from some swelling and tumefaction of the periosteum or other tissues along its course, it is impossible to ascertain. [F.C.H.]

**6.—The Toxemia of Pregnancy.**—Wells details at length the causes, diagnosis, pathology, prognosis and treatment of toxemia of pregnancy. This condition is not infrequently diagnosed as hysteria. In the majority of cases the prognosis of the toxemia of pregnancy, if not complicated by a preexisting or coincident nephritis, is good, providing the patient is under the careful observation of a competent physician. The diet is detailed. Those remedies which eliminate by the liver and intestines are of the utmost importance, the most valuable of which is calomel in 5 or 10 grain doses daily, combined with phosphate of sodium. When nausea a marked and constant symptom it is best to depend upon enemas to move the bowels, leaving the stomach free for nourishment. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

### REVIEW OF LITERATURE

**Infection and Immunity in Tuberculosis.**—Beever,<sup>1</sup> contending that tuberculosis is but mildly infectious, states that we should educate the public in the matter, stating that the disease does not require isolation, and that only under certain quite exceptional conditions does it appear to be infectious at all. He insists that healthy people enjoy extraordinary immunity, that fresh air and open windows are the great armor against its attacks, and that the instruction of the young in the principles of hygiene will prove more valuable eventually than

the isolation of the unwilling artisan or the excommunication of the clerk. [A.O.J.K.]

**Practical Thoughts on Pneumonia.**—The increase in incidence of lobar pneumonia is attributed by Anders<sup>1</sup> to the prevalence of influenza and changed habits of the people. Various types of pneumonia are considered in detail, special attention being directed to the difference in the anatomic, clinical and etiologic peculiarities of pneumococcus and streptococcus infections. These two affections should be separately described, even though mixed cases are not uncommon. In pure streptococcus pneumonia associated with influenza we have septic manifestations and the looked-for irregular fever and sweats, with profound prostration. The patient is desperately ill of his pneumonia for days before the physical signs, which are those of bronchopneumonia, appear. Many of the so-called typhoid pneumonias are due to the pneumococcus, though a limited number are probably due to other organisms. In Anders' experience hemal leukopenia has not proved to be an unfavorable indication. Adiposity is unfavorable to recovery. Disinfection of the sputum should be employed. Emphasis is given to the fact that urgent indications for treatment during the course of pneumonia may develop with great suddenness. For this reason no physician who pays one or two calls daily can possibly give his patient all the benefits of medical art. In other words, the situation demands the constant presence of either a very skilled nurse or competent physician. [A.G.E.]

**Acute Syphilitic Nephritis.**—Waldvogel<sup>2</sup> reports a case of undoubted syphilitic nephritis. The patient was a man of 31, who, three weeks after the appearance of a number of condylomas around the rectum, presented among other secondary lesions general edema, dyspnea, and dysphagia; within the next week an extensive thoracic and abdominal effusion appeared, and he had to go to bed. His heart was considerably dilated, the urine scant, and contained albumin in large quantities and many casts. Mercurial inunctions were ordered, and the patient began to improve at once. Within a very short time the quantity of urine increased, the amount of albumin diminished, and all the symptoms improved. Three weeks after his admission into the hospital, the patient receiving no treatment but mercury, was free from edema, of pleural and abdominal effusion. He voided a normal amount of urine which contained neither albumin nor casts. [E.L.]

**The Etiology of Acute Rheumatism and Allied Conditions.**—Beaton and Walker,<sup>3</sup> as a result of experimental investigations, state that they agree with those observers who maintain that a particular microorganism is constantly associated with acute rheumatic lesions; that this microorganism can be cultivated on artificial media outside the living body; that on inoculation into animals it gives rise to the characteristic lesions of the disease, and can again be isolated from those lesions; and that culturally the microorganism resembles a streptococcus, but it is specifically different from the ordinary streptococci, according to the test of Marmorek. Accordingly it is concluded that the bacterial specificity of acute rheumatism has been satisfactorily established; its toxic specificity remains to be investigated (at present under examination). [A.O.J.K.]

**Errors in the Estimation of Urea by the Hypobromite Method.**—Elliott P. Joslin<sup>4</sup> considers that this method is usually satisfactory, but errors of nearly 100% may occur. Such errors depend upon the fact that ammonia, acetone, and B-oxybutyric acid are readily decomposed in the performance of the test, yielding products which act in the Squibb's apparatus quite the same as urea. Ammonia acetone and B-oxybutyric acid occur chiefly in diabetes. Reports of large quantities of urea in this disease should therefore be closely scrutinized, and if these bodies are present, such estimations are useless. [F.H.C.]

**Gastric Disorders in Old Age.**—Washburn<sup>5</sup> holds that special instruction regarding the diseases of old age should

<sup>2</sup> Deutsche medicinische Wochenschrift, October 30, 1902.

<sup>3</sup> British Medical Journal, 1903, 1, 237.

<sup>4</sup> Annals of Gynecology and Pediatrics, January, 1903.

<sup>5</sup> Wisconsin Medical Journal, February, 1903.

have a place in the medical curriculum, as gradual progressive alterations in tissues and functions make the anatomy and physiology of the aged differ from that of either the adult or child. Some of these alterations are depicted. Dilation of the stomach is an important cause of gastrointestinal disturbances in the aged. Three cases are cited to illustrate points in treatment. In the way of dietetics old people should eat often and little at a time of a dry, varied diet. Special forms of food are not needed. Medication in the dyspeptics referred to consists of creosote, strychnin, aloin and hydrochloric acid. Antiseptics are of great importance, and if creosote be not tolerated others should be substituted. [A.G.E.]

**Phosphaturia.**—A disease under this name has been described by a number of authors of late. Its symptom-complex shows many clinical variations, but it has one constant symptom: a urine already cloudy at the time of micturition, due to the large amount of its phosphates. Soetbeer<sup>1</sup> reports such a case, which characterized itself by attacks of abdominal colic, catarrh of the large intestines, nutritional disturbances, and phosphaturia. To determine if possible the cause of the latter, which he believed to be due to diminished acidity, he made a number of observations, comparing the excretions of the patient with those of a normal individual under exactly the same conditions of life. He found a great difference in the amount of lime excreted through the urine of the two patients, the sick individual excreting 269% more than the other. This excess coming from his food found its way into the kidney, instead of being excreted, as is usual, by the large intestine. The amount of phosphates did not show any variation from the normal. The author believes that the intestinal catarrh is the cause of the phosphaturia, and that the other symptoms, as the pain, indigestion, etc., are a variety of kidney colic, brought on by excess of lime passing through the renal tubules. [E.L.]

## GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### REVIEW OF LITERATURE

**Transthoracotomy.**—Newbolt<sup>2</sup> reports that a female child of 12 years gave a history of impaired respiration, pain and tenderness in the right hypochondrium, and general discomfort. There was marked distention in the region of the liver, where dulness extended from the third rib to three fingers' breadth below the costal border. A tentative diagnosis of hydatid cyst of the liver was made. Under chloroform a needle was thrust through the eighth interspace and mid-axillary line, which withdrew yellow, foul fluid. The same was true in a thrust through the ninth interspace. The lung was found healthy and retracted, and the wall of the cyst in the liver bulged up at the lower part of the wound. Aspiration drew off eight ounces of pus. The cyst wall was drawn up and sutured to the soft tissues of the wound to cut off the chest cavity. A number of small cysts were found. The large cyst wall was removed and drainage instituted. The patient made a perfect recovery. Another case was that of a man aged 37, who complained of slight tenderness on the right side of the chest with impaired movements, wooden dulness extending upward to a level with the right nipple, breath sounds were diminished, and there was skodac resonance at the right apex. The patient had the appearance of profound illness. The liver extended below the costal border, and was tender. Under general anesthesia a needle was thrust through the ninth interspace and midaxillary line and the pleural cavity opened. It was plainly evident that a large abscess of the liver existed. It was packed with gauze to shut off the pleural cavity and freely incised; the pus evacuated. The chest cavity was shut off, drainage instituted, and the patient made a good recovery. Examination showed the cyst to be of hydatid origin. [A.B.C.]

**The Use of Wet Dressing in Surgery.**—Eisendrath<sup>3</sup> writes on the above subject because the profession in general has not yet learned the lesson of simplicity in surgery. Free

incision in infected wounds is necessary and general anesthesia is always preferable. Freezing mixtures render the parts so hard to cut that they should be limited to cases in which a single small incision suffices. Gauze drainage and wet dressings are recommended and weak antiseptics are better than strong ones. In an experience comprising 2,000 infected wounds a 1:1,000 salicylic acid solution has been used in every case with satisfactory results. The parts involved must be kept at rest and the kidneys, liver, and intestines kept in good eliminatory condition. The conclusion reached is that the wet dressing is the most logical treatment in infected and accidental wounds. They must be saturated with mildest solutions and frequently changed. [A.G.E.]

**Further Report on the Use of Ethyl Bromid as a Primary Anesthesia to Ether.**—Emery Marvel<sup>1</sup> claims the following advantages of anesthetizing by this method over that of the administration of ether alone. The lesser time required to secure anesthesia; the reduction of the discomfort to the patient taking ether shown in the absence of the bronchial irritation, with the increased mucous secretions and consequent coughing; the diminished dangers by injury to the violence from the more marked and longer-lasting excitation in the muscular contraction that frequently takes place in the first stage of ether narcosis; and the lesser amount of ether required, with the consequent more rapid regaining of consciousness and the diminished tendency to postanesthetic vomiting. [F.C.H.]

**Suture of the Brachial Plexus for Birth Palsy.**—Kennedy<sup>2</sup> states that many of these cases recover without treatment; many, however, fail to recover, and he is doubtful as to the efficacy of electrical treatment in birth palsies, though electricity is of undoubted value for diagnostic and prognostic purposes. He holds that the only rational way to treat birth palsies is that of injuries to peripheral nerves in general. No operation should be attempted until sufficient lapse of time has occurred to determine whether electric reactions will indicate an approaching recovery of the muscles. By the time the child is two months of age ordinary electric reactions of the child's muscles are sufficiently stable to determine whether the nerve and muscles properly respond. If after this age there be no response to the faradic current, although of course the galvanic current evokes good contractions, it is safer to proceed with operation than to put it off in the further hope of recovery. Comparatively few secondary operations on the brachial plexus are reported, and in most of these the subsequent history of the cases is not given. The author has operated on three cases, but in only one has sufficient time elapsed for recovery to be well advanced. In this case commencing restoration was first noticed about 12 weeks after the operation, and now after nine months recovery is almost complete. The operation is described in detail. The author advocates exposing the cords of the brachial plexus, following them in the region where injury is probable, breaking up all adhesions. If masses of cicatrices have occurred in the injured nerves these should be resected and the severed cords approximated by sutures. [A.B.C.]

**Hypertrophy of the Prostate and Galvano-Cautery Treatment After Bottini-Freudenberg's Method.**—Bierbaum,<sup>3</sup> at 62, reports his own case of enlarged prostate, which annoyed him since early manhood. Three years ago urinary retention resulted and catheterization had to be resorted to. Under local anesthesia, which only lessened the pain, he had a Bottini operation performed on himself and was at once able to void urine spontaneously. Six days later the catheter showed no residual urine and he has not had to use it since. He had some discomfort for a month, but since then has been a well man. [E.L.]

**Appendicitis from a Physician's Standpoint.**—Castelli<sup>4</sup> argues against surgical interference in every case of appendicitis and says that the necessity of surgical intervention within 24 or 48 hours depends in a greater degree upon the physical constitution of the patient than upon his apparent condition.

<sup>1</sup> Jahrbuch für Kinderheilkunde, Vol. lvi, p. 1, 1902.

<sup>2</sup> British Medical Journal, January 24, 1903.

<sup>3</sup> Wisconsin Medical Journal, February, 1903.

<sup>2</sup> British Medical Journal, February 7, 1903.

<sup>3</sup> Münchener medicinische Wochenschrift, November 25, 1902.

<sup>4</sup> Washington Medical Annals, January, 1903.

In a strong individual the inflammatory process has a tendency to reach its final stage and it is quite impossible to stop its course. In these cases the only chance of recovery is by immediate operation. In weak individuals inflammation progresses more slowly and it may be checked by the resistance of the patient and rational medical intervention. If the physician believes in operating all cases he had better in the latter class wait until the period of recovery, when operation, even if useless, will not be dangerous. [A.G.E.]

**TREATMENT**

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

**EDITORIAL COMMENT**

**Thyroid Extract and Hemophilia.**—Despite our empiric acquaintance with certain pathologic phenomena due to failure of glandular function—as in myxedema—and the effect of supplementing such deficient function by the administration of appropriate substances derived from the lower animals—as thyroid extract—we have but little exact knowledge of the physiologic function and therapeutic action of animal secretions and extracts. Every addition to empiric knowledge in this field should therefore be welcomed; and from analysis and comparison of all the data gathered by experience there may result eventually not only a definite understanding of physiologic and pathologic problems now obscure, but also and in consequence the establishment of sound therapeutic principles from which further practical advances may be made. These remarks are suggested by the report of Dr. Eugene Fuller's experience,<sup>1</sup> abstracted elsewhere in this issue, with the administration of thyroid extract as a hemostatic, especially in hemophilia. The results are evident; there are the facts, reported by a trustworthy observer. The recoveries may have no logical connection with the treatment, it is true, but this proposition is much more improbable than the supposition that the treatment produced them. Knowing so little of the actual pathology of hemophilia—absolutely nothing of its etiology—it would be rash to dogmatize as to the rationale of the cure. Speculation is at least as likely to be wrong as right unless one is willing to deceive himself by repeating words such as "metabolic alteration," "nutritional change," "somatic chemistry," "molecular vibrations," "organic harmonies," etc., etc., which sound well enough but as applied to this problem mean nothing in particular. Certain it is, however, that the role not only of the ductless glands and their secretions, but of many other of the structures and fluids and products of the animal body is but little, if at all understood; and that every fact bearing upon these important questions should be noted and held in mind. Dr. Fuller has therefore not only served his immediate patients and perhaps many others by his new use of thyroid extract, but has added one more drop to the stream that shall finally wear away the stone of our ignorance concerning the physiology, pathology and rational therapy of the thyroid gland and allied structures.

**REVIEW OF LITERATURE**

**Pulmonary Tuberculosis Treated with Lime and Tuberculin.**—Rudolph<sup>2</sup> treated five cases of pulmonary tuberculosis, two of which were very far advanced, with the following combination: Every night he gave from 150 to 200 grams (5 to 7 ounces) of limewater, diluted with an equal quantity of warm water, by rectum. The patient retained it very well, and prompt absorption resulted. They were given a powder of carbonate and calcium phosphate three times daily. The lime was given to increase the lime of the blood and aid in the calcification of the tubercles. This was associated with graduated injec-

tions of tuberculin to set up renewed inflammation. In one of the cases, all symptoms, even the tubercle bacilli, disappeared, the other four improved more than any cases ever under his treatment. [E.L.]

**Pyranum.**—Schlesinger<sup>1</sup> describes a new antipyretic analgesic formed by a combination of benzoic acid, salicylic acid and thymol, being chemically benzoylthymol—sodium benzoyl oxybenzoate. It is a white crystalline powder, soluble in water in the proportion of 1 to 5. Experiments upon the lower animals showed that it has a very low toxicity. Studies made upon the blood-pressure in human beings by a Basch sphygmomanometer showed that large doses cause a slight fall in the pressure, so small, however, as to be within possible physiologic limits. Schlesinger has employed the drug in 146 cases, including such diseases as acute rheumatism, chronic rheumatism, gout, bronchitis, pneumonia, neuralgia, etc. His conclusions are as follows: In various forms of neuralgia and symptomatic pains the remedy shows itself possessed of very marked analgic powers. In acute rheumatism it lessens both the fever and the pain, exercising an action similar to that of salicylic acid, but without the drawbacks of this remedy, such as depression of the heart, too free sweating and disturbance of the stomach. It was used in a few cases of bronchitis and bronchial asthma with apparently good results, although the number of observations was too small to allow of positive conclusions. Pyranum may be given either in a solution or in gelatin capsules, the preference being for the latter mode of administration. After its administration in capsules the salicylic acid reaction was demonstrated in the urine within 20 minutes. The dose is from ½ gram to 2 grams (7 to 30 grains) two or three times a day, according to the individual indications. The effect of the drug is greater than would be the corresponding effects of any of its three components in equivalent dose. The results of its administration may, therefore, be attributed to the peculiar combination. [H.C.W.]

**Treatment of Varicose Ulcers.**—A. Robin<sup>2</sup> directs that the ulcers be covered with compresses which have been dipped in a mixture of 1 part of Labarraque's solution to 3 parts of water, and these covered with oiled silk and held in place by a bandage. The strength of the solution may be increased ¼ or ½ if the application causes no pain. The dressing should be renewed every morning. If this treatment fails, skin grafts may be tried. The patient should be kept at rest and the limbs massaged daily. Internally, small doses of hamamelis have proved beneficial. [L.F.A.]

**Paraldehyd and Hyoscin as Somnifacient and Quiescent Drugs in Disease.**—Bumke<sup>3</sup> has used paraldehyd in a large variety of diseases and refers to it as being a drug which, when properly prescribed, always produces sleep, and even when continued for a long time is never dangerous, not even carrying with it unpleasant after effects. On account of its strong odor and taste it should be given highly diluted in very sweet tea or other liquids, but never in beer, wine, cognac, etc. Its dose varies from 3-6 grams (45-90 grains). Natural sleep follows within 3 to 15 minutes and lasts from 5 to 8 hours. Cases of paraldehyd poisoning and habit have never been observed by him. In only a few cases of violent mania and other forms of insanity have the results been disappointing, and in such cases hyoscin hypodermically has had to be resorted to. It produces sleep by diminishing the excitability of the brain. Its after effects are mydriasis and diminution of the secretion of saliva and sweat. Death due to poisoning with it has never been reported. [E.L.]

## NERVOUS AND MENTAL DISEASES

J. K. MITCHELL

F. SAVARY PEARCE

## EDITORIAL COMMENT

**Lunacy and the Law** is the title of an address delivered by Sir William R. Gowers, M.D., F.R.S., before the Medico-Psychological Society of Great Britain and Ireland. This address, which is a modern criticism of some of the methods now in vogue for the treatment of the insane, is worthy of comment. In presenting this very important topic in mental medicine the author first criticises the stone wall about the asylum at Hanwell, and then discusses the things which have prevented to some extent a just appreciation of the advancement already made in the treatment of this class of patients, the greatest factor in this probably being the indignation of the public over the alleged ill treatment of imbeciles, and the incarceration in insane asylums of certain persons who have been proved sane at the time of their commitment. The author emphasizes strongly the importance of distinguishing between the different forms of mental derangement and deplors the tendency to use the same restrictions for the various types of insanity. He believes the present English law is faulty, as in certain cases in which it is not considered necessary to confine the patient to an asylum, the patient is branded as insane the same as those whose cases demand commitment to the asylum. In this connection he states: "This is compulsory (upon the physician) under heavy penalty irrespective of the character of the malady from which the patient is suffering and without the least regard for any necessity for it; without the least regard for the harm to the sufferer which may ensue, and which does and must result in a large number of cases." He dwells on the injustice of a such a course, particularly in a certain class of "border line" cases, in which the two Commissioners are very apt to take opposite views, and also of its workings in many cases of mental alienation in which the patients quickly recover. "To compel every person of unsound mind to be certified cannot secure that no sound person shall be certified." Many measures are discussed that bear the broadest humanitarian aspect. Reference is made to a patient with tumor of the brain who was partially paralyzed in the legs and arms and bedridden, and who was sent to an asylum because the Commissioner knew she had delusions, her doctor being fined for not certifying that his patient was insane. To our minds one might as well commit a patient having typhoid fever with delirium to an asylum. It is very evident, as Dr. Gowers suggests, that the mere advancement in psychiatry has been misinterpreted by those who, having a limited knowledge as to the therapeutics of mental disease, would claim the insane asylum to be the proper habitat of every person of unsound mind.

**The Relation of the Medical Expert Witness to the Lawyer and the Court.**—There has been much just criticism by the legal profession regarding the so-called medical expert witness and his testimony. There can be no doubt that expert testimony is at times lacking in accuracy, speaking, of course, of the honest witness. The subject is not finished when the medical profession has been thoroughly overhauled and placed in the direction of rectitude; and we would therefore emphasize the fact that scientific evidence alone should be tolerated. Also a better sense of justice toward medical men is needed by the lawyer, who has great advantage when the expert is placed upon the stand. There seems to be a tendency among legal minds to assume knowledge of medical matters which we have learned only through years of research. An example is that of a judge in one of the courts of Philadelphia, who presumed and did support his own theory that the "previous history" of a case of mental disease bore no

relation to the mental status of the criminal some months before his coming to trial, when he had committed a murder. It is needless for us to call the attention of the medical profession to the desirability of holding together in the endeavor to teach the judicial man that when an expert is called there are matters of evidence that should be admitted which the judge is not able to decide upon, and that, therefore, if the expert is put upon the stand he should be given the right to explain why a previous history bears upon the case, especially when the defendant's insanity is questioned. It is by no means entirely the fault of medical witnesses that damage suits and murder cases do not always receive full justice. An astute lawyer may juggle scientific data of which he knows absolutely nothing; and by superior excellence in declamation may induce a jury to assume that his wordy opinion should be the final judgment. There are many lines in which the medical guild should be at one, and not the least is that in training themselves as experts and in seeing also that our worthy professional brethren, the lawyers, do not trespass upon truly medical matters any more than they will tolerate the doctor-lawyer.

## REVIEW OF LITERATURE

**The Criminal Responsibility of the Epileptic.**—John Punton gives a brief summary defining the demarcation between empiricism and scientific knowledge in the study of epilepsy. He holds that the modern conception of epilepsy is based on cerebral localization and that epilepsy is a symptom of brain disease whose continued presence tends to mental deterioration. The mental responsibility of the epileptic depends largely upon the extent to which the brain and its functions were impaired. The fallacy of legal tests as applied to epilepsy is noted and criminal irresponsibility is not incompatible with a true knowledge of right from wrong. Hence the criminal responsibility of the epileptic should be based upon his power of self-control. Punton holds that the opinion formulated by Justice Stephen, of London, is eminently proper and should be universally adopted. It is as follows: "No act is a crime if the person who does it is at the time when it is done prevented either by defective mental power or by any disease affecting his mind from controlling his own conduct *unless the absence of the power to control has been produced by his own default.*" Epilepsy may be congenital or acquired, hence the importance of its etiology and the relation it bears to crime. None doubts that alcohol and syphilis are potent factors in causation and promote the development of homicidal acts so common in epilepsy. When murder has been committed by an epileptic the law should hold the criminal epileptic under medical surveillance the rest of his life. Careful discrimination should be made between punishment and medical treatment. No insane criminal epileptic should be punished unless his epilepsy was brought about by his own default and even then his pitiable condition appeals to medicine rather than law. The question of mental responsibility should be decided by a medical commission appointed by the court; and their report returned to the court prior to the trial should be the basis of adjudication independent of the lawyers engaged. Suitable compensation should be allowed by law for such service. The following deductions are offered: Epilepsy is a symptom of some brain disease; its continued presence tends to mental deterioration; the mental responsibility of the epileptic depends upon the extent of self-control; the legal test of insanity is not sufficient, as mental irresponsibility is not incompatible with a knowledge of right from wrong; epileptics are to some degree at least responsible for criminal acts, more especially when the epilepsy is produced by their own default; criminal acts of epileptics appeal to medicine rather than law for their proper adjudication; in case of murder where epilepsy is proved the law should permit life commitment to an insane hospital rather than a penitentiary; the mental responsibility of the epileptic should be referred to a medical commission appointed by the court which again may be referred to the local county or State medical organizations; a just recompense

should be legally allowed for such medical service. [It might well be added to these recommendations that the epileptic criminal and the insane criminal should be confined in institutions especially devoted to them and not in general insane hospitals. In this State at least a verdict of guilty but insane frees the criminal instead of carrying with it as it properly should a condemnation to a place of detention until cured and surveillance afterward. An even better summary of the test of responsibility than that of Mr. Stephen may be thus stated: If the accused person could refrain from the act he is responsible; if the disorder of mind has so injured his power to inhibit his impulses that he cannot control them he cannot be considered responsible. But neither of these formulas will suffice to include all possible cases. Mr. Stephen is defective in making an epileptic answerable for his epilepsy, for though he may have acquired it by his own fault, vice or ignorance, its presence may result in the destruction of his inhibitory control.]

**Paramyoclonus Multiplex.**—Langdon<sup>1</sup> reports a new case with further history of a case reported in 1896, which has since recovered. The new case was a girl of 13, generally delicate; no gross defects physical or mental. There was onset of muscular spasms in paroxysms shortly after being frightened in play. The spasms were shocklike and clonic in character, typical in distribution, affecting muscles of trunk and those connecting trunk and extremities. The face, hands and feet were not affected. There was no paralysis, no anesthesia, no contraction of visual fields. The reflexes were highly exaggerated, both cutaneous and muscular. There were no sphincter defects. Ankle clonus and Babinski's sign were absent. The mental state was not emotional. The frequency of shocks was from 30 to 100 per minute. Paroxysms lasted during waking hours as a rule, and always ceased when the patient slept. The sense of excessive fatigue was constant. Temperature normal. Pulse 72 to 108, low tension. Heart and lungs clear. Urine normal. The treatment was by antispasmodics, tonics, and rest in bed, with full feeding. The child remains well to date (four months after last paroxysm). The case reported in 1896, male, age 48, presented practically the same distribution of spasms following mental worry and a light attack of la grippe. Duration of shocklike contractions about 14 months, with occasional intervals of comparative freedom for a few days. Patient remains well to date (about five years).

**Pathogenesis and Surgical Treatment of Exophthalmic Goiter.**—A. E. Halstead<sup>2</sup> thinks the thyroid is the seat of disease on account of the remarkable antithesis that seems to exist between the symptoms of exophthalmic goiter and struma-thyropriva when the functioning gland does not exist; also in the effect of struma operations since the improvement following removal of the vascular gland is most notable. The bad effect of administering thyroid in Basedow's disease is another point as regards etiology. The author does not approve of exothyropepy as practised by Jabaulay since symptoms of acute thyroid intoxication are frequently noted. Partial resection of the cervical sympathetic, including both unilateral and bilateral resections, is the most favorable operation. Balascescu reports nine cures, eleven greatly improved, and two unimproved. There were five deaths but not due to the operation.

**Treatment of Epilepsy.**—P. Jarnot<sup>3</sup> writes a short paper approving the use of bromids in treatment. He claims that the general irritability of the nerve centers in epilepsy, both in the paroxysmal and interparoxysmal states, is best allayed by the use of this drug, though without specific action. Granting the cortical origin of epilepsy, he refers to most all the classic writings of Locock (1851), Voisin, Damourette, Relvis, Legrand du Saule, Charcot and others, and considers the bromids, therefore, the most rational remedies to allay such irritability. Potassium bromid he considers in the first rank. The dosage should be uniform and regular as possible—60 grains per day up to 150 grains a day, depending on the effect. He particularly dwells upon the careful continuous dosage and the very remarkable results in some cases.

**Mental Dissolution the Result of Alcohol.**—Robert

Jones<sup>4</sup> goes carefully over the statistics of the general effects of alcoholism and of alcoholism and insanity in which claim is made that 21.8% in men and 9.5% in females in the yearly admissions as prepared by the Lunacy Commissioners are of insanity due to alcohol. Special effects of alcohol is also dwelt upon, such as degeneration of nervous and nonnervous tissues, due to disturbed metabolism. He claims convulsive symptoms are more prone to occur from absinthe and of analgesia from wines. Inheritance of insanity or nervous disorders is found in from 25% to 33% of insanity induced directly by alcohol. Desiring to avoid the "fallacy of extremes," the author is of the opinion that the best working hypothesis for the prevention and cure of all forms of alcoholic disorders, whether mental or physical, must be that based upon the practice of total abstinence.

**Tube-like Field of Vision in Hysteria.**—R. Greff<sup>5</sup> refers to the central limitation of the field of vision being very reliable in the diagnosis of hysteria. The patient in such cases says he sees objects as through a hollow tube. The writer has found it present in no other disease, hence he considers it a positive diagnostic mark of hysteria when present. Acuity of vision in such patients is, however, normal. The ophthalmoscopic findings are of course normal. Also when the distance of examining is increased the patient's field of vision does not increase in proportion, a valuable sign that when present simulation is thus ruled out. A definite venous and arterial pulse was also seen in the papilla in the case reported, due to abnormal irritation of the entire vascular system, as no arterial disease was found to exist.

**Pseudomeningitis of Psychological Origin.**—Starck<sup>6</sup> reports upon this class of cases. Symptoms of meningitis existed, and yet at postmortem no lesion was found. Schultze first described the condition. Krannals, Cohts, and Strumpell have all reported cases of similar nature. The toxic process is the theory which alone explains the symptomatology. There is another class of cases somewhat similar to the above, first described by the French in 1870, but in which the patient invariably recovers. This last class is supposed to be entirely of psychic origin. In the latter an important point in diagnosis is that the disease runs its course without fever. The patient the author reports gave a history of headache and vertigo lasting eight days. There developed pain in the back, vomiting, chills, and contraction of the muscles of the neck. The man was immovable in bed, passive movements producing great pain. Every few minutes there were tetanic convulsions accompanied by cries of pain. The eyes were closed, but no ocular palsies existed. All reflexes were much increased. No fever. Hypnotism was resorted to, and with suggestion all the symptoms disappeared.

**Alcoholic Epilepsy.**—T. D. Crothers<sup>4</sup> says alcoholic epilepsy is increasing rapidly in this country. It is a neurosis which should be recognized, having distinct symptoms, the recognition of which is imperative in treatment. When the toxic symptoms are convulsive and explosive and come on suddenly the future of the case is very ominous, and the warnings from these symptoms should be heeded. The connection between mixed drinks and these spasmodic symptoms are traceable and should be considered in the prognosis and treatment. The treatment and curability of these cases can be carried on with great hopefulness, and undoubtedly in the future will become a prominent part of the work.

**Feigning of Insanity by a Traumatic Lunatic for Personal Damage Reasons.**—Kiernan<sup>5</sup> speaks of the lack of appreciation of the fact in forensic neurology or psychiatry, and that this bias, foreign alike to science and the spirit of common law, too often exerts a baneful influence in thus taking a "danger to society" viewpoint as proof alone of insanity. The simulation test of sanity by the insane is recorded as long ago as the sixteenth century. At the time when Shakespeare wrote "King Lear," feigning insanity by the insane was a familiar street sight. But still records show comparatively

<sup>3</sup> Gazette des Hôpitaux, November 13, 1902.

few cases in which insanity has been feigned by the insane for self-interest alone; usually it is to avoid the consequences of violation of the law. Simulators are apt to manifest a loss of memory which is so great as to render it practically impossible that it should be real. When the insane answer questions at all they usually answer with some degree of sense, whereas if he is simulating this phase of an insane person he may manifest an entire absence of relation to the question. Kiernan wishes to demonstrate that the case reported shows that simulation *per se* is not positive evidence against actual mental disease.

**The Tics in General.**—E. Noguès<sup>1</sup> goes carefully over the subject of tics and decries the confusion of the subject brought about by the improper use of the term *tic* which applies to movement. Hence *tic douloureux* he considers a misnomer. Also with Meige and Feindel the author insists on the difference between *tic* and *spasm* which latter is a motor reaction the result of imitation within a reflex spinal or bulbospinal arc and due to some pathologic cause. *Spasm* to no degree is under the influence of the will, while *tic* is (Charcot). There is definite relation therefore between *tic* and the mental state. The general characteristics of *tics* then are of involuntary movements modified by the action of the will, which may *arrest, transform or avert*. A *tic* is also periodic.

**The Rational Treatment of Locomotor Ataxia.**—Curran Pope<sup>2</sup> considers only the medical treatment. The first and most important thing to decide is whether the case demands antisyphilitic drugs. Spinal syphilis must be carefully differentiated from tabes. He denies the excessive use of iodids and mercury. In the use of the latter the patient's color, hemoglobin, and weight should be watched. Silver nitrate, grain  $\frac{1}{2}$  to  $\frac{1}{4}$  after meals, is the drug he has found most useful. The tonics of value are iron, arsenic, quinin, cannabis indica, and the phosphates. Strychnia is apt to produce nervous erythrm, and increases the pains. The serums can not be recommended. The symptomatic treatment used for pain is acetanilid, caffeine, camphor monobromate, and cannabis indica combined; or phenacetin or salophen, but general treatment helps most. Morphia in the cases should be used with caution. For vesical retention and incontinence, the catheter is best used. Internally, hyoscyamus, buchu, and boracic acid are of benefit. Faradic electricity gives good results. For amaurosis hypodermic injections of strychnin, gr.  $\frac{1}{100}$ , cautiously increased, or of a cyanid of gold and potassium. Mechanical measures: Hydrotherapy is first begun by means of the half bath, the patient being seated in a tub of water, 12 to 14 inches deep, at a temperature ranging from 70° to 85°, of two minutes' duration, gradually increased. This is followed by a hard rub with a Turkish towel. The use of the spray or rain bath at 104° for two minutes following the use of electric light bath until sensible perspiration occurs is of value. Static electricity in the form of heavy sparks to spine, extremities, epigastrium, and bladder, followed by bead shower is a valuable agent. Massage and suspension are mentioned as valuable adjuncts as is the method of reeducation as outlined by Fraenkel.

**Secondary Traumatic Insanity.**—S. A. Dunham<sup>3</sup> speaks of etiology, symptomatology and pathology in a paper giving the report of a case 18 years after injury, and recovery after trephining. He confirms in this reported case the statement of Theodore Kellogg, viz.: "There are cases in which we find intervals of weeks and months or years between the cranial injury, which may have caused slight depression of the skull, and the attack of mania or melancholia, which may manifest a recurrent tendency." Head injuries as a physical cause of insanity attract attention because of the possible opportunities offered for cure. In some cases even concussion of the brain alone may produce insanity. In the case reported there was no traceable hereditary or acquired neuroses to predispose the patient to insanity. Gradual change in disposition, loss of memory, confused ideas, which later developed into hallucinations, delusions and periodic attacks of mania, were all in the initial stage of the case. The man suffered from headache and vertigo, with various disturbances of the special senses. He

was 42, and had been struck upon the head at 24 by a club, and was unconscious for two hours. He could feel a soft spot on the vertex next day, but no physician saw him. He has never felt well since injury, and was unable to work more than half time during the two years previous to the insanity. Changes of character, such as impatience, apprehension, loss of memory, confusion of ideas then followed. At the time of trephining over the "tender spot" the man had just recovered from one of his periodic mental storms. During the past two years he had suffered from maniacal outbursts, followed by great mental depression. The button of bone (one inch in diameter) was removed from the anterosuperior angle of parietal bone of right side. The dura was a little thickened, but no adhesions. The bone was thickened on the inner table. He recovered promptly and has been well ever since.

**The Depth of Sleep.**—Sante de Sanctis and U. Neyroz.<sup>1</sup> This interesting communication on the depth of sleep in normal individuals and in psychopathic persons deals with the degrees of stimuli that are required to arouse the sleeping person. Instead of using auditory stimuli, as employed by previous observers, such as Kohlschütter and Michelson, Sanctis and Neyroz adopted tactile and pressure stimuli, using for the purpose esthesiometers with both sharp and blunt points, the pressure of which could be nicely regulated to a degree just sufficient to cause awakening. The experiments made upon each person lasted over six months, and were carried out at different hours on successive or irregularly alternating nights. Four were normal and five were abnormal subjects. Hourly oscillations in the depth of sleep occurred, although the greatest depth occurred within 1½ hours after falling asleep. A secondary deepening occurred during the middle period of total duration of sleep. In all five pathologic patients the depth of sleep was greater than in normal persons.

**Cerebral Sclerosis and Focal Symptoms.**—Seven years ago Gussenbauer<sup>2</sup> trephined a patient who presented symptoms of focal epilepsy; at the time he found no growth, but a localized induration of the brain. During the remaining years of the patient's life the epileptic convulsions became more and more frequent, the right side and later the left became paralyzed, and his intellect deteriorated until he was a pronounced idiot. At the autopsy the following lesions were found: Multiple sclerosis of brain and spinal cord; atrophy of brain, especially its left side, where the sclerotic areas were most numerous; chronic internal hydrocephalus and lesions of less importance in other organs. The disease probably began as an apoplexy, leading to a sclerosis of the ascending parietal lobe, and from thence the sclerosis with its secondary atrophy spread to its present dimensions. The absence of choked disc and the infrequency of headache excluded at all times the existence of a growing tumor or cyst. [E.L.]

**The Treatment of the Crises in Locomotor Ataxia.**—Hirschkron<sup>3</sup> says that although we can scarcely count on a cure or a lasting cessation of the symptoms in tabes, the condition of the patient may be made much more comfortable and the progress of the affection retarded. If possible the diagnosis should be withheld from the sufferer. The patient must be taught to live a quiet life as if he were an old man, avoiding all excesses and excitement. He must also guard constantly against cold. Hirschkron deprecates the rest cure for tabes, as it only increases the muscular weakness. No drug has any marked effect on the progress of the disease. Only two exert any influence, ergot and sodium iodid. Hirschkron has not seen any beneficial results from either antiluetic treatment or organotherapy. The aim of the physician therefore should be to ameliorate symptoms. One of the most urgent of these is the lancinating pain, for the relief of which Hirschkron prefers the coal-tar antipyretics, and has had especial success with citrophen in doses of two or three grams daily. The long continued use of the bromids is also beneficial. Salicylates are sometimes of value, especially in cases following exposure to cold. Very frequently the pains are reflex from irritation of the anus by a chronic eczema. In this condition he recommends a proprie-

<sup>3</sup> Therap. Monthly, April, 1902, p. 127.

tary ointment called Analon, composed of astringents, antiseptics and ichthyol. Various external measures are useful for the relief of ataxic pains. Wet pack at a temperature of 18° C. or a half bath at 28° C. are of value in different cases. Sometimes the local use of ethyl chlorid spray will check the pains. A very valuable mode of applying heat is by the use of ichthyol mud. The patient is laid on an old blanket, a piece of mull wrung out of a warm 30% ichthyol-glycerin solution is placed over the aching spot and the whole part wrapped in a sort of poultice made of ichthyol mud between two sheets, and the whole well covered to keep it warm. In the visceral crises the only thing of value is a hypodermic injection of morphin, which is better given in a single dose sufficiently large to control the pain than to be forced to repeat it. A combination of morphin with the bromids, as in the following prescription, is very useful:

Sodium bromid . . . . .	40 grains
Potassium bromid . . . . .	40 grains
Morphin hydrochlorate . . . . .	½ grain
Syrup . . . . .	4 drams
Distilled water, enough to make . . . . .	6 ounces

One tablespoonful every 2 or 3 hours. [H.C.W.]

**Prognosis in Neurasthenia.**—The observations of Bradley<sup>1</sup> are based on the study of 104 cases of neurasthenia occurring in a total of 424 cases of nervous diseases of all kinds. Of the 104 patients 64% were females and 36% males. Prognosis, based on the etiology of the disease, is as follows, beginning with those most amenable to treatment: External toxins, overwork, following childbirth or lactation, toxic, sexual excesses, worry, metabolism. The writer calls attention to a point in neurasthenia (applying also, though to a lesser extent, in other neuroses) that he has never seen mentioned in literature, viz., the depressing or inhibitory effect of coffee on the reflexes. Series of tables show that in neurasthenics using three or more cups of coffee daily the knee-jerk was normal in 34%, diminished in 43%, increased in 23%. In those using less than three cups, 54% were normal, 34% increased, 12% decreased. This fact, if coffee causes the greater number of diminished reflexes, may help explain why those cases make more rapid and permanent recovery, the toxic substances present being rendered more soluble by the coffee. [A.G.E.]

**State Care of the Insane.**—Hurd<sup>2</sup> discusses the present method of treating the insane in Maryland, and shows that although the county almshouses and county receptacles are in a better sanitary condition, and that the insane therein confined are better cared for than they were five years ago, still these institutions present great defects, and the methods employed are very imperfect. He says that it should be the effort of every physician in Maryland to promote State care, and that there is every reason to believe that the insane of Maryland will not be properly cared for until all the dependent insane are gathered into State institutions. A reception hospital for the reception and treatment for a limited time of alcoholic and nervous border-line cases, and insane cases, is advocated for Baltimore. When the character of the case has been ascertained, the patient may then be removed to the proper institution. Hurd says that the colored insane of Maryland, especially, do not receive good treatment, and that these patients are constantly increasing in numbers. He advocates their treatment in a separate institution in the center of the colored population of the State. In speaking of the criminal insane, a separate building should be erected for the criminal insane and for those who are dangerous. Colonies are recommended for the chronic insane, the epileptic, and the feeble-minded, where they may have manual labor, open-air life, and agreeable environments. [C.A.O.]

**Disadvantages of Active Mercurial Treatment of Syphilitic Spasmodic Paraplegia.**—E. Brissaud and Pierre Marie<sup>3</sup> believe that active mercurial treatment should not be instituted in syphilitic spasmodic paraplegia when at the end of 18 months or 2 years it has become chronic. If used at this time, patients who still walk with difficulty sometimes lose this power and are forced to be confined to their beds, the move-

ments of flexion of the lower limbs becomes worse and sometimes are totally lost; parasthesias and paralyzes of the upper extremities at times appear and the general nutrition of the patient is decreased. At the very beginning of the affection, when there is still only slight difficulty in walking and slight feebleness in flexing the legs, active treatment may be employed. [L.F.A.]

**The Diagnosis of Neurasthenia.**—The diagnosis of neurasthenia is frequently made in cases of paralytic dementia, dementia præcox, mild mania, and melancholia, and to prevent further errors of this kind, Kraepelin<sup>1</sup> carefully discusses the differential diagnosis of these diseases. He considers neurasthenia a chronic exhaustion of the nervous system, brought on by long continued overwork, either mental or physical, by accumulations of the poisons of fatigue, alcohol, morphin, debilitating disease with incomplete recovery, sudden and violent mental shock. In many cases an inherited predisposition to it exists. [E.L.]

**Some Mechanotherapeutic Measures Useful in Locomotor Ataxia.**—Hirschkrone<sup>2</sup> believes that baths are very useful in tabes, not by producing any anatomic cure but on account of their sedative action. Highly concentrated salt solutions or excessive temperatures are to be avoided; the temperature should be from 30° to 32° C., and the time not over 15 minutes. Sweat and steam baths should be employed only in the early stages; brine and carbonic acid baths are useful when there is debility or anesthesia. The dry electric brush is also useful for the anesthesia or paresthesia. The results of the suspension treatment are not so brilliant as at one time claimed, although it sometimes affords considerable relief. True suspension, as recommended by Charcot, is often dangerous, and he has abandoned it. A useful means of applying the suspension principle is to place the patient on an inclined plane and employ weight traction, as in fractures of the leg. Another ingenious method is by bending the body forward. The use of corsets which support the shoulders from the hips is frequently grateful, perhaps by a sort of suspension effect. [H.C.W.]

**Tumor of the Fourth Ventricle.**—Bruening<sup>3</sup> reports the case of a boy of 3 years, who two months prior to his death fell from a chair, striking his head, and from then complained of frontal and occipital pain, vomited frequently, and lost weight. He occasionally cried out loudly; a peculiar percussion note was elicited by striking over the occiput, and there was a slight general tremor. He held his head spastically to the left, and later downward on the chest; his gait was ataxic. Numerous other peculiar symptoms existed at times, but no symptoms seemed constant until toward the end of the disease, when an acute hydrocephalus developed, and all reflexes became increased; strabismus and nystagmus appeared. A few days later he became paralyzed and comatose; repeated attempts at lumbar puncture failed, no fluid being aspirated. A diagnosis of tumor was made, but neither its character nor location could be agreed upon. The autopsy revealed a degenerating ependymal glioma the size of a hen's egg springing from the floor of the fourth ventricle. The author has collected 33 cases of tumor of the fourth ventricle from literature, and but 6 were in children; 4 were boys and 2 were girls; none of them was tuberculous. In 2 cases traumatism was the exciting cause, 1 followed varicella; in 3 the cause was not determined. The most characteristic symptoms were the negative lumbar punctures, the tumor occluding the communication with the subarachnoid space of the spinal cord, and the spastic inclination of the head down to the chest. [E.L.]

**Treatment of Infantile Epilepsy.**—Méry,<sup>4</sup> in discussing the treatment of infantile epilepsy, states that when the attacks are preceded by an aura they may sometimes be prevented by the application of a ligature or blister on the part which is the seat of the aura. When the attacks follow each other in rapid succession, an active purgation, by relieving cerebral congestion, at times lessens the severity of the attacks. These procedures, however, are only palliative. To prevent the return of the attacks, potassium bromid gives the best results, espe-

cially when the chlorids in the diet are lessened to about  $\frac{2}{3}$  of the normal amount. The average dose of potassium bromid for a child is from 80 to 75 grains daily, although this may be decreased when the chlorids in the food are diminished. [L.F.A.]

**The Spasmodic Form of Syringomyelia.**—Guillain<sup>1</sup> showed three cases of spasmodic syringomyelia before the Medical Society of Paris, and referred to two others on which he had made postmortem examinations. The following symptoms are peculiar to this form: The attitude of the patient is characteristic, the arms hang alongside the trunk, the forearms are flexed on the arms, the shoulders are elevated, the head depressed. The outer border of the trapezius projects forward, showing marked depression in front of it, the back is curved; the entire attitude gives the impression of rigidity. The last three fingers of the hand are flexed progressively in the palm; the index finger and thumb remain apparently normal for a much longer time, and are used by the patient in the manner of a pair of forceps. The patient's disturbances of motion and gait do not depend upon muscular atrophy, but upon the spasmodic and contracted state of his muscles. All the reflexes of the lower extremities are exaggerated; ankle clonus is easily demonstrated; the toes extend when the plantar surface is irritated. Disturbances of the bladder are present, such as painful contraction of the muscle, urinary retention, painful micturition, hematuria, cystitis, sometimes ulceration of the bladder. Death results from uremia, exhaustion, or intercurrent affection. In both studied cases, extensive destructions of the cervical cord, degenerations of the lateral pyramids of both sides along the entire cord, a condition which does not occur in the ordinary variety of syringomyelia, were present. Guillain says that it is impossible to clinically differentiate between cervical pachymeningitis and spasmodic syringomyelia. [E.L.]

**Raynaud's Disease.**—Souques presented to the Société Médicale des Hôpitaux, June 6, 1902,<sup>2</sup> a man of 28 years who for five years had suffered from crises characterized by local cyanosis of the extremities, particularly of one hand, sometimes of both. These crises, habitually provoked by the sensation of cold, were accompanied either by anesthesia or by sharp pain; during the paroxysm the local temperature was lowered from 1° to 5° C. Examination of the subject demonstrated the existence of hysteric stigmata, and a cure was effected by indirect suggestion, a pill of methylene-blue being prescribed and the patient told that the blue coloration of his hands would pass away in the urine, from which time the coloration and temperature of the extremities remained normal. [C.S.D.]

**Treatment of Neuralgia.**—Bernard<sup>3</sup> states that he has cured many cases of neuralgia, and especially sciatica, by the subcutaneous injection of artificial serum at the level of the painful points. The following solution is usually employed:

Sodium chlorid . . . . .	75 grains
Sodium sulfate . . . . .	3 ounces
Distilled water . . . . .	1 quart

This should be carefully sterilized and 1 dram of it injected daily beneath the skin at each painful point. In sciatica, when the pain is felt in the region of the buttocks, the injection should be given deeply into the tissues. The injection would should be closed by collodion to avoid infection. Good results have followed this treatment in intercostal and facial neuralgia. [L.F.A.]

**Contribution to the Anatomy and Physiology of the Cerebellum.**—Since the various investigators differ in the description of the degenerative process after cerebellar lesions, Probst<sup>4</sup> seeks to verify their statements. Numerous experiments were performed by him on different animals, lesions being produced in different portions of the cerebellum. The animals were closely observed before and after the operation, and he describes their antemortem behavior as carefully as the postmortem findings. To determine the extent of the lesions, the anatomic and pathologic condition of the tracts leading to and from the points of lesion, and the terminal points of the

degeneration, very careful histologic examinations were made by securing uninterrupted serial sections. The stain used was Marchi's osmic acid stain as modified by him. The description of the details of the experiments is lengthy but interesting, and the conclusions are summed up at the end of the article. [E.L.]

**Antipyrin in Chorea.**—Comby<sup>1</sup> has had good results from antipyrin in chorea. It is necessary to give very large doses. For a child of 10 he uses a dram a day. To avoid accidents from the drug he enjoins rest and the free drinking of water. [We should think that despite these precautions such heroic doses would be very dangerous. H.C.W.]

**Sodium Cacodylate in Mental Diseases.**—Paulet<sup>2</sup> reports the use of sodium cacodylate in place of other arsenical preparations in 17 patients suffering from certain mental diseases. Of these 13 were personal observations. Of the 17 cases 2 have given absolutely negative results, 4 have given a good result from the physical point of view without mental improvement; 11 have shown more or less marked mental and physical improvement. In some cases the improvement may justly be called a cure. The cacodylate should be given in doses of not over 2 grains daily, preferably beginning with doses of  $\frac{1}{2}$  of a grain daily and gradually increasing it. After giving the drug for eight days there should be a similar period of rest in order to avoid toxic effects. [L.F.A.]

## THE PUBLIC SERVICE

### Changes in the Medical Corps of the U. S. Army for the week ended February 23, 1903:

KENNEDY, Captain JAMES M., assistant surgeon, is granted leave for one month, with permission to apply for an extension of one month.

WOOD, HALSEY L., contract surgeon, will proceed to Fort Wright for duty, to relieve Contract Surgeon John C. Byrne, who will proceed to Fort Flagler for duty.

MASON, Major CHARLES F., surgeon, will rejoin his proper station not later than February 23.

### Changes in the Medical Corps of the U. S. Navy for the week ended February 23, 1903:

FIELD, J. G., surgeon, detached from duty with recruiting party, and ordered to the Bennington—February 20.

HART, G. C., acting assistant surgeon, ordered to duty with recruiting party—February 20.

ROSS, J. W., surgeon, appointed medical director from February 5, 1903—February 21.

DEVRIES, J. C., acting assistant surgeon, appointed acting assistant surgeon, February 16, 1903—February 21.

MARSTELLER, E. H., surgeon, ordered to the Panther, via the Raleigh—February 24.

PRICE, A. F., medical director, detached from the Naval Hospital, Washington, D. C., and ordered to the Navy Yard, New York—February 24.

WILSON, G. B., surgeon, detached from the Panther and ordered to the Naval Hospital, Chelsea, Mass.—February 24.

STOKES, C. F., surgeon, detached from the Oregon and ordered home to wait orders—February 24.

WRIGHT, B. L., assistant surgeon, detached from treatment at the Army General Hospital, Fort Bayard, N. M., and ordered to the Naval Hospital, Pensacola, Fla., for treatment—February 24.

SCHWERIN, L. H., acting assistant surgeon, ordered to duty with recruiting party, No. 4—February 24.

### Changes in the Public Health and Marine-Hospital Service for the week ended February 26, 1903:

KERR, J. W., assistant surgeon, to report at Bureau for special temporary duty—February 21, 1903.

WARREN, B. S., assistant surgeon, granted extension of leave of absence, on account of sickness, for thirty days from March 1—February 24, 1903.

ROSS, M. H., acting assistant surgeon, relieved from duty at Cairo, Ill., and directed to proceed to Los Angeles, Cal., and report to medical officer in command for duty—February 24, 1903.

SAMS, F. F., acting assistant surgeon, granted extension of leave of absence, on account of sickness, for thirty days from February 17—February 24, 1903.

RICHARDSON, S. W., pharmacist, granted leave of absence for seven days from February 21, 1903, under provisions of paragraph 210 of the regulations.

THURSTON, E. J., pharmacist, to report to chairman of board for physical examination to determine fitness for promotion to the grade of pharmacist of the first class—February 24, 1903.

MORRIS, G. A., pharmacist, granted extension of leave of absence for seven days from February 18—February 24, 1903.

**Should Diphtheria Antitoxin, etc., be Inserted in the Pharmacopeia?**—The Committee on Revision of the Pharmacopeia has under advisement the question, most difficult to decide, as to admitting diphtheria antitoxin, serums, vaccine, etc., to the new edition of the Pharmacopeia. In seeking a decision the fact is manifest that therapeutics has now entered upon a phase not contemplated by the materialistic medicine of the past. The Pharmacopeia is designed to establish standards of identity, purity, etc., in the drugs used in practice. So long as those drugs were inorganic or capable of chemie analysis, this was possible. Within a few years, however, we are using as therapeutic agents the products of living tissues, intensely unstable, and necessarily variable, which admit of no analysis, and almost of no tests of identity, purity, etc. What, then, shall be done? If they are excluded from the Pharmacopeia this work represents but a part of our therapeutic agents. If included, the fundamental principle on which the Pharmacopeia is built is destroyed. There is no doubt as to the value of the diphtheria antitoxin in the treatment of the disease, but a phial of it cannot be tested and then sold (except to be used immediately), and even if it could, the test of one phial could not be made to hold for another; and, lastly, there is no definiteness as regards the length of time during which the stability, etc., could be guaranteed. We think that the conclusion of the committee will be to exclude such products. If this is done, there seems no outcome except to place the testing and certification of antitoxins, serums, etc., in the hands of either the National Government or the State Boards of Health.

**Abolish the coroners' office** has been the command of the medical profession for many years, but like many other of its orders, it received but little attention, because there was no unity and organization to force the attention of the politicians and the people. At last Massachusetts did away with the coroner and has never regretted it. A year ago Buffalo, N. Y., did the same, and the abuses of the office at once ceased. The laughers of New York City have for a long time made merry over the continuous farce enacted by its "vaudeville quartet" of coroners. The serious-minded, however, who have been shocked by the failure of justice and the shamelessness of these unworthies, have finally united

and have a chance to rid the city of the blackmail and buffoonery coroner disgrace. A bill supported by the Medical Society, the Association, and the profession generally has been introduced at Albany to abolish the coroner's office and his useless jury in Greater New York. This, if it becomes law, will reduce the expense from \$150,000 to \$60,000 and transfer the duties to the Health Department. The charter of the city will be amended so as to provide a new bureau of the Department of Health, which shall have charge of the verification of the cause of death in suspicious cases. The chief of the bureau shall be a physician who is a skilled and practical pathologist, and who shall be appointed by the Board of Health after a competitive civil service examination. The board may appoint not over 17 medical examiners to be assigned to the districts in the five boroughs. The amended bill transfers the judicial functions of the coroners to the present city magistrates, whose duties are not mixed, but essentially those of judges. Their civil duties are transferred to the City Chamberlain, and the legal duties to the District Attorney, where they naturally belong.

**Medical University Extension.**—According to a press report from Berlin the country medical practitioner in Germany is to have an opportunity to learn the latest developments in surgery and general medicine from a traveling university that will bring postgraduate instruction to the nearest large town in his vicinity free of charge. Emperor William gave his signature Monday to the plans for this work, which will be paid for by the government and by small contributions from medical societies. Great specialists, such as Professors Lassar, Bergmann, and Rumpf will charge small fees for their services. Professor Lassar already has contributed 1,000 specimens of skin diseases to the museum, which will be carried from place to place with laboratory appliances. The country doctor can thus come to his neighboring city for a week or two once a year and hear the leaders of his profession explain the latest processes for treatment or see celebrated surgeons operate. The idea of the traveling university appears to have originated with the late Empress Frederick, who used to talk with Professor Renvers about it. The Bavarian Government already has made a limited use of the suggestion. In our country there has been a vague attempt to meet this

need in two ways—by the postgraduate school, and through the growing custom of asking leading practitioners to visit and lecture before the medical societies of the smaller towns. It must be confessed that neither nor both of these methods meet the want so effectually and admirably as this of our German colleagues. The country physicians are often, indeed, fully as capable and instructed as their city confreres, but the majority of them, of course, are not so, and there are many reasons why it is impossible for the distant and busy practitioner to attend postgraduate schools. Why should not the medical Mahomets go to the mountains? Is not the plan an excellent one? Would not the profession by these scientific and social meetings profit greatly? And would not the public and the patients also profit?

**The medical sanction of marriage** has been long demanded, and in several of our States bills have been introduced to make it the law. In only one, so far as we know, North Dakota, is a medical examination demanded to prohibit the marriage of those suffering from venereal disease, tuberculosis, epilepsy, hereditary insanity, and confirmed inebriety. Attempts at similar legislation have been made or suggested in Europe, and our contemporary, *The British Medical Journal*, says that the Spanish Minister of Justice recently mentioned the medical sanction of marriage contracts as a reform to be attempted. Sir Thomas More in his *Utopia* describes the custom of that land to be the exhibition to each other of "those chusing wyfes and husbandes," of the naked bodies of the "wowers," in order that physical blemishes, etc., may be detected before it is too late.

"Not long ago," says our contemporary, "a German physician suggested that the Röntgen rays should be employed to ascertain whether a bride was fit for the chief end of marriage—the reproduction of the species. There would, he says, be no indignity in such an examination, which would be the means of detecting any pelvic contraction that would make delivery difficult or impossible. With what we suppose to be Teutonic jocularity, he suggests that the bride should be required to supply such a radiograph to any suitor for her hand. He thinks this method would be invaluable to members of royal and noble families, to whom the birth of an heir is a matter of great importance."

We had supposed that the fashionable dressing of modish ladies had long since rendered the Röntgen method unnecessary for such ends. But neither jocularity, indifference, nor conservatism can do away with the propagation of the unfit if there are no medical restrictions imposed by the law. It has been gravely said that the medical man's advice privately given is wiser and will prove more effective than any attempt at control by the law. The idea that physicians could exert any influence in this way upon the millions who care nothing for medicine or medical men, or who hate them, is calculated to arouse the derision of the cynical as we watch the unrestricted increase of the defective classes by defective parents. Certainly the law should and must direct such limitation as will stop the procreative *descensus Averni*.

**The Nostrum Syndicates and Advertisers as Owners and Supporters of Crazy Literature.**—We have lately been at great pains to secure sample copies of the periodicals devoted to fads and crazes, and after glancing over them we are astounded to find how completely they are under the control of the nostrum sellers. A few columns of wild-eyed trumpery serves as the so-called reading portion of the periodical and then follow pages of the moral and mental filth supplied by the advertiser-owner. And of all this stuff not a line would be allowed to appear in a newspaper that had any intellectual or social standing. Perhaps the worst of these frauds are the hypocritically religious ones. Mme. Humbert, it will be remembered, when establishing her insurance company in Paris, "capital ten millions," made her game sure by securing the help of the most vociferously pious of the theological newspapers. No one was so ostentatiously pious as Mme. Humbert while she was ruining her thousand poor victims. So fast as our better journals attain self-respect and exclude the horrors that fill the columns of the yellow newspapers and crazy journals, so fast are the advertisers driven to seek customers among the more degenerate classes. Hence the multiplication of a hundred kinds of cheap serials exploiting the monomanias and driveling follies of daft ignorance. In the reading columns there may be furious antimedicine or mad faddism, while in the intermingled advertising columns bombastic tales of miracles by means of patent medicines abound. That great world, indeed, would seem absolutely medicine-mad. There is some consolation in the thought that these hundreds of periodicals do not represent paying millions of insane subscribers, but only the new method of circularizing the depraved and savages among us to which a lot of "business" scalawags have been driven.

**Medical Terminology.**—An eminent practitioner recently remarked in a discussion of the problems of medical education that the mere matter of keeping abreast of the terminology of modern medical research is a task in itself; in Prof. Welch's recent Huxley lecture, for instance, he had counted 25 words about which he knew almost nothing. The multiplication of terms necessary to the development of the side-chain theory of immunity; to the new science of hematology; to the correlation of zoologic and embryologic data relating to the transmission of some hitherto obscure diseases, has certainly been unprecedented in the history of medicine. The advances in anatomic knowledge which followed the patronage of the medical sciences of the Italian aristocracy at Padua, Bologna, Pisa, etc., at the period of general scientific renaissance, led to the introduction of a series of eponyms marking the discoveries of Fabricius, Eustachius, Stensen, Malpighi, and others. In its turn the development of physiologic chemistry gave rise to numerous terms, many of which, such as the archæus of Paracelsus, remain only as milestones to the development of the biologic theory, while others, such as gas, introduced by Van Helmont, have become a part of the common property of mankind. There was abundance of time in the infancy of scientific medicine to acquire the verbal symbols necessary to mark the progress of

discovery and theory, whereas at the present time the annual crop of words is simply astounding. Many of these words are the legitimate and necessary accompaniments of new facts, but it is time to call the attention of medical writers to the importance of avoiding the coinage of synonyms. There has scarcely been a fact or structure recently elucidated which has not been buried under a drift of terms. An examination of those used to designate the ultimate physiologic units involved in the building of germ plasma, or those suggested for x-ray effects, for phototherapy, for the effect of cold on organic fluids, for the action of serums, lysins, etc., is sufficient to demonstrate the necessity of some philologic clearing-house, some academy which shall pass on the legitimacy of medical terms.

**The Naming of the Synthetic Products.**—The complete synthesis of a vegetable alkaloid has recently been accomplished. This alkaloid is *theophyllin*, discovered by Kossel in 1888 in tea leaves and shown to be isomeric with theobromin and to possess the most powerful diuretic properties of any alkaloid of the purin class. Owing to its therapeutic value many chemists became interested in attempts to discover some method for preparing it economically on a commercial scale. This has finally been accomplished, and the fact that the manufacturers have given the synthetic product a special name is a matter of interest, as it is in line with the policy adopted by manufacturing chemists in connection with a large number of products. In the first place the adoption of a copyrighted name in place of the real chemical name of a synthetic product makes it possible to distinguish readily the artificial from the natural product, there being some physicians who think that the synthetic products lack the efficiency of the natural bodies. Another reason for the coining of trade names for medicinal products is the cumbersomeness of the technical name, as for example, *phenylacetamidacetanilid*, and the greater ease with which such a simple synonym may be remembered. The chief object, however, undoubtedly lies in the protection afforded the firm which first exploits any given synthetic product, since, having established its use under a protected name, it becomes almost impossible to supplant it with the same product under its proper designation. This leads to further trouble in that competing firms hasten to put out the same drug under new copyrighted names until the practitioner finds himself puzzled by the many guises under which a valuable product may be paraded by rival medical concerns. From some standpoints there is little to choose between a medicine that is patented and a medicine the name of which is copyrighted. The professions of pharmacy and of medicine must some time grapple with this problem, however complicated it may be and however hopeless may at first appear its solution.

**The "steady drinker"** is the man against whom the temperance and the prohibition parties may and should unite their forces. There are many who think the scientific conclusions from Professor Atwater's experiments are scientifically true, and yet they do not

believe that steady drinking is either necessary or good. Alcohol may under some circumstances be a food, but the fact does not demonstrate that it is the best food, or even a good food, or that it is to be used every day. That kind of "science" which says that as to alcohol individuals must take care of themselves, learn wisdom and moderation, etc., is not true science because it leaves out of view many facts that modify or neutralize such a partial view. Sociologic and benevolent facts are as much scientific as are physical and physiologic ones. The French scientist, Berthelot, as regards legislation against alcoholism, said, "I do not see that much can be done until the human species becomes wiser and more master of itself." He should have recognized that he himself belongs to the "human species," and he might with profit have begun with himself. The steady degradation of his nation in many ways, largely consisting in and due to the "steady drinker," is a demonstration of the fallacy of M. Berthelot's contention.

**The "steady drinker" in France**, it seems plain, is bringing on himself and on his nation the inevitable ruin that comes from too steadily used and too much used alcoholic "food." It is a "far cry" from the use by physicians of alcohol temporarily and when wise, to the folly and sin of its use by the "steady drinker." In time he gets very unsteady. Witness France! Since 1874 no special license has been required for selling liquor, and the number in the trade has doubled. The elections depend upon the liquor dealers. A union of dealers entered suit in the courts against the Prefect of the Seine for an antialcoholic placard. The liquor unions get up placards on their side rehearsing the merits of alcohol as a food as proved by American scientists. In Normandy the baby is given alcohol at the christening, and thenceforward "to kill worms." When the worms no longer serve as an excuse the drinking goes on all the harder. In the Department of the Eure the adult citizen consumes 96 liters of brandy (50° alcohol) a year, *i. e.*, about 10 drinks a day. There is 1 liquor dealer to every 23 people. A well-paid workingman was found to spend 84 cents for drink and 22 for food. Before 1870 an equal population of the Eure consumed 20,000 hectoliters of drinkable alcohol; in 1880 the amount was 30,000; in 1890, 56,000. Per head of population the average consumption has mounted from 7 to 16 liters—alcohol at 100°. In the last century the average mortality of France fell from 25 to 23 per 1,000 inhabitants; in the Eure it has risen from 22 to 26. Fifty years ago there were 12 suicides to the 100,000 inhabitants in that country province; now there are 46 as against 22 for the rest of France. In other ways the progress—downward—is still more headlong. In 1890 there were 40 lunatics in the asylum of Evreux; in 1898, without any change of system, there were 200.

**Convict Insane in Hospitals.**—In his 1902 Report of the New Jersey State Hospital Dr. Evans renews his recommendation that the criminal insane should be removed from the State hospitals. It seems strange that such advice should be needed and that the Legislature should so long leave it unheeded. In how many States

does this most reprehensible custom obtain? In New Jersey at the end of 1902 there were 65 convicts and 33 criminals in the Mt. Morris Hospital, and in all 217 convicts and criminals have been transferred to the hospital by order of the courts. What a political and moral blunder! Dr. Evans wisely says that to those patients who realize that in their affliction and loss of liberty they are kept in the same building with convicts of the vilest sort, the effect is to bring about feelings of dissatisfaction, humiliation and resentment, and in many instances improvement and recovery are retarded if not made impossible. State hospitals are not so constructed as to make the detention of convicts secure, and many of them escape in spite of vigilance and the best efforts. They then return to lives of crime until again apprehended. It is therefore clear that in attempting to keep them in the State hospitals a gross injustice is done, not only to all other patients forced in some degree to associate with them, but the public generally suffers from the escape of dangerous criminals.

**The Essential Life Substance.**—The iatrochemist has ever sought to trace the phenomena of life to a single essential upon which might be shifted the responsibility previously imposed upon the anima, the archæus, or the blas of early writers. A Chicago savant recently elevated certain sodium salts to the supreme position in the determination of protoplasmic activities. Another writer finds abundant reasons for the belief that the *succus nervus* has been demonstrated to exist in an enzyme secreted by the pancreas, while Sacharoff hypothesizes a substance which he terms *bionuclein*, a combination of iron and nuclein, existing in all enzymes and essential to those decompositions of protoplasm from which all vital processes arise. It is to the iron in this combination that its potency belongs. All vital phenomena, according to Sacharoff, are due to the oxidation of iron. In general, the trend of such pseudophilosophies is to confound the means or instruments of the life-principle with that principle itself. There is a multitude of instrumentalities without any one of which the phenomena of life cannot be manifested—nutrition, carbon, heat, motion, etc. Put them all together and shake them to eternity and *omne vivum ex vivo* is not disproved.

## EDITORIAL ECHOES

**Professional Unselfishness.**—It might almost seem to a philosophical observer as if the leaders in this movement had unselfishly made up their minds to prove to men and women that if they had more common sense they would promptly abolish the medical profession by taking away its *raison d'être*. One seldom hears of a lawyer exhorting his neighbors to avoid litigation so that they may not require his services. Yet every reputable physician is expected not only to cure diseases, but to give his patients such hygienic advice as may prevent them from needing him again. This is a good deal to expect of human nature in individual cases; but the problem which is at the present moment most strenuously attacked by the medical men of Europe and America is how to reduce the number of their patients and the amount of their own income by 10% at one fell swoop. At least one person out of every ten dies of pulmonary tuberculosis and other forms of tuberculosis,

and it is this disease that physicians are now striving with all their might to exterminate utterly, or at least to limit as much as possible. Since tuberculosis is rarely contracted by the medical practitioner, his labors in striving to eliminate it from his practice accordingly stand as a remarkable exemplar of humanitarian altruism.—[*N. Y. Evening Post.*]

**A Case of Christian Science.**—Dr. Lorenz, a member of the Medical Society of Vienna, Austria, having acquired fame in his successful setting of dislocated bones without the use of the knife, was called by a wealthy man in Chicago to come and restore to his crippled child the use of her limb. He came and performed the operation successfully and received presumably a very large fee for his highly appreciated service. He could doubtless in the few weeks of his stay in America have reaped thousands upon thousands of dollars in operating upon the crippled children of wealthy parents had he so chosen. Instead of this, he chose to go from one large city to another and offer to give free clinic operations on children of the poor, or any needing his help, for the benefit of the medical and surgical students who would come and learn, free of all expense, his bloodless method of cure. Courtied by the highest medical and civil authorities, and the recipient of unbounded praise and gratitude, Dr. Lorenz has in reply only modestly to refer to the excellent medical society of which he is a member, to the ease with which his method of cure may be learned and practised by others, and his great desire to use every opportunity freely to give relief to the suffering, and to impart this information to those who will use it to the same end. Is not this a case of true Christian Science?—[*The New Church Messenger.*]

**The Medical College Statistics for 1902.**—One hundred and fifty-six medical colleges, with 6,776 instructors, enrolled 27,501 students and graduated 5,002 students in the school year 1901-1902. In the year previous, 1900-1901, 156 colleges, with 5,958 teachers, enrolled 26,417 students and graduated 5,444. Twenty years ago there were 89 medical schools with 14,934 students and 4,115 graduates. The increase in the number of schools and students is far in advance of the increase in the number of graduates. The graduates twenty years ago were 4,115; in 1900, 5,314; in 1901, 5,444, and in 1902, 5,000. The attendance in twenty years has, therefore, increased nearly 200%, and the number of graduates has increased less than 25%. The decrease in the number of graduates in the last year is assigned to the increased length of course of study and increased requirements by State boards. It is considered by many a temporary decrease and one that will be changed to an increase as soon as the temporary check is overcome. The decrease in graduates is classified thus: There were 4,879 graduates from the regular colleges in 1901; 387 from the homeopathic; 148 from the eclectic, and 30 from the physiomedical and nondescript; total, 5,444. In 1902, 4,498 graduated from regular schools; 336 from the homeopathic; 138 from the eclectic, and 27 from the others; a decrease in every class. The increase in students is classified thus: There were 23,846 students registered at the regular colleges during the year ending July 1, 1901; 1,683 at the homeopathic; 664 at the eclectic, and 224 at the physiomedical and nondescript; a total of 26,417. During the year ending July 1, 1902, 24,878 students registered at the regular colleges; 1,617 at the homeopathic; 765 at the eclectic, and 241 at the physiomedical and nondescript; total, 27,501. This is an increase among all but the homeopathic schools. In the year the regular schools increased in enrolment 1,032 and decreased in number of graduates 381. The homeopaths lost in enrolment 66 and in graduates 51; the eclectics gained in enrolment 99 and lost 10 in graduates; all other schools gained 17 in enrolment and lost 3 in graduates.—[*Jour. Am. Med. Asso.*]

## BOOK REVIEWS

**International Clinics.**—Edited by HENRY W. CATTELL, A.M., M.D., Philadelphia, U. S. A., etc. Vol. iv. Twelfth series, 1903. J. B. Lippincott Company, Philadelphia.

This volume well maintains the interest and standard of the series. So many and so varied contributions in one volume do not well lend themselves to critical review; we can only call a few titles. The first paper, on "The Sanitary Tent and Its Use in the Treatment of Pulmonary Tuberculosis," by Chas. Gardner Fox, is eminently sound and practical and describes a useful device. Perfect ventilation is its keynote. The last paper, a monograph of 96 pages, on "The Blood in Health and Disease," by Thomas R. Brown, gives a clear, definite, full and judicial presentation of the status at the moment of one of the most important questions of clinical and pathologic research. There is a short sketch of Dr. W. W. Keen. A paper on "Pernicious Anemia, with Extensive Pigmentary Changes in the Skin," exhibits the characteristic accuracy and painstaking, the erudition, and the sound judgment of its lamented writer, the late Frederick A. Packard. W. G. Spiller gives a masterly study of "Traumatic Lesions of the Brain in Their Relation to Operation." A. O. J. Kelly has well set forth some of the clinical aspects of thoracic aneurysm, and so we might go on mentioning good articles by good men.

**Diseases of Infancy and Childhood.**—By HENRY KOPLIK. Published by Lea Brothers & Co., New York and Philadelphia.

It cannot be denied that graduates of medicine go out from our best medical schools and even from the average hospital with far less accurate knowledge of the diseases incident to infancy and childhood than of those confined for the most part to adult life. Dr. Koplik has contributed to medical literature a splendid volume of almost 700 pages, which is especially designed for the student and the practitioner. In this work the author gives explicit directions and instructions, the results of his own experience together with that of the most advanced men in this branch of medicine in both America and the countries abroad. The reader is not befogged with numerous theories but is given information direct and succinct. The numerous illustrations and colored plates add greatly to the value of the work. All the diseases of childhood are arranged and discussed with that thoroughness and at the same time terseness which is characteristic of the author. Special consideration is given to the subject of infant-feeding. The whole work is a splendid discussion of the entire subject-matter under consideration.

**Progressive Medicine.**—Edited by HOBART AMORY HARE, M.D., of Philadelphia, assisted by H. R. M. LANDIS, M.D. Volume iv, December, 1902. Lea Brothers & Co., Philadelphia and New York.

This, the concluding volume for 1902, is fully abreast of the others of the series in literary merit and practical utility. It comprises a digest of the recent literature on diseases of the digestive tract and of the liver, pancreas, and peritoneum, by Max Einhorn; anesthetics, fractures, dislocations, amputations, surgery of the extremities, and orthopedics, by Joseph C. Bloodgood; genitourinary diseases, by William T. Belfield; diseases of the kidneys, by John Rose Bradford; physiology, by Albert P. Brubaker; hygiene, by Charles Harrington; and a practical therapeutic referendum, by E. Q. Thornton. On the whole, inasmuch as important additions to the literature of each of the foregoing subjects is fully covered, the volume will doubtless command the approbation of those that have used its predecessors to advantage.

**Physiology.**—By THEODORE C. GUENTHER and AUGUSTUS E. GUENTHER. Edited by V. C. PEDERSEN. Published by Lea Brothers & Co., Philadelphia and New York.

This is a manual of some 240 pages, with numerous illustrations. It covers briefly, clearly and comprehensively the principal subdivisions in the subject of human physiology. It is especially adapted to the needs of students of medicine and to those wishing to make a hasty review of the essential points

in physiology. At the end of each chapter is a series of questions relating to the subject-matter just discussed. The authors make no claim to exhaustive and complete discussion, and the work is therefore eminently suited to those who desire to refresh their memories in the essentials of the subject discussed.

**A Clinical Study of an Epidemic of Cerebrospinal Meningitis: With Special Reference to Symptomatology and Treatment.**—By J. RUTTER WILLIAMSON, M.D. Thacker, Spink & Co., Calcutta, 1902.

This brief monograph of 27 pages, though not exactly what the title indicates, is a valuable contribution to the literature of the disease in question. It is made up of an amazing number of statements from other writers on the subject, interspersed with the author's personal observations. The arrangement into short paragraphs with definite headings makes easy both reading and reference. The articles may be summed up as a great deal of information well arranged but containing little that is new.

**A Compend of the Diseases of Children.**—By MARCUS P. HATFIELD. Published by P. Blakiston's Son & Co., Philadelphia.

This little volume of more than 200 pages contains in terse and succinct form a short discussion on the various diseases incident to childhood. It is especially designed for the use of students in medical colleges, and makes no pretense to a full and comprehensive discussion of the subject-matter. It is admirably adapted to the purposes for which it was designed, and as evidence of its continued popularity this, the third edition, is now put forth. We can heartily commend it to students of medicine.

## BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

**Surgical Diseases of the Kidney and Ureter: Including Injuries, Malformations and Misplacements.**—By HENRY MORRIS, M.A., M.B. (Lond.), F.R.C.S., Vice-president and Chairman of the Court of Examiners of the Royal College of Surgeons; Senior Surgeon to the Middlesex Hospital; Honorary Member of the Medical Society of New York. Two vols., 8vo, 600 pages each, with two colored plates and numerous illustrations. Cloth, \$12.00 net. W. T. Keener & Co., Chicago, 1903.

**Therapeutics of Infancy and Childhood.**—By A. JACOB, M.D., LL.D. Third edition. J. B. Lippincott Company, Philadelphia and London, 1903.

**Diseases of the Skin: Their Description, Pathology, Diagnosis, and Treatment, with Special Reference to the Skin Eruptions of Children and an Analysis of 15,000 Cases of Skin Disease.**—By RADCLIFFE-CROCKER, M.D. (Lond.), F.R.C.P., Physician for Diseases of the Skin in University College Hospital; Honorary Member of the American Dermatological Society; late Physician to the East London Hospital for Children; Examiner in Medicine, Apothecaries' Hall, London, etc. Third edition, revised, rewritten, and enlarged. With 4 plates, 2 of which contain 12 colored figures and 112 other illustrations. Octavo, 1,400 pages. Cloth, \$5.00; sheep, \$6.00 net. P. Blakiston's Son & Co., Philadelphia.

**Practical Hygiene: A Manual of Practical Hygiene for Students, Physicians, and Health Officers.**—By CHARLES HARRINGTON, M.D., Assistant Professor of Hygiene in the Medical School of Harvard University. New (second) edition, revised and enlarged. In one octavo volume of 755 pages, illustrated with 113 engravings and 12 full-page plates in colors and monochrome. Cloth, \$4.25 net. Lea Brothers & Co., publishers, Philadelphia and New York.

**Tuberculosis.**—By ADDISON W. BAIRD, M.D. Popular presentation of the subject, with 30 illustrations. February, 1903. Publisher, James T. Dougherty, New York City.

**Index Catalogue of Medical and Veterinary Zoology: Part 2 [Authors B to Buxton].**—By CH. WARDELL STILES, Ph.D., Consulting Zoologist of Bureau of Animal Industry; Zoologist of U. S. Public Health and Marine-Hospital Service, and ALBERT HASSALL, M.R.C.V.S., Acting Assistant Zoologist of Bureau of Animal Industry. Government Printing Office, Washington, 1903.

**A Textbook of Practical Medicine: For the Use of Students and Practitioners.**—By WILLIAM GILMAN THOMPSON, M.D., Professor of Medicine in Cornell University Medical College; Physician to the Presbyterian Hospital, Bellevue Hospital, etc., New York. New (second) edition, thoroughly revised. In one octavo volume of 1,104 pages, with 62 illustrations. Cloth, \$5.00; leather, \$6.00; half morocco, \$6.50 net. Lea Brothers & Co., Philadelphia and New York.

**Physical Chemistry for Physicians and Biologists.**—By Dr. ERNST COHEN, Professor of General and Inorganic Chemistry in the University of Utrecht. Authorized translation from the German by MARTIN H. FISCHER, M.D., Instructor in Physiology in the University of California. Henry Holt & Co., New York, 1903.

**Obstetrics: A Textbook for the Use of Students and Practitioners.**—By J. WHITRIDGE WILLIAMS, Professor of Obstetrics, Johns Hopkins University; Obstetrician-in-Chief to the Johns Hopkins Hospital; Gynecologist to the Union Protestant Infirmary, Baltimore, Md. With 8 colored plates and 630 illustrations in the text. D. Appleton & Co., New York and London, 1903.

## AMERICAN NEWS AND NOTES.

## GENERAL.

**Smallpox** as officially reported in the United States from December 27, 1902, to March 6, 1903, amounts to 10,621 cases with 326 deaths, as against 20,054 cases and 616 deaths for the same period in the year previous.

**Plague Abating at Mazatlan.**—One or two deaths daily are reported from the disease, but for the past few days no new cases have occurred. The authorities are doing everything in their power to stamp out the disease, and have burned about 500 houses, with all their contents.

**Revision of the Pharmacopœia.**—The work of revision, which has thus far occupied three years, will not be completed before next October. Bacteriologists representing the State Boards of Health of Pennsylvania, New York, and Massachusetts, the Army and Navy, and two firms in Philadelphia and Detroit which manufacture diphtheria antitoxin met recently in Philadelphia to discuss the advisability of inserting the antitoxin in the Pharmacopœia. Since its discovery three years ago the proportion of deaths from the disease has been reduced from 35% to 5%.

**The Committee on Prophylaxis of Venereal Diseases,** appointed at the 1902 meeting of the American Medical Association, has organized as follows: Dr. Henry D. Holton, chairman, Brattleboro, Vt.; Dr. Ludwig Weiss, secretary, 77 East Ninety-first street, New York City; Dr. George M. Kober, 1600 T street, Washington, D. C.; Dr. W. H. Sanders, Montgomery, Ala.; Dr. L. Duncan Bulkley, 531 Madison avenue, New York City; Dr. Frank H. Montgomery, 100 State street, Chicago, Ill. The committee desires the support of the medical profession and solicits expressions and views editorially and otherwise. The committee would be glad of personal correspondence from those supporting the movement and who will contribute by papers, etc., in case the House of Delegates should favor the holding of a congress similar to the International Conference for the Prophylaxis of Venereal Diseases, which met in Brussels under the auspices of the Government of Belgium.

**Communicable Diseases.**—The Conference of the State and Provincial Boards of Health of North America has received the report of the committee appointed to prepare a list of diseases believed to be communicable and dangerous to the public, and which members of health boards may properly prevent or endeavor to restrict. The prepared list embraces the following:

Actinomycosis (lump jaw), ankylostomiasis (tropical anemia), anthrax, beriberi (epidemic neuritis), bubonic plague, chickenpox (varicella), cholera Asiatic (cholera, epidemic cholera), diphtheria (croup, membranous croup), epidemic cerebrospinal meningitis (spotted fever), epidemic dysentery, erysipelas, German measles (rôtheln), glanders, gonorrhœa, hydrophobia (rabies), influenza (grip), leprosy, malaria (intermittent, remittent, or pernicious fever), measles (rubeola, morbilli), mumps (epidemic parotitis), pneumonia (lobar or croupous pneumonia), puerperal fever (puerperal septicemia), scabies (iteh), scarlet fever (scarlatina, canker rash), smallpox (variola, varioloid), syphilis, tetanus, trachoma, trichinosis, tuberculosis, typhoid (enteric) fever, typhus (ship) fever, uncinariasis, whoopingcough (pertussis), yellow fever.

## EASTERN STATES.

**Korean Twins May be Separated.**—After a Röntgen ray examination of the Korean twins with a view to ascertaining if it would be safe to attempt their separation, it has been decided by the medical scientists having the case under consideration that no vital structures prevent the separation of the twins. Each twin is normally formed so far as the integrity of his own body is concerned, and they have in common only the flesh and cartilaginous connection which unites them at the base of the sternum.

**Epidemic of Diphtheria at Morristown, N. Y.**—It is reported that an epidemic of diphtheria has prevailed for the past three weeks in Morristown. Twenty cases have occurred with five deaths, and many patients are in danger from the disease. Ogdensburg is furnishing assistance in the way of trained nurses and physicians. It is stated that children infected with diphtheria have attended the schools in which many pupils were present and it is probable that many more serious cases will result before the epidemic is under control.

**Typhoid Disappearing in Massachusetts.**—Vital statistics show that the number of deaths from typhoid fever in Massachusetts in 1901 is smaller than in any single year since the beginning of registration in 1842, when the population of the whole State was no larger than that of Boston and immediate suburbs today. Figured in percentage the deathrate, from this disease, in 1901 in 33 cities is only a trifle more than one-fourth as large as it was in the same cities 30 years ago. In the decade ending 1865, only 25% of the population used water over which the authorities exercised control, and the deathrate from typhoid fever in those years was 92.9 per 100,000 inhabitants. Ten years later 41% of the population had public water and the deathrate decreased to 80 per 100,000. Thus the deathrate decreased with the extension of the public water system

until in the year ending in 1901 90% of the Massachusetts people were supplied through well-kept public water systems and the deathrate was only 19.5 per 100,000. Water supply improvements still continue.—[*Boston Transcript.*]

**Massachusetts State Association of Nurses.**—An association composed of the graduate nurses of Massachusetts has been formed for their mutual protection and advantage and also for the protection and advantage of the public in securing good nurses for the sick. It is announced that strenuous endeavor will be made by the Association to secure through legislation State registration of nurses in the same manner that registration of physicians is required. It is proposed that all persons desiring to be recognized as thoroughly trained nurses shall be required to pass a prescribed examination before an official board of experts.

**Low Birthrate in Massachusetts.**—According to the *Boston Transcript*, Massachusetts has for some years had an extremely low birthrate, and the year just passed shows no improvement. The rate, calculated on the estimated population of 2,870,710, is only 25.07 to 1,000 of the living population, less than that of the previous year, and the least since 1882. The marriage-rate of 8.67 to 1,000 (or when reckoned by persons married, instead of by marriages, 17.34 to 1,000) is scarcely more encouraging, for it is less than the rate of the previous year, and shows a decrease of .42 below the average rate for the ten-year period just closed. The deathrate during the year (16.82 to 1,000) is the least since the year 1851, so that the excess of births over deaths (8.26) is favored by other conditions than increase in number of children. The following table shows the birthrate per 1,000 inhabitants of Massachusetts as compared with the same number in various European countries:

Massachusetts, 1900.....	26	Russia, 1897.....	52
Hungary, 1899.....	39	Belgium, 19 0.....	29
Austria, 1899.....	37	Norway, 1899.....	30
Germany, 1900.....	35	Sweden, 1898.....	27
Italy, 1899.....	34	Switzerland, 1899.....	28
Holland, 1900.....	35	Spain, 1895.....	35
Great Britain, 1900.....	29	France, 1898.....	22

It may be noted in connection with the foregoing table that in Massachusetts the children of foreign-born mothers are largely in excess of those of natives, so that were Massachusetts not helped by immigration the rate would be far lower. In 1890 the percentage of native born was 34.82, foreign born 44.10, and in 1900 the percentage was 31.45 for native, 49.30 for foreign born.

**Marconi System in Medicine.**—One calling himself "Professor John Newsome, phrenologist and chycopoedist," has been arrested in Fall River, Mass., on the charge of having violated the medical statutes in practising medicine without a license. Various witnesses were examined by the court and likewise by the "professor." The man is from Blackburn, England, and he says that he possesses the "gift of herbs," and also the rare faculty of "doping out what's the matter with a man," without resort to the ordinary methods of diagnosis. He says: "I get the disease from the body by putting my thumb on the patient's forehead, and by a kind of mesmeric telepathy, which I cannot explain, I feel all the pain that is experienced by the patient and in the same location of the body. Then I give herbs." He confessed that to one of the patients who testified in his behalf he gave 33 different kinds of medicine, and to another 43, and to still another 27, all mixed up in a bag. He says: "The herb business comes natural to me, and I can explain it no more than I can explain my system of diagnosis." He further said that by using a magic tube placed behind the ear of the patient he can determine whether he has kidney trouble, catarrh of the stomach, and this he explained by saying that he understood the head, and can therefore tell if a man clings to life, and that he can tell if the blood is rising without looking at the tongue or feeling the pulse. "In a sense it's wireless telegraphy." Various patients of the "professor" testified strongly in his behalf and that after consulting numerous "regulars" they found relief only in the medication administered by the "professor." The court held that although the "professor" was "harmless" he was at the same time guilty according to the statutes; therefore he was adjudged guilty, and the complaint filed on the payment of costs.

## NEW YORK.

**House Disinfection in Ithaca.**—In accordance with recommendations made by Dr. Soper, who came to Ithaca at the instance of the State Board of Health, the Common Council has placed means at the disposal of Dr. Soper to combat the typhoid epidemic. Twenty men have been employed to make house-to-house visits wherever typhoid fever has occurred and thoroughly disinfect each house.

**Home for Consumptives.**—According to the *New York Sun*, the Arbeiter Ring, an organization of about 20,000 East Siders, composed principally of members of trades unions and social clubs, has decided to try to raise a fund to establish a home for consumptives. It has called a conference for the second Friday in May, at which the feasibility of such a project will be discussed. In the meantime committees are to be sent to investigate how far the working of people in sweatshops is responsible for the spread of tuberculosis.

**Columbus Hospital, New York**—This institution is to be enlarged shortly by the addition of new buildings, the ground for which adjoining the present property has already been purchased. The erection of these new buildings will increase the capacity of the hospital to 150 beds, instead of the present 98 beds. Funds for the erection of the buildings are available, which will be sufficient to provide for a modern equipment of the new wards. Dr. G. A. DeSantos Saxe has been appointed assistant pathologist to the hospital.

**Two Additional Hospitals for New York**—A bill has been introduced into the New York Legislature to constitute the group of buildings of the Manhattan State Hospital at Central Islip a State hospital, to be known as the Central Islip State Hospital, and to constitute the buildings of the Long Island State Hospital at King's Park an institution to be known as the King's Park State Hospital. The bill increases the supervision of the State Commission in Lunacy over the State hospitals by extending it to business and financial management.

**Sweatshops Closed in Brooklyn**—It is stated that 20 factory inspectors have made the rounds of 75 sweatshops in the Brownsville district of Brooklyn and closed most of them for violations of the law in regard to sanitary conditions. No arrests were made, but in every instance in which it was found that the law had been violated work was suspended in the shops by taking away the certificate without which they are not allowed to operate. Numerous complaints have been received by the department claiming bad ventilation and unsanitary conditions in the shops. The object of having the inspectors close the shops is to convince the proprietors that the letter and spirit of the law must be obeyed.

**To License Trained Nurses**—A bill has just been introduced into the New York Legislature which provides that hereafter trained nurses shall receive certificates, to be given by a Board of Regents appointed for that purpose. Applicants must be over 21 years old, of good moral character and hold a diploma from an accredited training-school covering a course of at least two years. The successful applicants shall be styled registered nurses and be allowed to use the abbreviation R. N. after their names. The regents shall annually appoint a board of five examiners selected from the nominees of the New York State Nurses' Association, and shall make the rules governing the examination. A sufficient fee shall be charged each applicant to pay the expenses. Upon the recommendation of the Board of Examiners the regents may waive the examination of any person possessing the required qualifications who has graduated before or may be in training at the time of the passage of the act. It is said the trained nurses of the State are enthusiastic supporters of the measure.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**Regulation of Child Labor**—A bill has been introduced into the Pennsylvania Legislature regulating the employment of children throughout the State. It is made unlawful to employ any child under 14 at any labor during the hours when the public schools are in session, and the working hours are limited to 10 hours a day and 55 hours a week. No child under 16 can be employed between the hours of 9 a.m. and 6 p.m.

**To Stop Six-day Races**—A bill has been introduced into the Pennsylvania Legislature which makes it unlawful for any person or persons to promote or manage or participate in any athletic contest or exhibition held within the State of Pennsylvania which shall continue for more than 12 hours in each calendar day. The penalty imposed for violations of the act is a fine of not less than \$100 or more than \$1,000, or imprisonment not exceeding two years, or both.

**Appropriations for Philadelphia Hospitals**—The bill for appropriations for Philadelphia hospitals has just passed its first reading in the House. The Medico-Chirurgical Hospital, which asked \$375,000, is allowed \$290,000; University of Pennsylvania, which asked \$350,000 altogether, is allowed \$100,000 for the University and \$110,000 for the hospital; Jefferson Hospital, which asked \$350,000, is allowed \$260,000. The least percentage of reduction, 23, is the Medico-Chirurgical's. Jefferson's is nearly 26. The heaviest, 40, is the University's.

**Freak Legislation**—A member of the Pennsylvania Legislature, frightened by the prospect of "race suicide" as feared by Presidents Roosevelt and Eliot, has introduced into the Legislature a bill, which among other things, provides that any lawfully married woman who is the mother of 6 children shall receive \$10 in money and a ten-dollar gold medal. Any lawfully married woman who is the mother of 9 children shall receive \$20 in money and a gold medal of similar value. Any lawfully married woman the mother of 12 children shall receive \$25 in cash and a medal of equivalent value. Any lawfully married woman who is the mother of 15 children shall receive \$50 in coin of the realm and a medal of the same value. It is also provided that every seventh son or daughter of any lawfully married husband and wife shall be educated by and at the expense of the Commonwealth in any school, or academy, or college desired by said son or daughter, provided the cost shall not exceed \$500.

**Prayer versus Vaccination for Smallpox**—A Philadelphia eddyite, after having been ill for a week in his home with a virulent attack of smallpox, and after having exposed his wife, children, and neighbors who shared his faith in the eddyite teaching to the disease, was finally taken forcefully from his home to the Municipal Hospital, where he is now under treatment. He absolutely refuses to take medicine prescribed by the physicians, claiming that it is so much poison, and firmly believes that the prayers offered by himself and his brethren will relieve him from the scourge of smallpox.

**New Jersey State Hospital, Morris Plains, N. J.**—The twenty-seventh annual report of the medical department of this hospital for the year ended October 31, 1902, states that during the year there were in all 1,742 patients under treatment, and the daily average for the year was 1,427. The proportion of recoveries, computed upon the number admitted, is about 28%. The deathrate, based upon the number under treatment, is 7.7%, and the average age at death was 64 years, showing that the average age of death was far above that usually given by statisticians. This reflects favorably upon the influence of properly regulated institution life, associated with good care and scientific medication.

**Doctors to be Instructed in Tropical Diseases**—A number of the leading physicians of Philadelphia have met and formed a Philadelphia Society of Tropical Medicine, the object of which is to prepare students of medicine and physicians for their duties in the Philippine Islands and other tropical countries of the world. No society of this kind has previously been formed in the United States. The founders of the society include the following members of the medical profession: President, Dr. Fenton; vice-presidents, Professors James C. Wilson and James Anders; secretary, Professor Joseph McFarland; treasurer, Professor E. B. Gleason; Executive Committee, Dr. John V. Shoemaker, chairman, and Dr. Fenton, Professor Judson Daland, Dr. R. G. Curtin, Professor Orville Horwitz and Dr. Hobart Hare.

#### SOUTHERN STATES.

**To Bar Eddyites**—Advices from Richmond state that after an exciting debate in the Virginia Senate a bill was passed forbidding the eddyites to practise the profession of healing in the State of Virginia unless they have been duly examined and licensed by the State Board of Medical Examiners. It was argued that lawyers might finally claim to be able to win suits by prayer if the thing was not nipped in the bud.

**Washington to Fight Tuberculosis**—Leading citizens of Washington, D. C., have organized a propaganda against tuberculosis. Every effort will be made to spread intelligence which will tend to prevent and combat the disease. The work meets the approval and cooperation of the city health authorities, and its organizers embrace many prominent physicians, charity workers, philanthropists, and clergymen. Public lectures will be given, and reprints and scientific documents are to be published by the society in the dissemination of knowledge with the hope that the progress of tuberculosis may be arrested.

**Antitoxin to Combat Cholera Infantum**—Dr. Hurd, of Johns Hopkins Hospital, is quoted as making the following statement with reference to antitoxin treatment for cholera infantum: "The new serum for dysenteric diseases is in such an advanced state of perfectness that it can be announced with absolute certainty that it will by the end of the year be in the hands of every up-to-date practitioner of medicine. It will be a specific remedy for cholera infantum, since the bacillus at the root of this trouble has been absolutely proved the same germ as that of dysentery and must yield to the same antitoxin. This antitoxin directly attacks and destroys the poisonous germs in the blood infected with dysenteric bacilli and recovery—unless complications have set in that cause death—is a scientific certainty."

#### WESTERN STATES.

**To Study Tropical Diseases**—It is reported that the trustees of the Michigan College of Medicine and Surgery have established two new chairs in tropical diseases, with the object of preparing medical practitioners to deal with those affections in the Philippines and in Cuba.

**Smallpox in Chicago**—The health department officials of Chicago have called attention to the virulent type which smallpox has assumed in all sections of the city. There existed a greater number of cases two years ago than at the present time, but the type was mild and but few fatalities resulted. Widespread vaccination is insisted upon. A feature of the epidemic is the number of small children who are affected.

**High Mortality in Chicago**—The Bulletin of the Health Department states that the week ended February 28 broke all records of mortality for any single February week in the history of the department, while the total deaths are the highest in proportion to population since February, 1882. The 713 deaths recorded during the week represent an annual mortality

rate of 19.73 per 1,000 of population—a rate unpleasantly near that of the older eastern communities—and the 2,570 for the month give an annual rate for the 28 days of 18.30 per 1,000 of population. The only comfort to be gleaned from the situation is that found in a comparison of the deaths at given ages. As compared with February, 1902, there were 16.2% more deaths over 60 years, and 4.6% fewer under 5 years.

**Repeal of the Former Statutes on Grave Robbing.**—A bill recently signed by the Governor of Indiana it is believed will nullify the indictments against physicians said to be implicated in the late grave robbing scandal and will also free the prisoners who are now under arrest on that charge. The new law repeals all the existing statutes on grave robbing, creates a State board whose duty it will be to distribute unclaimed bodies among the various medical and dental colleges of the State, and requires that all such unclaimed bodies shall be turned over to the board by public institutions. The new law also contains sections defining grave robbing and providing punishment for their violation. In consequence of this new law it is now claimed that the indictments against those accused of grave robbing are invalid, as the laws under which they were found no longer exist. A number of lawyers, however, claim that the present law will not affect indictments returned under the laws that are repealed.

**Birthrate of Chicago.**—Figures lately compiled by the health officials of Chicago tend to prove that the percentage of infants to total population is gradually increasing. The results obtained are based on statistics concerning the enrollment of school children. In this connection the Bulletin of the Health Department states that in 1890 there were 135,541 children enrolled, of which number 20,175 were under 7 years of age. Those under 7 formed 1.83% of the total population—1,009,850—of the city in that year. In 1900 the total enrollment was 225,861, of which number 48,817 were under 7—a proportion of 2.87% of the total population—1,698,575—in 1900. These two sets of figures show an increase of 57.3% of children under 7 in proportion to total population, and of 141.9% in the actual number of children under 7 during the ten years. But a still greater improvement in the relatively better conditions for life which exist in more recent years is shown by the following figures from the same source: In the census year 1890 there were 21,856 deaths at all ages, of which number 9,884 were under 5 years, 45.2% of the total mortality. In the census year 1900, out of the total 24,941 deaths at all ages there were 8,283 under 5 years, or 33.2% of the total mortality.

#### CANADA.

**Hospital for Detained Immigrants.**—It is said that the Elder-Dempster Steamship Company, which brings the largest number of immigrants to St. Johns, is preparing to care for its own detained immigrants. A hospital will be opened at Carleton. Heretofore immigrants who had been temporarily detained for illness, pending their admission into the Canadian borders or those of the United States, have been cared for by the company at the General Public Hospital at the rate of \$1 a day per patient. The company has decided that less expense will be incurred in establishing a hospital of its own to care for afflicted immigrants.

## FOREIGN NEWS AND NOTES

### CONTINENTAL EUROPE.

**Test for Canned Meat.**—Dr. Giovanni Grixoni, an Italian bacteriologist, who has made a study of preserved meats, has found that when a can of meat gives forth a splashing sound on shaking it is due to the liquefaction of the gelatin of the meat by bacteria. From meats in this condition he was able to obtain many bacteria and to make cultures which when administered to animals caused death. Many meats, though not spoiled in the ordinary sense, were found to have been so deteriorated as to be wholly unfit for consumption. He recommends that legislation should make it compulsory to mark all tinned meats with the date of canning.

**The Latest "Discovery" from Paris.**—The *Revue des Revues* states that Professor Peter Stein has invented an apparatus which not only restores lost sight, but gives vision to those who have been blind from birth. Dr. Caze, who publishes the announcement, says that Professor Stein took him into a dark room and securely bandaged his eyes so that he could not possibly see. The lamp was then lighted and the apparatus was fastened around his temples when instantly he became conscious of a dim light. The light became stronger, and he was now able to count the professor's fingers when they were held up before him and to enumerate other things in the room. Just as he was feeling that his vision was clearing and he was convinced that he would soon see normally, the apparatus was suddenly removed and he was left in total darkness. Professor Stein rests his claim on the theory that man does not see with the eye, but with the brain, the eye only serving to receive the image, which the optic nerve transmits to the seat

of perception, and if, therefore, the image can be transmitted to the brain without eyes a blind person can see as well as anybody else.

**Quackery in Berlin.**—A man named Nordenskoetter was recently convicted and sentenced to three years' imprisonment for practising medicine in Berlin without a license. He had studied chemistry at a university for six semesters, and after that gained some medical knowledge by serving as a clerk in a drug store. He considered this sufficient training for the treatment of the sick, and by the means of widespread advertising he soon gained a lucrative practice. He was in the habit of mixing his medicines in a bathtub in which his wife "occasionally" took a bath. Before the trial ended he fled, forfeiting his bail of 15,000 marks. He is said to be worth over \$150,000. He was assisted by a regular practitioner named Kronheim, who was also up for trial, but who was acquitted.

### OBITUARIES.

**Charles H. Ohr**, in Cumberland, Md., March 8, aged 93. He was graduated from the University of Maryland, Baltimore, in 1834. In the cholera epidemic of 1853 in Baltimore he introduced the use of strychnin, and, despite the great mortality of the time, he lost only 113 out of 600 cases. He wrote many books on medicine and was a contributor to medical journals. He was president of the Maryland Medical and Chirurgical Faculty in 1872. Dr. Ohr was for 10 years consulting physician to the Cumberland Board of Health, was a member of the city council, a former mayor of Cumberland, and a State Senator. He was also surgeon at the Federal Hospital of Baltimore. He was said to be the oldest past grand master Mason in the world.

**Rafael Zaldívar**, former President of Salvador and lately Minister of that republic at Washington, died in Paris, France, March 3. He obtained his degree in medicine from the National University in Guatemala. He began the practice of medicine in that city and soon gained prominence as a physician. He was one of the three members of the medical profession allowed by the laws of the country to participate in legislation.

**John R. Casey**, of Joliet, Ill., March 1, aged 68. He was graduated from the medical department of the Washington University, St. Louis, in 1857. He was for 10 years physician for the State penitentiary, and had been a member of the city council.

**James E. Ferguson**, in Bangor, Mich., February 16, aged 78. He was graduated from the Philadelphia Medical College in 1852 and from the Jefferson Medical College, Philadelphia, in 1870. He was twice a member of the State Legislature.

**Charles McDonald Cameron**, at Cobourg, Ont., February 28. He practised his profession for 30 years in Rochester, N. Y., and at the time of his death was one of the oldest graduates in medicine of McGill University, Montreal.

**Ingham W. Donnan**, of Pittsburg, Pa., died at Alken, S. C., February 13, aged 58. He was graduated from the Bellevue Hospital Medical College, New York, in 1871.

**William J. Springfield** died recently in Jolly, Daviess county, Ky. He was graduated from the Cleveland College of Physicians and Surgeons in 1874.

**Peter V. R. Dafeo**, of Tecumseh, Neb., February 17, aged 61. He was graduated from the University of the Victoria College, Cobourg, Ont., in 1864.

**Hiram W. Alexander**, in Muir, Fayette county, Ky., February 24, aged 73. He was graduated from the University of Nashville (Tenn.) in 1857.

**Bishop B. Sudworth**, in Ann Arbor, Mich., February 15, aged 73. He was graduated from the University of Michigan, Ann Arbor, in 1833.

**Robert R. Dorsey**, in Los Angeles, Cal., February 18, aged 43. He was graduated from the University of Pennsylvania, Philadelphia, in 1822.

**Carlos R. Allen**, in Vernon, Va., February 19, aged 83. He was graduated from the Dartmouth Medical College, Hanover, N. H., in 1838.

**Herman S. Bisse**, in Philadelphia, February 22. He was graduated from the University of Pennsylvania, Philadelphia, in 1830.

**Benjamin R. Dostor**, in Biakely, Ga., February 15. He was graduated from the Jefferson Medical College, Philadelphia, in 1853.

**Henry Gifford**, at Richmond, Ind., March 4. He was formerly an army surgeon and lately surgeon of the Vandalia Railroad.

**Martin K. Gage**, of Sparta, Wis., February 25, aged 78. He was graduated from the Geneva (N. Y.) Medical College in 1852.

**Martin B. Cherrie**, in Ankeny, Ia., February 20, aged 41. He was graduated from the Rush Medical College, Chicago, in 1888.

**S. B. Lawson**, at Camden, W. Va., February 24, aged 35. He was graduated from the Baltimore Medical College in 1894.

**Alexander S. Hancock**, of New York City, March 1, aged 65.

**Alexander C. Peters**, of Newark, N. J., March 1, aged 63.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

REPORT OF APPENDICITIS CASES.<sup>1</sup>

BY

WM. M. ROBERTSON, M.D., B.Sc.,  
of Warren, Pa.

During 1902 I had an opportunity to observe an interesting series of five cases of appendicitis, all early elective operative cases, and also to observe what conditions were present at operation. All of these cases occurred in boys and men in robust health. All were between the ages of 16 and 35. Three were less than 20, and two between 25 and 35. In three it was the first attack; two had had former attacks; all of the cases were severe. In the three boys under 20 the trouble was localized with commencing abscess. The other two patients had general peritonitis with pus formation.

Concerning the nature of the attack all were acute. As to time of operation two were operated upon the third day, or at the end of about 48 hours; two were operated upon within 24 hours after the onset of acute symptoms; one was operated upon 30 hours after the severe attack.

All of the appendices were intact, however, one had perforated and one had become partly gangrenous, while two were large, tumefied, and friable. The physical examination in all revealed great tenderness and muscular rigidity in the right iliac region; and in three cases there could be felt a distinct tumor. In only one case (No. 4) with general peritonitis was a rectal examination made, and this revealed the general extent of the inflammation in the pelvis. Four of the cases were distinctly fulminant in character and would probably have been beyond hope in a very short time had there not been early operation.

The leukocyte count in all was positive and, in these acute or fulminant forms, this is the earliest reliable indication for operation. It is positive for quite a number of hours before the pulse may indicate a grave condition. The highest count was 49,000, which occurred in Case No. 1, in which the appendix was partly gangrenous. The next highest was 40,000, in this case beginning general peritonitis from perforation was present. The other three cases had from 23,000 to 27,000 leukocytes, all being safely beyond the 18,000 limit of Dr. Tom R. Brown, of Baltimore, as the number sufficient to demand operation.

There was but one count made in three of the cases, which was but a short time before operation. Two counts were made in the cases of general peritonitis. Eight hours after the very severe symptoms following perforation in Case No. 2 the count showed 30,000 leukocytes, and six hours later showed 40,000; while the temperature, pulse, and general condition would have led many surgeons to delay operation. In Case No. 4 the leukocytes increased from 14,000 to 23,000 in six hours.

All of the patients made rapid and uninterrupted recoveries. Both patients with general peritonitis were operated upon by Dr. Eugene A. Smith, of Buffalo. In Case No. 2 the pelvis was filled with seropurulent fluid. After removal of the appendix the abdomen was irrigated with hot saline and closed without drainage. In Case No. 4 the pelvis and part of the abdomen were full of pus. The appendix was removed, the abdomen irrigated, and drainage made by placing a gauze wick to the bottom of the pelvis and a Mikulicz drain to the seat of the appendix.

In Case No. 1 there was pus formation amidst adhesions, with a gangrenous appendix. In this case the intestines were entirely packed away from the point of greatest infection—after removal of the appendix, breaking down the adhesions and irrigation—by a pack of washed-out iodoform gauze; this was removed after three days and a fresh small strip of gauze introduced.

In Case No. 3 only the Mikulicz drain was used, while in Case No. 4 wicks were left in the pelvis and to the site of the appendix.

Case No. 1, in which I operated January 21, 1902, assisted by Dr. J. R. Durham and the late Dr. W. V. Hazeltine, was the first case of appendicitis in Warren county in which the leukocyte count was used as an aid in determining the imperative-ness of operation; and was the first early elective operation for appendicitis performed in this county.

Taking into consideration the severity of these cases it is not putting the case too strongly to say that, without operation, four out of five of these patients would soon have succumbed to the disease. At least no one would contend but that two of the five would very quickly have been dead, and that chances of recovery were against the other three.

Altogether this plea for early prompt operation is a strong one. The rank and file of the profession, so far as practice is concerned, favors waiting in most cases, and it is humiliating to admit that there are many in the profession who will placidly allow the operative period to pass as though they carried no particular responsibility during that time, and then, when they see danger and destruction face to face, are perfectly willing to throw the case in the lap of the surgeon and place on him the responsibility. The time is past when there should be any dissension in the matter between physician and surgeon; the one trying how long a case may be withheld from the operative list, and the other seeking and begging for the early opportunity to remove the trouble while yet there is time. There should be one endeavor in both to bring the case to operation so soon as possible, provided the patient and the friends consent. In these as well as in other surgical cases, John B. Murphy recently said: "When will the medical profession fully appreciate the dangers of delay? When will they realize that the loss of a life by omission is as grave as a loss of life by commission?" In such cases Dr. Roswell Park says, "When in doubt, operate." It sounds well enough to raise the cry "do not operate till you have to!" but it is a fearful responsibility to wait until operation is too late. We owe it to ourselves and to our patients to be fair in such matters. We should ever hold our minds in a receptive attitude. There is too much of taking sides in such questions, and there are too many who can not be changed, who have not the mental aptitude to be able to change their views. It leads to dogmatism, and in medicine as a science "rationalism and progress" is the watchword, and that is entirely opposed to dogmatism and orthodoxy.

Lord Lister says that he worked for years with but little encouragement from his professional brethren. This is pathetic to think upon, especially when it is our professional brethren who are at fault. It is expected of the laity, but where it is true of the bulk of our profession, would it not be right to make the chief object of preliminary training for medicine that of training a rational and receptive mind?

## CASE OF FIBROSARCOMA TREATED BY OPERATION, SERUM INJECTION, AND X-RAYS.

BY

J. P. TORREY, M.D.,  
of Andover, Mass.

The following case is of interest because affording a pathologic examination of the site of a malignant growth which had disappeared under exposure to the Röntgen rays:

Mr. J. J. A., aged 43, a hack driver, having a good previous and family history, received a blow from a fall some weeks before noticing a tumor in the left side. The tumor was first discovered in September, 1901, as a painful, tender, movable, hard bunch about the size of a horsechestnut. Operation was refused until December 22, 1901, when a flattened nodule  $1\frac{1}{2}$  inches in diameter and 1 inch thick was removed. The wound healed by first intention, but after a time reopened and discharged a bloody fluid. On February 22, 1902, a recurrent nodule the size of a cherry was removed, and on May 5, 1902, Dr. Charles L. Scudder, of Boston, resected a portion of the tenth rib and followed the growth down to the peritoneum. The wound was drained and the upper end healed, but the lower end granulated for some months. Dr. Whitney, pathologist to the Massachusetts General Hospital, reported the growth as fibrosarcoma.

Dr. William B. Coley, of New York, kindly advised regarding the use of his serum injections and Röntgen ray exposures.

<sup>1</sup> Read at the Warren County (Pa.) Medical Society, January 13, 1903.

Injections of the mixed toxins of erysipelas and *Bacillus prodigiosus* were begun May 10, 1902, and continued every other day until July 1, 1902, the dose varying from .03 cc. to .5 cc. (.5 to 8 minims), which produced a chill at four different times. During this period there was loss of weight and general decline, accompanied by a third recurrence.

Between July 1 and September 11, 34 Röntgen ray treatments were given from a small 8-inch Ruhmkorff coil, operated by eight storage batteries.

Treatments were given two or three times a week from 10 to 15 minutes at about 8 inches from the target of the tube. Injections of the toxins were also used once or twice a week. The general health began to improve, and the four tumor nodules which had developed diminished in size.

From September 11 until November 6 a 12-inch Heinze coil attached to a street current, transformed to 104 voltage, was employed. Improvement was very marked during this period, the skin became bronzed, then reddened, so that treatments were omitted October 28.

After this the two remaining nodules completely disappeared, leaving at the site of the granulating wound only an indolent ulcer the size of a dollar, which reopened after having nearly closed, and was doubtless a Röntgen ray burn. At this time the patient was feeling well, working every day, and weighed 190 pounds.

November 6 the patient developed typhoid fever, the only known exposure to the disease having occurred through lifting a convalescent typhoid patient into and out of his hack. After ten days of severe fever death occurred.

Postmortem examination of the side was allowed, and the entire scar with its underlying tissue to the ribs and peritoneum was removed for examination. No sign of newgrowth was found by Drs. Whitney and Simmons, who examined the specimen, nor was there any abnormal gross appearance about the stump of the resected rib, nor within the pleural or abdominal cavities, the viscera of which were palpated and exposed to view as far as possible through the incision in the left side.

Dr. Simmons, of Boston, writes: "All the specimen shows is normal skin and an old scar. I have looked up Dr. Whitney's specimen removed by Dr. Scudder, and have gone over both specimens with Dr. Whitney. In the specimen the tumor was without doubt fibrosarcoma, and shows best where it was invading the muscle. The ulcers are very chronic and might well have been caused by a Röntgen ray burn. I do not think that the specimen shows conclusively from a pathologic standpoint that the sarcoma was cured, although certainly there was none of it in the scar."

While complete autopsy by a competent pathologist would have decided the question of cure conclusively, yet the fact that subcutaneous nodules visible and palpable had completely disappeared, leaving no trace in the tissues upon microscopic examination, and that the clinical symptoms of malignant disease had gone also, render it quite probable that cure had taken place.

## CHROMATOPSIA FOLLOWING LABOR.

BY

A. M. DAVIS, M.D.,  
of Philadelphia.

Pathologist to the German Hospital.

The patient is R. W., a primipara of 26. Her family and previous history are negative. She is of good physique, well-nourished, and has always had excellent health. Repeated examinations of the urine throughout pregnancy gave invariably negative results. The position of the child was diagnosed as that of L. O. A.

Labor began at term and terminated normally, with the exception of a central perineal tear requiring three sutures, and which healed without suppuration. During the course of labor (which occupied about 10 hours) nervous symptoms were apparently absent. The second day after delivery, quarrelsome neighbors gave the patient a severe fright, and at the same time her nurse was unexpectedly called away. Complete insomnia ensued the following night, but no untoward symptoms were noticed the next day. At midnight of the next day I was called to see the patient. I found her in a condition of partial shock, the skin was cold and clammy, respirations sighing, with slightly subnormal temperature (98° F.). The pupils were widely dilated, and the patellar and bicipital reflexes were diminished. Upon questioning, she complained of great alarm because the white bedspread appeared a golden yellow, as did any light object about the room; dark objects appeared absolutely black. There was also an inability to concentrate the sight upon objects, which became dim and indistinct, but after closing the eyes they again appeared normal (except in color) for a few moments and then again become blurred. At the same time olfactory delusions appeared; a sudden and suffocating odor seemed to penetrate her nostrils, this being only relieved by inhaling some volatile substance, such as camphor or aromatic spirits of ammonia. The milk secretion (which

had appeared the second day after labor) was apparently normal, the lochia were entirely so, and the uterus seemed to be involuting nicely. An examination of the urine at this time showed it to be intensely acid, specific gravity 1.030, and to contain an excess of urates and uric acid, but no pathologic elements.

With the relief of the insomnia, the visual and olfactory delusions were relieved to a certain extent, although they persisted with varying intensity for at least six weeks after labor. At no time was there any disturbance of cerebration apparent. The child weighed 8½ pounds at birth, and at the age of two months was well nourished from the breast, and in the best health. The patient, notwithstanding her peculiar condition, insisted upon getting about the fourteenth day following confinement, and is now (two months later) able to resume her household duties, being fully recovered. At no time during the puerperium was there any rise of temperature.

## AN IMPROVED ROUND POINT SURGICAL NEEDLE.

BY

HOWARD LILIENTHAL, M.D.,  
of New York City.

Attending Surgeon to Mt. Sinai Hospital.

To the Editor of *American Medicine*:—In your issue of January 10 I note an article by Dr. George Erety Shoemaker, of Philadelphia, on "An Improved Round Point Needle for Intra-abdominal Use." Permit me to say that, without controversy as to priority, George Tiemann & Co., of New York, have for

the past eight months or more made for me a full curved, round pointed, flat shanked needle much like the one described by Dr. Shoemaker. It will be noted that the eye of the needle has been made very large by slightly spreading the tip of the shank. This greatly facilitates threading and does not impede the needle in its passage through the tissues. I had these needles made especially for the insertion of the deep layer of sutures in the Bassini operation for the radical cure of inguinal hernia. The making of surgical needles, by the way, is not a particularly new industry in America, Tiemann having made them for many years.

Lilienthal's needle. Figure shows the eye a trifle too wide.

## CAUSES OF EPILEPSY IN THE YOUNG.

BY

F. J. CAMPBELL, M.D.,  
of Fargo, N. D.

To the Editor of *American Medicine*:—In your issue of December 13, Dr. Jacobi makes the following statement in his article on "Causes of Epilepsy in the Young:" "I can say that I never in my life saw a recovery from paralysis, idiocy or epilepsy due to circumcision."

This statement, coming from such a high authority as Dr. Jacobi, leads me to put on record the following case of cure from epilepsy by the operation of circumcision. While I have considered the result a remarkable one I was not aware that it was so rare as seems to be the case, or that well authenticated cases of cure were seriously questioned.

Some time during the summer of 1892 a well developed boy of 13 was brought to me by his father, a farmer, to be treated for epilepsy. His father gave the following history: For several years he had had an occasional convulsion, and these had increased in frequency and in intensity till at the time of consulting me they occurred daily and often several times a day. The convulsion that I witnessed was a typical one of grand mal. They, of course, incapacitated him from farm work and rendered him entirely useless and an object of constant care. Noticing a marked phimosis with balanitis and irritating smegma, I circumcised him. He had one slight convulsion the next day. Over 10 years have passed and he called at my office last week and stated that he has never had another since. He is a picture of a healthy farmer. As I did nothing else but the circumcision I consider the case one of complete recovery from epilepsy by circumcision.

## ARTIFICIAL RESPIRATION IN CARBOLIC ACID POISONING.

BY

WALTER S. CORNELL, M.D.,  
of Philadelphia.

The value of artificial respiration in poisoning by carbolic acid seems demonstrated by the following case:

N. M., aged 58, a blacksmith, of heavy and powerful physique, was brought to the Presbyterian Hospital about 10 minutes after taking a quantity of carbolic acid. The patient was unconscious and slightly cyanosed. The respirations were 40 and stertorous in character. Pulse was 100-110. The muscles were not quite relaxed. A stomach-tube was at once inserted and the stomach thoroughly washed out with two quarts of water containing 250 grams (8 ounces) of Epsom salts and 125 grams (4 ounces) of sodium bicarbonate. A hypodermic injection of 5 mg. ( $\frac{1}{10}$  grain) of strychnia and 1 mg. ( $\frac{1}{60}$  grain) of atropin was also given.

These measures occupied about five minutes. The patient meanwhile had sunk rapidly into an apparently moribund condition—absolutely relaxed, the eyes opened, and the conjunctival reflexes lost. The cyanosis was more pronounced, the heart-beat was not palpable, and there was no radial pulse. A running, soft carotid pulse of 110 could just be felt. This slight pulse and the absence of respiratory movement brought to mind that carbolic acid kills usually by paralysis of the respiratory center. Artificial respiration was accordingly instituted at once. There was also given 30 cc. (1 ounce) of whisky hypodermically and 235 cc. (8 ounces) by rectum; only a part of the latter was retained.

Respiration was maintained by an operator on each side bringing the patient's arms down from the level of the head to the sides of the chest, the expiratory movement being finished by a heavy pressure on the anterolateral aspect of the thorax. A mouth gag was inserted, and oxygen administered by a rubber tube introduced into the nose.

At the end of 30 minutes, during a momentary rest of the operators, the patient was observed to make a single weak inspiratory effort. The movements were resumed with intermissions every few minutes. Inspections made during these resting periods showed returning respiratory power, the number of automatic movements being increased each time until they reached 10 continuously. This was 45 minutes after the beginning of the treatment. The conjunctival reflex returned and the cyanosis disappeared. The administration of oxygen was stopped. At the end of another half hour the patient was breathing feebly but regularly, and the artificial movements were discontinued. The patient was transferred to the medical ward and consciousness returned in the succeeding hour. Small doses of olive oil were given for the next 24 hours. Stomatitis and esophagitis, a diarrhea for three days (rather longer than the action of the salines would warrant), and a natural chest soreness, were the only sequels. Unfortunately no order for a special urinalysis was given, but the urine showed such quantities of free carbolic acid that the laboratory resident made a note of the fact.

The quantity of acid taken is uncertain, being between 7.5 cc. and 60 cc. (2 fluidrams and 2 fluidounces). An investigation showed that the patient had received 30 cc. (1 ounce) of Merck's pure carbolic acid from the druggist's boy, of which 22.5 cc. (6 fluidrams) remained in the bottle. The boy had disappeared, and the patient claims that the (4-ounce) bottle was originally half full. Allowing for the patient's misstatement, the boy's generosity probably raised the absolute minimum 7.5 cc. (2 fluidrams) to 15 cc. ( $\frac{1}{2}$  ounce). According to Tyson's "Practice of Medicine" 3.75 cc. (1 fluidram) is the maximum dose followed by recovery.

## NONSUSCEPTIBILITY TO VACCINATION.

BY

ARTHUR E. SWEATLAND, M.D.,  
of Little Rock, Ark.

To the Editor of *American Medicine*:—In the past eight years I have used only fresh vaccine, the best to be procured, and the methods of application have been those of the best advocates of the process. I have endeavored to get a successful vaccination upon myself on an average of twice a year for the past eight years, not having been vaccinated in youth. Last September, while in a somewhat lowered condition physically, I was vaccinated and secured a most beautiful result. Experience in vaccinating my patients has convinced me that the

physical condition of the subject has much to do with results. Even a "bad cold" will lower the vitality of the organism sufficiently to allow the vaccine to perform its work when otherwise it would not have done so. Before ever having been successfully vaccinated I attended numerous cases of smallpox with impunity, being at those times in a robust condition. The failures in obtaining successful vaccination are numerous, but I believe these same persons some time, either by exposure, overwork or sickness, could be rendered susceptible to the virus.

## COMMENT ON SOME QUEER THINGS IN MEDICAL JOURNALS.

BY

JAMES MOORES BALL, M.D.,  
of St. Louis, Mo.

In *American Medicine* for January 17, 1903, is an article by D. H. Galloway, M.D., Ph.G., of Chicago. He writes concerning "Some Queer Things in Medical Journals." In his letter the following occurs:

"Dr. James Moores Ball, in an article in the *Tri-State Medical Journal* of October, 1898, speaks of sterilizing a slipper-elm tent in alcohol containing 1 to 4,000 mercuric chlorid solution. He fails to tell us how much of the 1 to 4,000 mercuric chlorid solution his alcohol contains. It is inferred, however, that the alcohol itself holds in solution one part of mercuric chlorid to 4,000 of the alcohol."

Now, the facts are:

1. I did not write the article in question or any part thereof.
2. It was written by Dr. L. L. Renshaw, of Monona, Iowa, and was credited to him ("Endometritis and its Treatment," by L. L. Renshaw, M.D., of Monona, Iowa, *Tri-State Medical Journal*, October, 1898, p. 505).
3. The objectionable quotation should be credited where it belongs, viz.: to Dr. Frank A. Glasgow, a professor in the Medical Department of the Washington University, St. Louis, whom Dr. Renshaw quotes. (See *Tri-State Medical Journal*, October, 1898, p. 505, twenty-fifth line from the top of page.)

## RECOVERY AFTER LIGHTNING STROKE.

BY

A. F. MCKENZIE, M.D.,  
of Monkton, Ont.

To the Editor of *American Medicine*:—In your issue of November 22, 1902, there is a communication on this subject from F. J. Bardwell. He says "It is not uncommon for people to be stunned by lightning but so far as I know this is the only person ever struck and marked by lightning who lived to tell the circumstances." An examination of available literature shows that although rare, the case he reports is by no means unique. In Taylor's Manual of Jurisprudence two or three somewhat similar cases are described. In the October (1901) issue of the *Dominion Medical Monthly* I reported a case occurring in my own practice. In this instance the patient was standing in an open doorway when struck by lightning. The last circumstance, before the accident, she could remember was that of laughing at some men who were running from the storm. The lightning mark extending from the left shoulder to the gluteal region was plainly seen nine weeks after the injury.

## THREADBARE AND STILTED EXPRESSIONS.

BY

ARTHUR DEVOE, M.D.,  
of Seattle, Wash.

To the Editor of *American Medicine*:—I have noted with interest and approval your editorial comments on the prevalent use in medical communications of various "threadbare and stilted expressions," and am moved thereby to call to your attention certain hackneyed formulas which I believe are not only bad English but misleading and unscientific.

First: It is a very common thing for medical writers of all

classes to refer to "diseased conditions" instead of disease conditions. Exceptionally the latter term is employed. Placed side by side it seems to me the two expressions show their inherent weakness or strength. Tissues and organs may be diseased. Conditions are the result of disease or the habit of health.

*Second:* Operations for appendicitis are recommended by authorities and others to be done "in the interval between the attacks," or simply and briefly "in the interval." Now, if the appendix be removed by operation there can be no after attack of appendicitis, hence the organ and the interval are alike cut off. The death of the patient under operation similarly terminates the interval idea even if the appendix be not cut off. The complete and final recovery of the patient without operation, a common occurrence, likewise vitiates the in-the-interval formula. What good and important surgical purpose is advanced by maintaining this fatuous surgical expression?

### EYE-STRAIN AS A CAUSE OF CHOREA.<sup>1</sup>

BY

ALBERT R. BAKER, M.D.,  
of Cleveland, Ohio.

Doubtless many of you have met school children who wink incessantly, a habit for which the child is frequently punished. The winking is due to an error of refraction, and the effort made in accommodation reminds one of the boy who first attempts to do without suspenders, and as his trousers keep slipping down he hitches them up in sailor fashion; and so in a case of the hyperopic child kept at school tasks, he finds his ciliary grip on his lens sliding back until the page becomes blurred. He then winks and metaphorically spits on his hands, takes a new hold, increases his accommodative efforts and the letters again clear up. After reading a few words or lines the same blurring again occurs and the renewed effort at concentration is made and thus the habit of winking is acquired. Not infrequently sooner or later a spasmodic closure of the lid is added to the winking, and after a time the whole face participates in the act, accompanied by the peculiar grimaces and muscular movements characteristic of chorea. From numerous observations in my own practice I am thoroughly convinced that this is the genesis of many cases of chorea occurring in school children.

It may be there is a general neurosis back of this trouble; there may be rheumatism and valvular heart disease. Poorly nourished and anemic these children almost always are, but I am thoroughly convinced that the error of refraction is the exciting cause in very many cases. It is possible these are not true choreas and should be called habit choreas, in any event they are met frequently and often are not treated intelligently. I have so frequently met children who have been removed from school on account of chorea, and upon each return to school have had a recurrence of the choreaic movements until carefully fitted with spectacles, and subsequently have had no recurrence, that these observations have in my own mind the certainty of a scientific demonstration.

My first thought when the subject of this discussion was suggested was to report a number of cases; but it seemed unnecessary as I believe every one present can call to mind cases of chorea benefited if not cured by the use of lenses. The lesson I wish to teach is this: Send the patient to the oculist first and not waste valuable time in giving drugs. Give the spectacles first and follow up with your hygienic and medical measures if necessary.

The stereotyped letter I get is something like this:

DEAR DOCTOR: This little patient has been under my care for chorea for a long time. She has been better and worse. I am about discouraged and so are the parents, and we have concluded to try spectacles. Do the best you can.

Yours, etc.,

I prescribe spectacles, the family physician continues his general treatment, the child soon returns to school cured, and I sometimes doubt whether the oculist receives the credit he

deserves for the cure. It does seem sometimes that the profession as a whole are very obtuse in adopting new ideas and new methods. They will prescribe unhesitatingly an unknown and untried remedy that some smooth drummer recommends, but will ignore the most valuable remedies that are seen close at hand. Migraine, that typical eye headache which can almost always be cured with spectacles, is still doped, purged, and dieted, world without end, forever, until the patient takes the matter in his own hands and consults an oculist. So, too, in chorea I find the patients are beginning to come directly to the oculist, and not infrequently against the advice of the family doctor. Within the past year physicians on different occasions have ordered my patients with chorea to discontinue wearing spectacles; in each case the disease became worse, and the glasses were soon restored. I realize the disadvantage the general practitioner labors under in these cases, and I have no doubt but that he suffers in reputation and in pocket therefrom.

Specialists are not all saints, and even though they were, the general practitioner would suffer the most. So that I believe the remedy for this condition lies in all the profession preparing themselves to fit spectacles, and especially those who have to do with the treatment of children. Dr. Kelley has long held his clinics on the same morning in an adjoining room at the Cleveland General Hospital. Judging from the large number of children in attendance upon my clinic, it would sometimes be difficult to say which was the children's clinic and which the eye clinic, especially as so many of them in my service are suffering from headaches, chorea, and other nervous disorders of childhood.

What is true of my dispensary practice is even more so in private work, and I doubt not is so in the practice of every oculist. This condition will continue until the general practitioner prepares himself to do this work. The practitioner who thinks that because a child sees perfectly that the eyes are not at fault makes a most serious mistake. Often those who see the best suffer the most from eye-strain. It is not how much, but how we see that causes trouble. A patient may see perfectly without a mydriatic, but cannot see 20/20 with it. If the general practitioner used mydriatics more frequently, even though not fitting spectacles himself, he would not so frequently fall into error.

The interdependence between accommodation and convergence is a most prolific source of nervous trouble in children, as well as in older people, but I fear it would lead us too far afield to undertake its discussion at this time and place.

### OPERATIVE TREATMENT OF RUPTURED URETHRA.

BY

A. GROVES, M.D.,  
of Fergus, Ontario, Can.

There are few things more difficult in surgery than the operation required when the urethra has been torn completely in two. Extravasated blood and urine in the bruised and torn tissues render the task of finding the distal end a very trying affair and I have known the search to be abandoned. Usually, with sufficient practice, the torn end can be found and in locating it pressure over the bladder will often cause a flow of urine which promptly solves the problem. In one of my cases, after making every reasonable effort, I was unable to locate the opening and I then made a suprapubic incision into the bladder and passed a catheter from the bladder along the urethra and in this way accomplished the object. The subsequent progress of the case was entirely satisfactory. When great difficulty is experienced, this will be found an absolutely certain method of overcoming it. The torn ends should be accurately stitched together, the permanent patency of the canal depending upon the healing together of the edges of the mucous membrane. If the edges are not approximated cicatricial tissue will result and a troublesome stricture develop. If the wound in the urethra is properly put together there should be no stricture. In one case in which there was an old stricture which was very tight, I dissected out the cicatrix and brought the urethral ends together with good results.

<sup>1</sup> Opening discussion of Dr. Dicky's paper on chorea before the Ohio State Pediatric Society, Toledo, Ohio, June 9, 1902.

## ORIGINAL ARTICLES

OBSTINATE SUBACUTE RHEUMATISM.<sup>1</sup>

BY

JAMES J. WALSH, M.D., PH.D.,

of New York City.

We are getting farther and farther away from the idea of specifics in medicine. Time was when the principal effort of the medical man was the search for the specific drugs which would cure the ills that flesh is heir to and for which it was thought special remedies had been provided in nature. For a time quinin seemed to be one of them, and encouraged the old idea. Now we know that it is not a specific for fever, that it is only an antiseptic, which is not harmful to the tissues, and which makes short work of the parasite of malaria. We no longer believe that iron is a specific for anemia, since clinical observations have shown that corresponding doses of chemically similar metals, such as manganese, nickel, and cobalt will produce similar effects. Mercury remains as a specific for syphilis, but it seems probable that when we know more about the cause of the disease, we shall learn that it is probably because of the special susceptibility of the microorganism causing the disease to very dilute solutions of the mercurial salts that is the basis of its therapeutic effect. Such idiosyncrasy to certain chemicals is not unknown in bacteriology, and has been noted particularly in the relation of aspergillus to very dilute solutions of silver nitrate.

There remains in certain minds an idea that the salicylates are specifics for rheumatism. Any one who has seen patients with acute rheumatism treated with other coaltar products, such as antipyrin or phenacetin, soon realizes that the effects are practically the same from the various coaltar products, and that what the salicylates really do is to lessen the pain, lower the fever and make the patient more comfortable. There seems to be almost a consensus of clinical opinion, however, that the salicylates are the best symptomatic remedies for rheumatism. There are, in spite of this, a certain number of cases of acute articular rheumatism, however, which are not affected even by large doses of the salicylates. We know that certain specific affections as, for instance, gonorrhoeal rheumatism, so-called, or pyemic arthritis, which for a time may simulate rheumatism very closely, are not affected by the salicylates. There comes at once the thought that certain cases of rheumatism which are obstinate to the salicylates are really due to some other cause than true rheumatism.

In recent years it has been noted that affections of serous membranes, as for instance an ascending infection of the membranes of the cord and of the brain, may result from the presence of pyogenic cocci localized in some part of the body. Meningitis has been known to follow a localized abscess, especially in cases in which the abscess was due to a pure culture of the pneumococcus. It has been known to follow also even in cases of ordinary felon due to pyogenic cocci. There would then seem to be a tendency in certain irresistible tissues to permit the invasion of serous membranes whenever pyogenic cocci get into the circulation. Malignant endocarditis has been known to follow very simple and supposedly thoroughly localized purulent foci. It would not be surprising then if certain cases of supposed rheumatism were really due to an invasion of pus cocci whose virulence is rendered very much less by the fact that the supply of oxygen to be obtained in joint cavities is very limited.

There are certain cases, however, of so-called obstinate rheumatism in which hypothesis need have no place, and actual observation shows the reason for the

failure of the salicylates to relieve symptoms. I have seen within the year a case of rheumatism, so diagnosed by several physicians, in which the patient had had recurring severe attacks, each one of which, however, left some changes in the joints, the joints mainly affected being the fingers and wrists. In this case the diagnosis rheumatism was absolutely unjustified. The condition was evidently gout, and should have been treated as such. The salicylates used over a long period instead of doing good had done harm by increasing the destruction of red blood cells and adding to the patient's anemic condition. In this case suspicion of the nature of the affection should have been aroused by the fact that the patient's father had suffered from a similar condition and that the family was of English extraction. Personally, however, I feel that true gout is much more frequent in this country than has been thought. In a report from Dr. Osler's clinic made at the last meeting of the American Medical Association, it was shown by carefully-kept statistics extending over 12 years that gout was by no means infrequent in and around Baltimore. Compared with the statistics of St. Bartholomew's Hospital, London, the Baltimore report shows that gout is only one-fourth less frequent in this country than in England, though the general supposition has been that we were comparatively free from it, while our English cousins were especially prone to it. We would not have been surprised at statistics showing that gout was four or five times as frequent in England as it is here, instead of existing in the proportion of only four to three.

How difficult may be the recognition of some of these gout cases that now masquerade as rheumatism can perhaps be best realized from the confession frankly made that at Johns Hopkins one patient had been under treatment three times for rheumatism before the discovery, on admission for the fourth time, of tophi in the ears showed that the case had always been one of gout. Gout is especially liable to occur in those who indulge freely in malt liquors, or in those who have some habitual association with lead, as those engaged in the manufacture of white lead: painters, plumbers, tanners, and the like. Men affected with anomalous rheumatic conditions, having such elements in their history, should be suspected, and if the salicylates prove failures in the treatment of their symptoms, careful investigation should be made for the stigmata of gout.

In a certain number of other cases the obstinacy of rheumatic symptoms to the salicylates are due to a nervous element in the patient. Within the last year I have seen a patient who, after two weeks, was still suffering acute pain in various joints notwithstanding the fact that the salicylates had been used freely. In this case at the beginning the affection was almost surely acute articular rheumatism. Later on, as the result of the irritation set up in the joints by the rheumatic arthritis, a tendency to neurotic arthropathy or hysterical joints developed. The affection did not remain for any length of time in one joint, but skipped around. The swelling and tenderness was complained of in one wrist today, in the other wrist two days later, and then it skipped to the knees, occasionally even to the smaller joints. To continue the use of the salicylates in such a case is sure to do harm to the patient.

Of course, it is not easy to know just what to do for these cases. Hysterical affections of any kind are likely to be very capricious toward any treatment. If the patient is anemic, the effect of iron may well be tried, and will often be found of help, notwithstanding the fact that this drug is sometimes said to be contraindicated in rheumatism. Stimulant remedies of almost any kind are nearly sure to prolong the symptoms. On the other hand, any of the stronger sedative drugs, especially the bromids, are likely to have similar effects, and the hypnotics are not advisable. Usually valerian in some form will prove helpful.

Alcoholic patients are prone to have a prolongation

<sup>1</sup> Read before the Section on General Medicine, New York Academy of Medicine.

of their symptoms of acute rheumatic arthritis beyond what is noted in normal patients. The reason is not far to seek. Often before there is any distinct evidence of alcoholic neuritis—that is, before there is any loss of power—the nerves are affected. It has been frequently noted that after a sprain of the ankle an alcoholic neuritis asserts itself that had evidently been in preparation for some time. Alcohol affects the nerves, especially of the lower extremity. Before any disability is noted, nerve degeneration may have progressed so far that the vital reaction of the tissues of the joint is not sufficient to enable them to throw off the arthritic process.

The same thing may be noted with regard to lead. A man who works in lead falls on his hand, sprains his wrist, and then about the time the sprain is getting better has a distinct drop-wrist develop. There have been no signs before the accident of any affection of the nerves. It is evident, however, that a definite neuritic condition existed for some time before. Should a patient contract rheumatism under these conditions there often is a development of a subacute arthritic condition after the true rheumatic arthritis has subsided. In these cases it is important that the underlying condition should be treated, and that the use of the salicylates shall not be continued too long. In both alcoholic and plumbic conditions there is apt to be an associated low grade nephritis. Whenever the kidneys are in a condition so that they do not promptly excrete the salicylic acid administered there is danger of these drugs doing harm. As a rule, the kidneys should be watched, and if the urine becomes smoky early in the administration of the remedies the method of treatment should be changed. Rest, the alkalies, and other coaltar products must be depended on in these cases.

Anemic patients and those suffering from blood dyscrasias of various kinds, as scurvy and hemophilia, are prone to have painful affections of their joints occur almost spontaneously, and it is evident that these important structures, the tissues, which by the way have the hardest work in the body with the exception of the heart, are not receiving their due share of nutritious material.

Patients suffering from such conditions not infrequently have a continuance of their rheumatic symptoms beyond the time when they would normally be expected to have relief because of the administration of the salicylates.

In such cases to persist in the administration of the salicylates is almost sure to do harm. All the coaltar products increase the destruction of red blood cells, and the salicylates are no exception to this rule. Of course, the underlying condition must be treated, and such supporting and dietary regulations advised as may prove helpful. Here, as in hysteria, patients are capricious, and nothing sure can be prescribed.

Finally, there remains a class of ailments which are liable to cause a proration of relief from the symptoms of acute rheumatism by the administration of the salicylates. Most of the infectious diseases may cause passing painful conditions in the joint that show how sensitive these structures are to the presence of toxins in the circulation if the joints are much used, as happens when the patient moves around while the toxins are present. This tendency to affect the joint is well illustrated in influenza, which may itself cause joint pains, simulating rheumatism, and when it follows rheumatism after only a brief interval may cause what appears to be a relapse of the rheumatic condition. If influenza precedes rheumatism by only a short time the rheumatic arthritis usually runs a longer course than normal and is more obstinate to treatment.

Long ago Hippocrates pointed out that dysentery might be accompanied by joint pains, or even by some swelling, that is by effusion into the joint capsule. In conditions in which the digestive tract is seriously disturbed and toxins are being absorbed from it the pres-

ence of these in the circulation may interfere with joint nutrition. This makes the reaction to a process like rheumatism much less active than it would be under normal circumstances. If then there is any infection of the gastrointestinal tract some delay in the relief of the symptoms of rheumatism may be expected.

There are other chronic infectious conditions that may cause joint symptoms of themselves and may prolong the symptoms of rheumatic arthritis. Gerhardt pointed out a quarter of a century ago that patients suffering from bronchiectasis, especially those afflicted with offensive sputum, were liable to have coincident joint affections. In these cases the basis of the joint disturbance is the presence of toxins absorbed from the putrid material in the bronchial dilation. It is not impossible, however, that even microbial invasion of serous membranes should take place in such patients, for it has been often noted that purulent bronchiectasis may be associated with brain abscess, though the abscess may give no symptoms up to the very end of the disease.

Patients who are liable to suffer from urticaria not infrequently have some joint swellings and tenderness, evidently connected with the urticarial underlying condition. Urticaria is now generally considered to be a result of absorptions, usually from the digestive tract. Its frequent occurrence when the serum of other animals is injected into the body for therapeutic purposes, especially if considerable quantities are used, is well known. It has been known to occur, however, in diphtheria when no antitoxin was used and would seem to be sometimes a manifestation of the development within the body itself of a superabundance of antitoxic material.

I have reported a case like this in which, owing to objections on the part of the family, antitoxin was not used in a very mild case of diphtheria, yet urticarial symptoms were noted just as the temperature fell and the child became more comfortable.

In such cases there is a special sensitiveness of the joint structures to be acted upon by toxic material within the body, and it is not surprising that the symptoms of rheumatism remain much longer than in normal individuals. In these cases after the first decided relief of symptoms is obtained by means of the salicylates, careful supporting treatment with rather liberal diet is indicated, and if anemia be present, as is so often the case, an iron preparation.

In general, it may be said that most of the cases of obstinate subacute rheumatism are not simple rheumatic arthritis, but consist of the joint affection developing in the presence of a diathesis, such as gout, or some blood dyscrasia, or some toxemia, such as alcohol or lead, or a neurosis or a hypersensitive condition of the vasomotor system, all of which factors tend to hinder the normal reaction and prevent the prompt relief of symptoms that usually occurs.

## ON TRANSPLANTATION OF TUMORS.<sup>1</sup>

BY

LEO LOEB, M.D.,  
of Montreal, Can.

From the J. H. R. Molson Laboratories of Pathology and Bacteriology, McGill University, Montreal.

### I.—ON THE RESISTING POWER OF EXCISED PIECES OF TUMORS.

In several former communications I reported the results of a series of transplantations of a cystic sarcoma and of a mixed tumor, a sarcomatous carcinoma of the thyroid.<sup>2</sup> In these investigations I used the method of transplantation (1) to determine experimentally the conditions of growth of tumors, and (2) to approach certain questions

<sup>1</sup>A somewhat fuller report will appear later.

<sup>2</sup>(a) On Transplantation of Tumors, Journ. Med. Research, n. s. Vol. 1, No. 1, 1902. (b) Über Transplantationen eines Sarcoma de Thyroidea bei einer weissen Ratte, Virchow's Archiv, Vol. clixvii. (c) Further Investigations in Transplantation of Tumors, Journ. Med. Research, Vol. iii, 1902.

of the structure of tumors. I also reported some experiments in which I tried to determine the resisting power of excised pieces of tumors to unfavorable conditions.

Since then these latter experiments have been continued and I now wish to report upon the results obtained, mentioning also some previous observations. In these experiments I used in part tumors derived from the sarcomatous part of the mixed tumor of the thyroid; mainly, however, tumors derived from a third sarcoma of the thyroid of a rat, which was cystic, like the first sarcoma.<sup>1</sup>

I. *Experiments to Produce Tumors by Transplanting Excised Pieces of the Sarcoma which had Previously Been Kept at a Temperature of 3° C. to 4° C.*—After I had succeeded in successfully transplanting pieces of tumor, which after the death of the animal had been kept at room temperature for 12 hours, I further extended the time of keeping the tumor outside of the living animal before transplanting it.

Pieces of a large tumor, which was infected in the center, having been kept on ice for 24 hours, were transplanted into seven animals, three of which developed tumors. One piece, kept at room temperature for the same time, only produced suppuration.

Tumors kept on ice for two days resulted, after transplantation, in the growth of two tumors. Pieces kept in the thermostat for the same time did not grow. Pieces kept on ice for five days produced, after transplantation, three tumors.

In the summer of 1902 a series of further experiments was made in which other parts of the third cystic tumor of the thyroid were kept from 1 to 28 days at a somewhat higher temperature, at about 10° C. Transplantation of such pieces, or an injection of a suspension of small particles of the sarcoma in normal salt solution, gave without exception no result. Control pieces, however, which were transferred at once, resulted in the majority of cases in the successful development of tumors. In one case, for instance, four out of five transplanted pieces, in another five of six transplanted pieces, grew.

The cause of the want of success in these latter experiments probably consisted either in the somewhat higher temperature at which these pieces had been kept, or in the fact that only very small pieces were transplanted. I had observed in my second series that under unfavorable conditions, in which infection of the piece is present, the size of the transplanted piece is of importance.

II. *Experiments on the Influence of Heat on Excised Pieces of Tumor.*—Experiments to determine the maximum temperature to which tissues can be exposed without losing the power to grow after transplantation have not to my knowledge been recorded. It was therefore of especial interest to try such experiments with sarcomas, it being *a priori* uncertain if they would behave like ordinary tissues. In these experiments pieces were cut out of transplanted tumors and either minced at once with sterile 0.7% sodium chlorid solution and then heated in a sterile dish on the water bath, or the whole piece was first heated and afterward transplanted as a whole or minced in salt solution and injected.

Pieces kept 40 minutes at a temperature of 43° C. to 44° C. and a piece kept for 25 minutes at a temperature of 43° C. and afterward 15 minutes at a temperature of 45° C., all grew, but pieces kept for 30 minutes at 45° C., as well as pieces exposed to a still higher temperature, up to 50° C., for 30 minutes, did not grow in a single instance. In all eight series of such experiments were made. Seven rats were inoculated with pieces of tumor kept at 43° C. for 30 to 40 minutes, and of these seven, four developed tumors. Of the other three cases, in one rat the inoculation was without success, in another the

tumor developed after inoculation, but later ceased to grow, in the other the microscopic examination showed only the presence of some doubtful nodules.

In the unsuccessful cases in which pieces were kept for 30 minutes at a higher temperature than 43° C. to 44° C., simultaneous control transplantations with the same, but not heated material, were to a large extent successful. On April 18, for instance of two control experiments one was successful; on May 27, of six control experiments, five were successful; on May 29, of four control experiments, three were successful; on June 13, of six control experiments, two were successful.

One might have expected that pieces previously heated would either have been made entirely ineffective by the heating, or if their power to grow had not been destroyed by the heating, would under the favorable circumstances in which they are situated after injection in a living rat, recover in a short time and grow just as well as the piece previously not heated. This, however, was not the case. All tumors formed after transplantation of pieces previously heated, were markedly weakened in their growth. They began to grow later than the control tumors, and after having started to grow, the rate of their development was slower; growth practically ceased after about five to eight weeks. The power of the transplanted pieces to produce tumors was therefore weakened by the heating. Three of these tumors were examined microscopically.

III. *The Influence of Glycerin on Excised Pieces of Tumors.*—Pieces which were kept after extirpation of the tumor for 17 to 24 hours in glycerin, either on ice or at room temperature, were transplanted after having been for a variable period washed with sterile normal salt solution. They were then minced in a 0.7% solution of sodium chlorid and injected in different experiments into seven animals. One developed a large and another a small tumor, while a third,<sup>1</sup> injected intraperitoneally, also developed a large tumor. (Injection of the material was both subcutaneous and intraperitoneal.)

For instance, in a successful series of this nature of July 7, of 13 control rats injected with fresh tumor seven developed tumors. Of the two pieces put into glycerin and implanted into rats one gave rise to a tumor.

Already in former experiments, in which the mixed tumor of the thyroid was used, pieces had been put into glycerin before transplanting them. These experiments could not be finished at the time; in two cases, however, when pieces had been kept in glycerin seven days and one-half day, respectively, they were transplanted into rats and taken out for microscopic examination one day later. Microscopically the nuclei of the cells showed in many places an irregular arrangement of the chromatin, otherwise the structure of the tumor was well preserved. In the piece put into glycerin for the shorter period mitoses were present, due perhaps to the migration of cells into this piece.

The number of positive results with glycerin being small, it will be necessary to continue these experiments further until more definite conclusions can be drawn.

IV. *Growth of Pieces of Tumor Which Before Transplantation Were Put Into Solutions of Potassium Cyanid.*—It was of interest to see whether pieces of mammalian tumors which had been kept in a solution of normal 1-700 to normal 1-1,000 potassium cyanid outside of the body were capable after transplantation of leading to the formation of tumors, it being known that potassium cyanid inhibits the growth of bacteria, and a tumor which has been transferred through so many generations of animals being usually no longer free of infection from saprophytic organisms. In several of the experiments the tumors used were too severely infected to give posi-

<sup>1</sup>I am indebted for this tumor to the kindness of Professor Herzog, of Chicago. The experimental part of this work was partly done in the Gratiwch Research Laboratory of Buffalo in the summer of 1902.

<sup>1</sup>In this case the possibility is not absolutely excluded that the animal in which this tumor developed had been previously inoculated with a piece of tumor which had been kept for 24 hours in chloroform water, their being a possibility of an interchange of animals.

tive results. In other cases the control experiments made with immediate transplantation of tumors did not give any positive results. In one control series five tumors grew, but the pieces previously kept in potassium cyanid did not grow. In two other cases, however, in which the control experiments were also positive, the pieces kept in potassium cyanid did grow. In one case a piece developed a tumor after having been kept for 24 hours in normal 1-1,000 potassium cyanid solution. Among three control animals two developed tumors, one did not.

In the second successful series four rats were injected with a suspension of minced tumor which had previously been kept for 40 hours on ice in a normal 1-700 solution of potassium cyanid, made up with physiologic (0.75%) sodium chlorid solution. In this last experiment three rats developed tumors. Among eight control transplantations six were positive.

In these cases again it was apparent that the pieces previously treated were not as efficient to produce tumors as the ones transplanted immediately; they began to grow some days later, and grew at a slower rate.

In all cases before the injection of suspension the potassium cyanid solution was removed from the piece by washing with normal salt solution.

#### 2.—ON THE INFLUENCE OF BACTERIAL PRODUCTS ON THE GROWTH OF TRANSPLANTED PIECES OF TUMORS.

In my former experiments I made some observations on the influence of bacteria on the growth of tumors, and this series of transplantations has confirmed those former results. It could be shown:

(a) That excised pieces of tumor so much infected with bacteria that later on ulceration of the growing tumor and coagulation of the cystic fluid took place, can lead to the formation of tumors.

(b) That if the infection reaches a certain point of severity no growth takes place, or that, in other cases, if the infection was not severe enough to prevent the growth in the beginning it will do so later on, if the cell degeneration in the center of the tumor had further advanced.

(c) From tumors which have ulcerated at one place frequently small well preserved nodules of sarcomatous tissue are separated and afterward are found lying free in the surrounding connective tissue.

(d) That pieces of tumor, after previous ulceration, may be able, by sloughing off of necrotic parts, to become covered by healthy tissue and that, in this way, sometimes multiple spheric nodules are formed, and that under these conditions these nodules frequently do not grow at all, or only grow slowly.

#### 3.—ON THE INJECTION OF TUMOR JUICE.

By injection of the cystic fluid of tumors derived from the first cystic sarcoma, into the peritoneal cavity of rats, I succeeded in four cases in producing the formation of sarcoma.

The second tumor, the sarcomatous of the thyroid, contained none or only small cysts. In several cases, however, during this series of experiments, a small quantity of tumor fluid was injected without any result.

The third tumor again, contained like the first one, many large cysts and the transplanted pieces also developed cysts. In several cases a few cubic centimeters of the cystic fluid were injected into the peritoneal cavity of rats but without any success. In this connection another fact might be mentioned which may have some relation to this result: In the first series of transplantations, at the place where the tumors were introduced into the subcutaneous tissue, or into the peritoneal cavity of animals, isolated nodules of sarcoma frequently developed. The mere contact of the transplanted piece with the surface of the wound, was evidently sufficient to bring about this result.

In the second series of transplantation such a formation of sarcomatous nodules after transitory contact during the introduction of a piece was very rare indeed.

In the third series it almost never occurred, although these tumors, again like the tumors of the first series, were cystic.

*This is an experimental proof of the fact that different tumors of similar structure may have a very different faculty to infect other tissues by mere contact.*

At various periods cases have been reported in which surgeons believed that contact metastases during operation had taken place. It is, however, difficult in any other than an experimental way, by transplanting the same tumor in many animals, to compare the faculty of different tumors to infect.<sup>1</sup> It is impossible at present to indicate with certainty the causes of the different behavior of different tumors. One difference between the cystic sarcomas of the first and the third series, consisted in the fact that in the first series cells dividing mitotically were found inside of the cysts; in the third series such cells were not present in the cysts. This fact may also explain the different results obtained by injection of cystic fluid in these two series.

#### 4.—ON THE INJECTION OF FILTRATES OF TUMOR TISSUE PREVIOUSLY MINCED IN .7% SODIUM CHLORID SOLUTION.

An important question was if it would be possible to produce tumor formation after having excluded the injection of tumor cells by previous filtration. In one of my former papers I reported upon an experiment which consisted in the injection of minced tumor filtrate through a Berkefeld filter. The result was negative.<sup>2</sup> The new experiments had the same result as the former ones, no tumors developing after the injection of tumor juice previously filtered through a Berkefeld filter.

Equally unsuccessful was the injection of a tumor suspension filtered through ordinary filter paper. The injection of the supernatant fluid of tumor suspension proved, however, successful in several cases. It would seem that the implantation of small masses of tumor cells, or of an agency connected with these tumor cells, is necessary for the production of tumors.

After all these experiments, it can with great probability be excluded that some microorganism capable of existing outside of the cell, and so small that it can be filtered through a Berkefeld filter, is the cause of these sarcomas. Such microorganisms however are, as is well known, responsible for several other pathologic processes, and according to the just published experiments of Marx and Sticker, they are the cause of contagious epithelioma of the fowl, in which proliferation of epithelium is taking place.<sup>3</sup>

#### V.—ON THE INJECTION OF HYALINE BODIES TO BE FOUND IN PIECES OF TUMORS KEPT OUTSIDE OF THE BODY.

Pieces of sarcomas kept outside of the body for several weeks frequently show under the microscope many hyaline bodies of different sizes. These globules have been believed to be microorganisms causing tumor formation. I injected the fluid containing large numbers of these bodies derived from the sarcoma of rats, into healthy rats without any subsequent growth of tumors. It seems much more probable that these hyaline bodies are disintegration products of cells or nuclei.

The experiments recorded here only represent the beginning of a line of experimentation which is capable

<sup>1</sup> By "infection" is not meant that a microorganism must be at the base of tumor formation.

<sup>2</sup> My first experiments on the injection of filtrates of tumor juice in animals of the same species were made in 1899 in cattle affected by carcinoma. Here also the results were not followed by the formation of tumors. Simultaneous with my second series of transplantations of tumors, M. Herzog carried on similar experiments on the injection of filtered juice, equally with negative results (Journal of Medical Research, Vol. III, 1902).

<sup>3</sup> Deutsche medicinische Wochenschrift, December, 1902.

of further extension. At the present stage of these investigations it is therefore not necessary to form conclusions of too definite a character. It may, however, be not without value to state in a preliminary way to what conclusions these experiments seem to lead.

(a) A microorganism living outside of tumor cells and passing through the pores of the Berkefeld filter is not, in all probability, the cause of the formation of sarcoma in rats.

(b) A microorganism living outside of tumor cells and resembling organisms like the tubercle bacillus, or belonging to the class of blastomycetes, is probably not the cause of the formation of sarcoma. Such a microorganism would probably not be made absolutely ineffective by heating to 45° C. for half an hour. A microscopic examination of tumors not secondarily infected does not show any bacteria or blastomycetes. No giant cells characteristic of granulomas caused by the tubercle bacillus or by the blastomycetes can be found in these sarcomas.

(c) The following possibilities remain: The formation of sarcoma is caused by an organism living outside the tumor cells, possessing however, a similar sensitiveness to heat as do the tumor cells themselves. Such organisms would have to be, as we may conclude from the foregoing experiments, larger than red blood-corpuscles as they seem to be unable to pass, at least under ordinary circumstances, through filter paper.

But since a careful microscopic examination of the tumors showed no structures other than tumor cells and their products of degeneration, and since also injection of the hyaline bodies referred to had negative results, the existence of such organisms would seem to be improbable. Still, further experiments ought to be made before these can with certainty be excluded.

The remaining possibilities are that a very small microorganism not capable of living outside of tumor cells is present; and lastly, that a microorganism is not the cause of tumor formation. It would therefore be impossible to produce tumors by the injection of microorganisms alone, if a microorganism incapable of living outside of tumor cells is present or if no microorganism is the cause of tumor formation.<sup>1</sup>

Further, we may conclude from these experiments that no organism sensitive to cold can be the cause of tumor formation.<sup>2</sup>

Without going into any details here I may add some further results of these experiments:

(a) After transplantation of these tumors there does not exist any appreciable period of latency in the growth of the peripheral transplanted tumor cells. They begin to multiply in a very short time, almost at once. This period of latency, however, seems to be different in different series of tumor transplantations; it was short in Hanau's and long in Moreau's experiments. It is of importance to investigate the cause of the different behavior of different tumors in this respect.

(b) Serial sections have shown that apparently separate tumor nodules of sarcoma may be connected by rows of cells, just as Petersen showed the connection of apparently separated carcinomatous cell nests.

(c) Tumor nodules smaller than a pea which never did expand actively when examined microscopically after two months, showed an active mitotic cell proliferation which is in all probability neutralized by the corresponding destruction of cells. In my former investigations I have shown experimentally that by cutting out a piece of such nodules an active growth may be produced.

(d) Sarcomatous cells are phagocytic and may, for instance, take up extravasated red blood-corpuscles. These phagocytic cells may have an appearance very

similar to the phagocytes which I found in the cavity of the Graafian follicles in the first stage of atresia. The corresponding follicular cells therefore need not necessarily be leukocytes, but may, just as the sarcomatous phagocytes, be connective tissue cells.

(e) It is an important problem under what conditions transplantation of normal tissues succeeds; about the conditions under which transplantations of tumors are successful hardly any investigations exist. It is not improbable that transplantation of sarcoma will be shown to be more frequently successful than that of carcinoma, although transplantations of different varieties of carcinoma have been successful.

(f) The result of transplantation of tumor cells as compared with transplantation of ordinary tissues seems to be a conclusive demonstration of the fact that mere displacement of adult tissue, if it plays any role at all in the production of tumors (which however is not probable), is certainly quite an unessential factor.

(g) The fact that not infected, fresh pieces of sarcoma can be successfully transplanted into the majority of animals of the same species proves that a predisposition for the growth of tumor cells is not the main factor which prevents or favors the formation of metastases.

(h) Transplantation of tumor cells through so many generations would seem to prove that the life of ordinary tissue cells may, under conditions not realized in one organism, be able to live much longer than the individual to which they belong.

## FIBROMA OF THE OVARY WITH ASCITES.<sup>1</sup>

BY

THEODORE A. ERCK, M.D.,

of Philadelphia.

Associate in Gynecology, Philadelphia Polyclinic; Assistant Surgeon to the Gyneccean Hospital; Gynecologist to the Frederick Douglass Memorial Hospital.

Cases of fibroma of the ovary are sufficiently rare to warrant the report of the following case:

The case was that of Mrs. N., aged 24. Puberty occurred at 13 years. Menstruation takes place every four weeks, the flow being painless and lasting four days. She has been married five years, and had one child four years ago; labor was normal, and the puerperium without complication. The menstrual periods reappeared when the child was 9 months old. The baby was nursed at the breast until it was 18 months of age, when the mother noticed that the menstrual periods became irregular in time, occurring every six to eight weeks, and the flow became scant. There was no increase in weight, nor did she experience any pain during menstruation.

In May, 1901, an abdominal enlargement was noticed, and although the menstrual periods were regular the amount of blood lost had become so small that she concluded she was pregnant. There was a continued enlargement of the abdomen, so that when seen with her physician December 22, 1901, the patient presented the appearance of a woman at term. The general health was good, although she was somewhat anemic. Examination of the heart and urine proved negative.

*Examination.*—The abdomen was greatly distended with free fluid, though the walls were not tense. A hard, nodular mass about the size of a cocoanut occupied the hypogastric region, which by combined examination was found to be freely movable and not connected with the uterus.

*Diagnosis.*—Solid ovarian tumor with ascites.

*Operation.*—This was performed December 28, 1901, at the Gyneccean Hospital. The abdomen was incised in the median line and several gallons of a clear straw-colored fluid was evacuated from the abdominal cavity. The pinkish-white, hard, lobulated tumor of the right ovary was readily delivered and ligated. The pedicle was very small and consisted of the thin broad ligament and tube. The fallopian tube was atrophied and spread out over the tumor. There was only one adhesion, this to the opposite ovary. The left ovary was small and quite hard and from one end projected a cyst about the size of a walnut; it was also removed. The uterus was small and the peritoneum appeared normal. The abdomen was closed without irrigation or drainage. The convalescence was normal.

The pathologic report by Dr. McLester is as follows:

Examination of two specimens: Uterine appendices of both sides, removed by Dr. Erck.

<sup>1</sup> Several investigators claim to have produced tumors by the injection of microorganisms alone.

<sup>2</sup> Schüller maintains for microorganisms described by him an extreme sensitiveness to a temperature lower than that of the body.

<sup>1</sup> Read before the Obstetrical Society of Philadelphia, October 2, 1902.

The larger specimen is a hard, tough, elastic mass about the size of a small cocoanut. It is lobulated and in appearance is not unlike a brain hardened in alcohol. A shrunken cord is attached to the surface at one point. The mass measures 10 x 8 x 8 cm. and weighs 200 grams. Sections taken from the surface and from the deeper portion of the tumor were imbedded in celloidin and stained with hematoxylin-eosin. The microscopic examination shows the specimen to be made up of dense, wavy bundles of typical fibrous tissue. The nuclei stain well. The bloodvessels are well formed but are exceedingly few in number. No other tissue is seen and there is nothing in the microscopic findings alone to indicate the source of the tumor.

**Diagnosis.**—Fibroma of ovary: The smaller specimen is hard, tough, and elastic. It measures  $3\frac{1}{2} \times 2 \times 1\frac{1}{2}$  cm. and weighs 5 grams. A fibrous cord is attached to the surface. Sections from the mass were imbedded in the celloidin and stained in hematoxylin-eosin. The section consists largely of rather dense fibrous tissue, with here and there a small nest of cuboidal cells, the cells in the center of the nest staining very poorly. In one place there are strings of elongated cells, with intervening bundles of loose fibrous tissue, converging toward a central mass of fibrous tissue, a typical corpus luteum. Occasionally a large cyst is seen lined by cubic epithelium and containing in its cavity a homogeneous gelatinoid substance, in which are small masses and columns of cells similar to those lining the cyst.

**Diagnosis.**—Sclerotic and cystic degeneration of ovary.

The case is of interest from the standpoint of the association of ascites with solid ovarian growths. The etiology of the ascitic fluid in these cases remains obscure. It is singular that in fibroma of the uterus such a complication is rare, while in fibroma of the ovary it is common. This would lead one to suppose that neither the mobility of the tumor, nor its size, have any causative relation to

Fibroma of the ovary with ascites.

its occurrence, for, as is well known, both conditions are common in ovarian as well as uterine growths, and mechanic irritation can safely be ruled out as an etiologic factor.

It seems more likely that the ascites is due to something intrinsic in ovarian growths, perhaps a secretion. The almost constant presence of free fluid in malignant ovarian growths would appear to support this theory. On the other hand, the absence of free fluid in almost all cystic growths of the ovary would require explanation.

Dr. Reuben Peterson<sup>1</sup> found ascites reported in 40% of the cases; in 8 of the 84 cases studied by him, the fluid reached such large proportions that tapping was resorted to. One of his own patients had been tapped 65 times. Dr. William Osler<sup>2</sup> reports two cases in which the ascites was caused by solid ovarian tumors, both of which had been tapped, one many times, the other four times. Both patients recovered after operation. Dr. Hunner has collected the cases bearing upon this point from the gynecologic clinic of the Johns Hopkins Hospital. Among 9,400 cases there have been 10 patients with solid ovarian tumors, the ages ranging from 32 to 63. In six of these cases ascites was present on admission. Three of the patients had required repeated tapping. All of the patients recovered after operation.

## ANALYSES OF THE FLUIDS FROM TWO CASES OF HYDROPS CYSTITIS FELLEÆ.

BY

TORALD SOLLMANN, M.D.,

of Cleveland, Ohio.

From the Pharmacological Laboratory of Western Reserve University, Cleveland, Ohio.

**Introductory.**—When the cystic duct becomes occluded, usually by a gallstone, the bile contained in the gallbladder undergoes very conspicuous changes. The bile acids and pigments disappear and the fluid becomes colorless, but remains viscid. These changes are commonly attributed to the absorption of the specific bile constituents, the bile being gradually replaced by the secretion of the mucous cells of the lining membrane. It sometimes contains an admixture of serous exudate, which is shown by the occasional presence of coagulable proteid. When stones are present these are usually also bleached.<sup>1</sup> The amount of pigment to be absorbed is generally so small and the absorption is so slow that there is no icterus. However, Gregor<sup>2</sup> reports an unusual case, in which the presence of a stone in the cystic duct caused jaundice. Neither the common nor the hepatic duct contained any obstruction. The fluid in the gallbladder was colored, and Gregor suggests that the stone formed a ball valve, allowing the constant inflow of bile into the gallbladder, but no outflow, resulting in the continued absorption of bile.

The only paper dealing at all exhaustively with the chemical examination of this liquid is by Winternitz.<sup>3</sup> He refers also to examinations by Frerichs, 1861; Koehl, 1886, and Terrillon, 1890. Their results, as quoted by Winternitz, will be considered in connection with my analyses. They appear to refer to cases of occlusion from gallstone. This is also true of my second case. My first case, however, is one of congenital atresia of the cystic duct.

The fluids which I examined, as also the clinical history and autopsy records of the cases, were furnished to me by Prof. Wm. T. Howard. I take this opportunity of acknowledging my obligations to him. I am indebted to Dr. R. A. Hatcher for the analyses of the second case.

### AUTOPSY RECORDS.

**CASE I.**—*Congenital Atresia of Cystic Duct* (autopsy 290): J. M., aged 56, died at 1 a. m., December 4, 1901, from carcinoma of the stomach with metastases and acute general peritonitis. Gallbladder was distended 8 by 3.5 cm. and contained about 50 cc. of the fluid. There were no stones. Common and hepatic ducts were patulous. Cystic duct was entirely occluded for .5 cm. about midway between the gallbladder and common duct.

**CASE II.**—*Occlusion of Cystic Duct by Stones* (pathology 311): Mrs. M. was operated upon by Dr. G. W. Crile November 7, 1902. Gallbladder was 8 by 6 by 4.5 cm.; walls were thin and it contained about 60 cc. of fluid and 115 stones, varying in size from a barley-grain to a hazelnut. Cystic duct was 6.5 cm. long. At the opening into the common duct there was a stone 2 by 1.5 cm.

### RESULTS OF THE CHEMICAL EXAMINATIONS.

**Quantity:** Case I was about 50 cc.; Case II, 60 cc. (W.,\* 145 cc.)

**Physical Characters:** The fluids were entirely colorless, opalescent, adhesive, and viscid (W. and most other observers). Fluid (I) contained a fair amount of white sediment, consisting of cellular debris, leukocytes, and few epithelial cells (as with W. there was no cholesterol). Fluid (II) separated on standing into an almost clear, yellowish fluid and a flocculent white precipitate.

**Reaction:** (I) was faintly acid; (II) fairly alkaline, to litmus (W. neutral).

**Depression of Freezing Point:** (I) 0.561°, (II) 0.536°. The freezing point was taken in lieu of determining the specific gravity, total solids and ash. It shows that the molecular concentration is about that of other body liquids. (W. found: Sp. g., 1.0067; total solids, 0.976%; ash, 0.883%; nitrogen, 0.014% cc.)

**Proteids:** Case I: Boiling of the acidulated fluid produces no precipitate; biuret test gives a very faint rose; xanthoproteic, a faint yellow color. Case II: Boiling gives a small precipitate. The faint color reactions of I, in the absence of

\* W. refers to the results of Winternitz.<sup>3</sup>

coagulable proteid, is attributable to the mucin. W., in his case, lays it to nuclealbumin. The cases of Frerichs, Koehl, and Terrillon contained coagulable proteid, as my second case.

*Reducing Sugar:* Negative in both cases (also W.).

*Amylolytic Ferment:* Absent in I (digested at 40° C. for four hours with boiled starch). The ferment appears to have been absent in every case in which it was sought. Since human bile very often, although not invariably, contains this ferment (Neumeister,<sup>4</sup> p. 200), it would appear that it is destroyed or absorbed in these cases.

*Bile Pigments:* These are excluded in both cases by the absence of color.

*Bile acids* are absent in both cases (as also in those of W. and Frerichs). Neither Plattner's crystals, nor Pettenkofer's test, nor Hay's test could be obtained.

*Glycoproteid:* The glycoproteid of human bile has been definitely proved to consist of true mucin, while the bile of cattle contains, instead, a nuclealbumin (Neumeister, p. 198). Winternitz claims, however, that the fluid in his case contained no mucin, but nuclealbumin. This interesting statement caused me to investigate the character of this constituent with great care. Both of my fluids gave identical results.

The following tests which are common to mucin and nuclealbumin gave positive results, and agree with Winternitz: Water gives a turbid solution; 1% Na<sub>2</sub>CO<sub>3</sub> gives a perfectly clear solution; dilute mineral acids give precipitates which redissolve in an excess of the reagents; alcohol produces a precipitate.

*Tests Characteristic for Mucin:* (a) Acetic acid produces a turbidity, but not a precipitate (agrees with W.). An excess of the acid does not clear this, nor can the turbidity be removed by filtration (with W. the filtrate was clear). Neumeister states (p. 198) that mucin is insoluble in an excess of acetic acid, whereas nuclealbumin is soluble. The solution may, however, be prevented by the presence of bile salts. Since these were absent in our specimens, the test favors the view that we are dealing with mucin. (b) The positive proof of the presence of mucin was furnished by the formation of a reducing substance on boiling with a dilute acid. This succeeded very well with both of my fluids, while it was negative in the case of Winternitz.

*Tests for Nuclealbumin:* I applied the test given by Neumeister (p. 200). Some of the fluid was put with an equal volume of 0.4% HCl; a few drops of 5% HCl were added to clear the fluid. This was divided into two portions. An active pepsin solution was added to one of these, and both were placed in a bath at 40° C. for four hours. No separation of nuclein occurred in either specimen.

*Examination of the Stones of Case II:* The stones are lobulated. The surface is smooth, of a grayish or slightly greenish color, soft, and of a soapy feel. The section is grumous and brownish red. The chemic examination shows these to consist of 93% of cholesterin, with 1.5% of ash, traces of bile pigments, and no bile salts.

#### CONCLUSIONS.

The contents of the human gallbladder in cases of obstruction of the cystic duct, whether this is congenital or through a gallstone, consists in a dilute solution of true mucin, of the molecular concentrations of the serum, devoid of bile acids or pigments, of ferments and of sugar. Traces of coagulable proteid may be present. No nuclealbumin was found. The gallstones producing the obstruction consisted essentially of cholesterin.

**Medical Theory in India.**—While in Pittsburg last week Dr. Bertha Caldwell, of India, told some good anecdotes on the doctors of that country. One day she was riding in the cars with a Mohammedan doctor. She asked him what kind he was—an allopathist, a homeopathist, or an osteopath. He answered: "I don't know." Dr. Caldwell asked him how he practised and what kind of medicine he gave. Opening up a box he carried he exhibited seven bottles containing liquids of all the colors of the rainbow. "You see," said the Mohammedan doctor, "fever makes the patient red, and then I give him red medicine. A cold makes him blue, and then I give him blue medicine. If he is bilious he is yellow, and then I give him yellow medicine." And thus he went on to the end. She remarked: "You must be a homeopathist." "Imagine my amusement," said Dr. Caldwell, "when, on walking down the street the next day, I saw this sign in front of the doctor's door:

"Gee-ul-whiz, Servant of God.

"Homeopathist."

## EMPHYSEMA DUE TO INJURY OF THE UPPER AIR TRACTS BY VOMITING AND PROTRACTED HYSTERIC ERUCTATIONS FOLLOWING ETHER ANESTHESIA FOR APPENDICECTOMY.

BY

FRANK BLATCHFORD, M.D.,

of Chicago, Ill.

Unusual complications following apparently trifling operations under anesthesia are of the greatest interest to the surgeon. The following case, which occurred under my own observation in the practice of Dr. Bayard Holmes, while possibly not unique, is rare enough to warrant its publication:

H. O., aged 23, is 5 feet 8 inches in height, weighs 160 pounds, and is a medical student of excellent habits, addicted neither to the use of liquor nor tobacco. He is a native of Chicago, was educated in the public schools, and began the study of medicine two years ago. He is a dark blond, with a heavy head of hair and a good growth of beard. He is athletic, of nervous temperament, a good conversationalist, a good dancer, and fond of the society of women. He is careful in matters of dress, but not over fastidious. He has an appearance of youth not wholly consistent with his years. He suffered lightly from the diseases common to children. For the past three years he has suffered from acne vulgaris, and at intervals has had attacks of vomiting and eructations, seemingly of an hysterical nature. Of this latter a history was obtained only after the present operation.

His present illness began in May, 1891, with a terrible attack of abdominal pain, coming on after a dance and a ride of 30 miles in the country. The pain was so intense that a physician was called, who made a diagnosis of appendicitis and sent him at once to his home in the city. He was confined to his bed for a period of two weeks, to the house for two weeks longer, and during the time of his convalescence and for some days after, walked with the aid of a cane, and with his body bent somewhat to the right side. A second attack occurred in June, 1902. It was much less severe than the former attack, and confined him to the house only two days. His third attack was of a similar nature, and came on in the latter part of the following September. His apparent recovery was again a matter of only a few days.

On October 4 I examined the patient with Dr. Holmes at the office of the latter. The patient stated that he thought he was fully recovered from his last attack, and that he had been eating heartily for the past few days. The abdomen was found to be tender only in the region of the appendix. The inguinal glands were not enlarged on either side, there was no jaundice, no rise of temperature, nor acceleration of the pulse. The history and the tenderness over the appendix seemed to warrant the diagnosis of recurrent appendicitis. On the day following the examination the patient entered the Mercy Hospital. Here an examination of a 24 hour specimen of his urine showed nothing abnormal either as to amount or constituents.

The operation was performed on October 6, at 3 p.m. Following the usual preliminary procedure, ether anesthesia was secured, the anesthetic being given by one of the hospital Sisters. An incision 1½ inches in length was made by Dr. Holmes over McBurney's point, the muscles were separated and the peritoneal cavity opened. The cecum was sought for and found without exposing any of the intestine. To find and draw out the appendix required one minute. A ligature was passed around the mesoecum, which was then separated from the appendix. It was not necessary to ligate any other vessels. The base of the appendix was clamped, a cuff of peritoneum was made, and the appendix amputated. After touching the cut surface with 95% carbolic acid, the stump was inverted, a purse-string suture was passed through the peritoneal cuff, and a second one, including the first, was passed, with a view to insuring greater security. The peritoneum was then sutured with catgut, and this followed by separate stitches through the fascia and muscles. The skin was approximated with silk-wormgut. The whole operation consumed 15 minutes. There was no sign of present infection in or around the appendix, although it showed distinct evidence of previous inflammation by a thickening of the muscularis and by a band of constriction 2 cm. from the distal end. The patient was taken from the operating-room in good condition, with a pulse of 80 and a temperature of 98°. Upon recovery from the anesthetic he had some vomiting spells, which were of the usual character. Later he grew very restless, suffered further attacks of vomiting, and eructated considerable gas.

On the morning following the operation he vomited frequently and eructated almost without intermission as many as 12 times in a minute. These eructations were exactly similar to those that are observed occasionally in hysterical and dyspeptic women except that they were more violent. The patient frequently complained of a choking sensation and he sat up in bed and threw himself around in so violent a manner as to alarm his nurse greatly. Several times in the afternoon he expectorated and vomited large quantities of bright red blood.

Once there was vomited as much as one and a half to two ounces which was collected by the nurse and kept for the purpose of demonstrating its character. The constant eructation and occasional vomiting persisted all night except for a few short intervals of sleep. Toward evening of this same day, however, a most interesting complication arose. The neck began to enlarge; the swelling was soft and there was no sign of any inflammation, the pulse ranging from 72 to 96, and the temperature from 98.6° to 100.4°. But even with these findings no suspicion of the true nature of the condition was aroused. On the second day the neck was greatly enlarged, and its character was recognized by the crepitation produced by pressure over the clavicle and left breast. It was a distinct emphysema. During this day the attending nurse noticed several periods of great cyanosis when the patient was sleeping or lying perfectly quiet. The pulse record showed a variation of from 80 to 100, and the temperature from 98.2° to 100.8°. The eructations continued in just as severe a form as on the day previous and almost without intermission, except for occasional periods, when they would be displaced by a severe form of hiccough, vomiting, or by short periods of conversation. Gastric lavage was administered by the house surgeon, Dr. Pirsons, but without apparent benefit. The patient continued to be in a very excitable condition, being extremely restless and unable to sleep except for a few minutes at a time. On the third day the emphysema had extended over the whole left chest and over the anterior surface of the right chest, including both cheeks as high as to the zygomas. On account of the extreme hysteric condition of the patient and on account of the threatening consequences which had followed his eructations, Dr. Holmes told him that if he did not stop eructating it would become necessary to cut around his trachea to prevent the spread of the emphysema. He also had him dressed as if for the street and walked him up and down the wards, hoping by this means to divert him from himself and thus quiet him. He was kept up for three-quarters of an hour, and after he was put to bed his abdominal wound showed no ill effects from the exercise. An assistant male nurse was put in charge of him, who attempted to restrain the eructations and hiccough by requiring him to breathe regularly and deeply with his mouth wide open. He was kept in a sitting posture and in this position he would occasionally sleep in a semihypnotic state. By this means he got considerable rest during the night. The next morning the change in his mental condition was marvelous; his hysteria had diminished to a marked extent. He no longer vomited nor eructated. He slept for half hours at a time. He was still troubled with cough, but not to so marked a degree as formerly, and from this time on it steadily diminished. The pulse on this day ranged from 70 to 90, and the temperature from 99.2° to 100°.

During the succeeding days the temperature gradually came down to normal, he slept better, the cough diminished, and the emphysema slowly subsided. His appetite improved and by the eighth day he was sitting up. He was dressed on the fourteenth day, and two days later was discharged from the hospital.

The only explanation that can be offered for this emphysema would be an injury to the larynx or upper part of the trachea, permitting the air from the normal air-passages to escape into the lymph channels, as it does in cases of fracture of the trachea, fracture of the petrosa and ethmoid and frontal bones, and opening the sinuses of the nose; also in cases of fracture of the ribs, perforating the lung. This injury might have been sustained during the operation, or it might have been produced by the violent and protracted eructations following his first attack of vomiting. The eructations appear to me to have been sufficient to produce a rupture of the trachea or the laryngeal tissues. The extent of the traumatism was shown by the repeated expectoration of large quantities of blood.

## BRIEFS ON PHYSICAL TRAINING.

BY

G. FRANK LYDSTON, M.D.,

of Chicago, Ill.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's Hospital.

No. 5.

### The Rational Aim of Physical Training Methods.

As already indicated, it is not my intention to discuss in detail, much less advocate, extremes in athletics. When I say extremes I allude to competitive athletics of various kinds—competitive in the sense of striving for records, medals or money prizes. It is obviously impossible to avoid discussing this subject incidentally and in

the way of warning against excess. When the individual desires to go into competitive athletics physiologic muscle training should be his foundation.

As I understand the subject, physical training should have four definite objects in view: (1) The acquirement of muscle command; (2) symmetric, physiologic muscular development; (3) and, this is a necessary concomitant of the foregoing, improvement in the general health, with all it implies in the way of normally increased metabolism, circulation, appetite, digestion, assimilation, and elimination; (4) specialization of muscular development in certain individuals, this specialization being necessary to attain symmetric proportionate development of various muscle groups, with due consideration of the individual equation.

The accomplishment of the first object of necessity brings with it the accomplishment of the second. The acquirement of muscle command soon enables the individual to bring about specialized muscular development where asymmetry exists. It is obvious that the fourth object is gradually attained without special effort as the other aims are being accomplished.

The first lesson that the subject should learn is the necessity of putting his brain cells in absolute volitional control of each of the various groups of muscles. His muscles should be educated to what may be termed a high degree of intelligence in order that the best results with the least strain may be accomplished. As an illustration of the principle involved I will mention the voluntary control which some individuals have over the muscles of the ear and the platysma myoides. These muscles, in the highest degree voluntary in quadrupeds, are but evolutionary vestiges and from disuse are, in the majority of individuals, practically involuntary, although their structure is of the voluntary type. In certain individuals these muscles may be readily moved voluntarily and the degree of control may be greatly increased by practice. It has been my observation that such individuals have an extraordinary degree of inherent voluntary control over the muscular system in general. It is noteworthy that even athletes who have not strived for brain-cell supremacy over muscle fiber during the early days of their training are usually devoid of control over the muscles mentioned.

The facility with which different individuals can bring the various groups of muscles under control varies widely. If what I believe to be the proper system of training is begun at a comparatively early period, it is, in my opinion, possible for almost any individual of even inferior physique to acquire the degree of muscular control absolutely essential to proper development. The length of time necessary for its acquirement varies with the degree of intelligence and persistence exhibited by the particular subject.

It is a noteworthy fact that the voluntary effort demanded for a physiologic system of muscle training has a marked developmental influence upon the brain itself. It is not possible properly to educate the muscles save through the medium of the motor centers of the brain. It is also not possible to educate the muscular system without developing the motor brain centers. This fundamental physiologic truth is too often forgotten.

The acquirement of volitional control over the muscular system demands (1) extreme concentration of the will, and the direction of the "thought current" to the muscle or muscles under immediate consideration; (2) the mutual antagonism of opposed groups of muscles.

One of the very desirable features of the system of exercises which I will suggest for the accomplishment of the foregoing objects is that it is absolutely devoid of danger.

An examination of each subject should be made to determine so far as possible the individual inherent muscular capacity and developmental necessities. A visceral examination is advisable, in case the individual should foolishly contemplate entering upon an athletic

career, and to determine the therapeutic necessities of the viscera in any given case, rather than to forestall possible dangers from the exercises themselves. When active exercises involving skill and endurance accompany or follow the system of muscle building a physical examination is a *sine qua non*.

The actual and relative development of the osseous system in any given subject is a point for very serious consideration. It must be remembered that the end and aim of physical training is, as already outlined, not the acquirement of phenomenal muscular bulk or strength, but symmetric muscular development and the acquirement of the maximum of strength and agility inherent to the subject. Mistakes in our estimation will inevitably occur, but it is better to fall far short of the ideal than to court the dangers of overstrain.

Attention is again called to the dangers of arbitrary estimates of the proportionate chest measurements in deciding the question of specialization in physical training. I would also again recur to the necessity of carefully estimating the probable capacity for muscular development of each subject. The relatively short-tendoned, bulky-muscled individual cannot be submitted to exercises tending to general muscle building without injury. He should have only such exercises as tend to promote agility and favor the acquirement of volitional control over his muscles, else he will become joint and muscle bound. The reverse is true of the long-tendoned, relatively long-muscled individual, in whom careful systematic muscle building is required.

In taking advantage of the normal muscular antagonism, the best example of which is the opposition of flexor to extensor, and *vice versa*, it is obviously impossible to inflict injury upon the muscular fiber. Powerful action of opposing groups of muscles is only possible after careful systematic training and acquirement of control of the brain cell over muscle fiber. By the time this has been acquired, although the muscles are immensely stronger than at first, and consequently are capable of exerting more power, their resistancy has become so increased that overstrain is a practical impossibility. In other words, the strain put upon any given muscle or group of muscles is never greater than the inherent capacity of resistance possessed by the opposing muscular group.

One of the paramount obstacles to the general adoption of physical culture has been the fatuous notion that a gymnasium or complicated home apparatus is necessary to training. The necessity of a simple system which can be practised without apparatus or by the aid of very few appliances is at once obvious. The question of time is a very important one and a successful system should give the maximum of developmental results with the minimum expenditure of time. Given a system which accomplishes the foregoing indications, and which at the same time is absolutely devoid of danger or overstrain, and the ideal method of physiologic muscle building is accomplished.

At the beginning of his training the average individual is likely to make the discovery that his muscle consciousness is very defective. He knows by experience in lifting or clutching at objects, perhaps, that he has muscles in his forearm. A consciousness of the presence of the flexors and extensors, pronators and supinators, he has never in his life experienced. It is well to begin educating the muscle centers of his brain and the muscle centers of the various groups of muscles by acquiring volitional control over the muscles of the forearm. This can be done by educating the muscle consciousness through movements of the fingers. The hand being placed and held in a position of extreme extension the movements of the fingers immediately discover the extensors of the forearm. The hand being held in the same position and the forearm rotated the supinator muscles are readily found. Movements of the fingers with the hand in extreme flexion demonstrate to the

subject the possession of the flexor group in the forearm. Rotation of the forearm with the hand in extreme flexion brings the pronators into play. It will, of course, be understood that in each instance the opposing groups of muscles are thrown into action to a sufficient extent to bring out of the muscles immediately under training the best that is in them. A certain amount of fatigue is experienced just as soon as the subject has acquired a certain degree of volitional control. Prior to that time little or no effect results. It is astonishing how rapidly the subject grasps the principles of this system of muscle building when once his muscle consciousness has been aroused in any given group of muscles. The acquirement of volitional control over the muscles of the forearm may thus be the foundation for the rapid education of the various groups of muscles. A number of weeks may perhaps be demanded in the acquirement of an intelligent idea of what is demanded, the time varying with different individuals, a single lesson being sufficient for some. Once the idea has been grasped, however, the progress of the subject is usually very rapid.

Once the control power over the various groups of muscles has been attained it requires but a short time to bring into subjection all of the muscles of the body. The pupil very soon learns so much of muscular physiology as enables him to determine the various opposing groups of muscles and to bring them into action. The same systematic play of the muscles should be brought about in each of the extremities in the abdomen, chest, back, and neck. Very little experience will enable the subject to exercise thoroughly all the important muscles of the body within a few minutes, from five to ten minutes night and morning being amply sufficient.

One of the advantages of the system of muscle movements outlined is that it not only does not require any apparatus whatever, but so soon as the subject has acquired a fair degree of muscle control it can be quietly practised at any time or place. I have repeatedly gone through the entire system of muscle training while standing on the front platform of a street-car, or taking an evening walk, without in the least attracting attention.

In instructing the subject in the *rationale* and method of this system of physical culture, he should be forcibly impressed with the necessity of concentrating his mind upon each particular group of muscles in succession.

There is another method that I frequently employ as an adjuvant to the foregoing which is very valuable. If the subject will concentrate his mind upon any given group of muscles, while at the same time setting the muscles rigidly, and expire vigorously and protractedly, he will find that the tension of the contracted muscles is thereby greatly increased.

This can be practised primarily with the muscles of the forearm until the idea is grasped. It can then be applied to any particular group of muscles, or to all the muscles simultaneously. Once the knack of the procedure has been acquired, this system of respiratory gymnastics is one of the simplest and most effective forms of physical culture with which I am acquainted. The subject should stand in the erect posture, maintaining as nearly as possible the normal center of gravity, with the abdomen well retracted; the arms should be extended, and the hands vigorously clenched. Every muscle should be rigidly set. The subject should now take deep inspirations, followed by vigorous, forcible, and prolonged expirations, his mind being concentrated on his muscles. A good way to accomplish the latter indication is to suggest to the subject that it is necessary for him to forcibly "blow his breath into his muscles" while contracting them with increasing vigor. This, of course, is a physiologic absurdity, but it enables the individual to concentrate his mind upon his muscles, and develops the muscle tension to an astonishing degree. The degree and rapidity of muscular development acquired in this manner is certainly surprising.

More surprising still is the slight expenditure of time and labor necessary to maintain the muscles in a physiologic condition when once it has been acquired. Ten violent expirations in the manner described, night and morning, are amply sufficient. It is, of course, better for the subject to indulge further in such muscle training at odd times, especially if he happens to be in the open air. If any particular group of muscles demands disproportionate exercise, because of asymmetry, it is a very simple matter to accomplish it by specializing voluntary movements and expiratory hypertension in the direction of the particular group of muscles demanding it.

A simple and effective method of muscular training is a combination of the foregoing with the use of a rubber cord of good size. This cord should be three feet in length and sufficiently strong to afford a pull of about five to ten pounds when put in extension. With a cord of this description, or, in lieu of it, even an ordinary towel or piece of rope, it is possible to exercise every muscle in the body, providing the individual has acquired a sufficient degree of muscle command. The individual who has acquired muscle control and a knowledge of the action of the various muscles will speedily learn the best movements and combinations of movements to accomplish muscular development by means of this simple device.

To add to the practicality of the suggestion, however, I will describe the principal movements involved in the thorough exercise of practically all the voluntary muscles. The first point to be borne in mind is the necessity of maintaining the normal center of gravity, with the abdomen well retracted, and all the muscles of the body set with moderate firmness. With the body in the position described, every movement of the arms tends to bring into action all the muscles. The play of the abdominal muscles is especially marked.

It is difficult for me to express without seeming exaggeration my view of the vital importance of training the abdominal muscles. Briefly, I believe that the muscles of the abdomen constitute the keystone of the athlete's body. Given a good, firm, well developed, abdominal muscle, and I believe it is hardly necessary to examine the rest of the muscular system, in order to estimate their condition. Any system of exercises which gives good abdominal development necessarily imparts, in my judgment, an excellent general development. A good condition of the abdominal muscles augurs well for the general condition. When the abdominal muscles are lax, the converse is true. Careful comparative measurements show that in a large proportion of cases abdominal protuberance in individuals out of condition is apparent, not real. The sagging down of the abdominal viscera and contained fat as a consequence of muscular degeneration and flabbiness of the abdominal walls, rather than an actual increase of fat or girth, is the usual explanation. I hold, therefore, that to attain the best results in exercises of a general character, for the purpose of muscle building, there should be a certain amount of specialization in the direction of exercise of the muscles of the abdominal walls. There is no danger of over-specialization, in the majority of instances, for, as has already been suggested, any exercises which are brought to bear with the body in proper position, and with the resulting tension of the abdominal muscles, is beneficial to the muscular system at large. So far as the specialization of the work in the direction of the abdominal walls is concerned, it is a very simple matter. All that is necessary is to retract the abdomen, thus putting the abdominal muscles on tension, and to practise subsequently any system of exercises that may be prescribed. A simple method of abdominal development is to walk a stated distance daily with the abdominal muscles in firm contraction. The building up of the abdominal muscular tone, and the reduction of abdominal fat is usually very rapid. Any individual who is not too lazy or too indif-

ferent to do so may accomplish a reduction of abdominal girth, and, more particularly, abdominal protuberance, simply by concentrating the attention on the abdominal muscles, and keeping them in contraction while walking about.

Another simple method of exercising the abdominal muscles, and one which gives speedy and excellent results, is the following:

The subject is instructed to sleep upon a hard mattress, without a pillow, lying upon the back. The arms are extended above the head, with the hands grasping the framework of the bed, although the latter is not absolutely essential. The best results are obtained by sleeping upon blankets spread upon the floor, when the subject is willing to tolerate the attendant discomfort. With the body in the position described, the abdominal muscles are placed in a state of tension, and each respiratory movement brings them fully but moderately into play without the exercise of the subject's volition. There is no possibility of undue strain, and the effect of this continuous moderate exercise of the abdominal muscles during the entire period of sleep is most salutary. The same position during sleep is an admirable method of securing chest development and straightening up round shoulders. I am aware that some physicians are opposed to the position described during sleep, claiming that it is injurious to health. I have never been able, however, to appreciate any rational objection to it, nor do I know of any evidence upon which such objection could be justly based.

The principal advantage of a rubber cord in practicing the exercises about to be described is that it gives a certain amount of elastic resistance to the muscles which is very stimulating to them when in action. Taken in conjunction with the resistance of the opposing groups of muscles, it constitutes practically "live resistance"—a very important factor in muscular training. The first essential in the use of this apparatus is to assume a correct position. The person should stand with his feet in the position ordinarily assumed in walking, so that the body is firmly placed, the heels being about four inches apart. This position enables him to use his muscles to the best possible advantage, this being especially true of the muscles of the lower extremities. The body should be held firmly erect, with the abdomen well retracted. The poise of the head is a very essential point, as upon it depends largely the tension of the muscular system in general. Excepting when the neck muscles themselves are to be exercised, the head and neck should be carried perfectly straight. In this position the trapezius and deltoid muscles can be best brought into play—a very important matter in connection with neck and shoulder development. A slight variation of the position of the neck forward, backward or laterally enables the subject to bring the various groups of neck muscles into action.

The correct position of the body having been assumed, the most effective movements are as follow:

1. The rubber cord is grasped in the hands, the length of cord between the hands varying with the length of the arms and the strength of the subject. Shortening the cord increases its resistance, and *vice versa*. Lengthening the cord increases the facility of movement of the scapulo-humeral articulations. The arms are now raised above the head in full extension, and the cord stretched in the hands by a pull of from 5 to 10 pounds, according to the age and strength of the subject and the progress that has been made in muscle training. The keynote of the system of training is the pull upon the cord. So long as this pull is continued, it is almost impossible for the individual to indulge in any limb or body movements whatever without bringing all of the muscles into play to a greater or less extent.
2. The pulling upon the cord being continued, it is brought down to the back of the neck. Care should be taken to keep the head in the same erect posture as in beginning the work. The arms are again extended above the head to their full capacity, and the movement slowly repeated a number of times proportionate to the experience and strength of the subject. Five or six times is usually amply sufficient, even after considerable progress has been made. With each movement full inspiration and expiration is made, the breath being held

at the end of inspiration, at a time corresponding with the greatest muscular effort, *i. e.*, in bringing the cord down to the back of the neck. This movement is especially valuable in developing the back muscles.

3. The arms being fully extended above the head, as before, the cord is brought down to the pectoral region, the number of times corresponding to the previous movements. It is well to systematize the various movements, so that the number of repetitions shall be the same throughout.

4. The cord being brought down to the back of the neck, the arms are fully extended horizontally, one after the other, the extension of one arm being resisted to a certain degree by forced flexure of the other. The amount of force necessary in extension is obviously regulated entirely by the amount of resistance afforded by the opposite extremity. This is entirely within the subject's control. This movement brings into play not only the muscles of the shoulder, back and upper arm, but also those of the forearm.

5. The arms being held horizontally at full extension straight in front of the body, the body is rotated, first, upon the hips, and, second, upon the thighs, as far in each direction as possible. The effect of this movement is much more general than might be supposed, for with the body in the proper position, *i. e.*, with the center of gravity properly maintained, practically every muscle in the body is brought into play.

6. The forearms are flexed upon the arms, the elbows brought well into the sides, the cord being stretched across the front of the chest at a level with the pectoral region. The arms are now alternately extended and flexed.

7. The arms being extended straight in front of the body, and the muscles firmly set, the cord is stretched by each hand in alternation. This movement brings the muscles of the arms and forearms into action in a manner to which they are unaccustomed, and is similar in this respect to some of the Swedish movements.

8. The forearms are flexed upon the arms, with the elbows to the sides, and the clenched hands in firm flexion. Maintaining the hands in this position, the arms are repeatedly extended in front of the body.

9. The foregoing movement is repeated with the clenched hands in extreme extension.

10. The arms are extended horizontally and the cord stretched and relaxed alternately, by rotating the arms and forearms.

11. The arms are placed in full extension behind the body, the cord extending across the thighs. Swinging movements of the arms forward and back, and from side to side, and pulling on the cord by separation of the arms, combined with rotatory movements of the arms, produces very powerful action of the arm extensors, and especially of the triceps.

12. The arms are held completely extended above the head, and the body flexed and extended from the hips, while the spine is held rigid. The hands are brought as far forward as possible in the forward movement, and as far backward as possible in the reverse movement.

It may be supposed that in the foregoing movements the muscles of the lower extremities are neglected. A few lessons, however, will convince the most skeptical that this is not true. If it is desired to specialize the movements in the direction of the lower extremities, all that is necessary is for the subject to raise and lower himself upon his toes, and rotate the body on the thighs while the arms are held in extension and the cord extended above the head.

One of the advantages of the foregoing system of muscle building is that it conduces to suppleness of joint and muscle fiber. Although the movements are not rapid, the quality of muscular fiber developed thereby is well qualified for rapid action, which depends upon the degree of muscle control and muscle sense, rather than upon muscle strength. The system differs in this respect from all other methods of muscle development which involve relatively slow muscle movements.

**Mortality in Montreal.**—The total number of deaths for Montreal during 1902 was 6,271, as compared with 6,915 of the year previous, a decrease of 644 deaths. This decrease is probably due to the cool summer of 1902, which affected the infant mortality to a great degree, but it may also be partly attributed to the general improvement in the health of the city.

## SPECIAL ARTICLES

### THE MODERN MATERNITY HOSPITAL: ITS CLINICAL MATERIAL, EQUIPMENT AND INFLUENCE UPON SPECIALIZATION IN AMERICAN SURGERY.<sup>1</sup>

BY

BARTON COOKE HIRST, M.D.,

of Philadelphia.

Our maternity hospitals have been designed and conducted heretofore for the sole purpose of housing a woman during her parturition and a short lying-in period. Their management, both lay and medical, has ignored the fact that almost all the diseases of women are the direct consequence of childbirth and could be cured or prevented by appropriate surgical or other treatment during or at the close of the puerperium, and that all of them, with one or two exceptions, are complications of childbirth. What are the results of this practice? As one example, the most dangerous and interesting complications of the child-bearing process, such as neoplasms of the genital tract, cannot receive proper treatment in the very places that should be designed for their reception. Many of these institutions, presided over by professed experts in obstetrics, have discharged numberless women with unrepaired injuries of the genital tract, displacements of the uterus, subinvolution, endometritis, the pelvic inflammations of infection, diastasis of the recti muscles,

Maternity Hospital of the University of Pennsylvania.

splanchnoptosis, and lacerations of coccygeal joints, so that the sins of omission and commission on the part of one set of specialists have developed another set to do the work properly belonging to the first. Many of us have seen a more logical system. We have been compelled to complete our special education in Germany. We have seen there the maternity hospital as the basis of the department of gynecology, in the proper sense of the word, including both the diseases of women and obstetrics, and the professor of obstetrics in all of the great medical schools of Europe in charge of the department for diseases of women.

We began a movement here some years ago, which is becoming general in America, and will have far-reaching consequences. As a result of hard and unremitting work for the past 13 years in raising the money, there has been established a maternity hospital on the University of Pennsylvania Hospital grounds that satisfies the ideals with which the undertaking was begun. There is provision for privacy and isolation of the patients so that thorough instruction of students can be carried out in the individual case without undue exposure; there are 52 beds at present; the equipment in instruments, appliances, and furniture is the best that can be procured, but what constitutes our special claim to distinction, I think, is the addition to the hospital building of the Anna Dike Scott Memorial Operating Amphitheater, built, furnished, and equipped for the performance and exhibition of the pelvic and abdominal surgery frequently demanded in the proper treatment of child-bearing women as well as for the display of all the operations and maneuvers required by the child-bearing act itself.

<sup>1</sup> Read before the Philadelphia Obstetrical Society, March 5, 1903.

No patient leaves the institution with any of the injuries of childbirth, displacements of the uterus, subinvolution, endometritis, injured coccyx, splanchnoptosis, diastasis of the recti muscles, the pelvic inflammations, neoplasms of the genital canal—in short, with any disease or abnormality of the pelvic or abdominal organs which follows or complicates parturition.

Anna Dike Scott Memorial Amphitheater. The sterilizing plant is purposely put in view of the students.

All the obstetric operations proper are conducted with the same attention to the details of aseptic technic that should prevail in any surgical clinic, and are all performed before the class.

That the patient should leave a maternity hospital in as good or in better physical condition than she entered it, is a proposition no one, I think, can successfully dispute. I find all of my associates in the important obstetric chairs of the country in agreement with me. In New York a hospital is in course of erection embodying this idea in the most liberal way.

It is safe to say that a maternity hospital in the future must be erected and equipped for the broader work now demanded of it, if it is to rank in the first class.

Granted that such institutions in the future in America will do all that their patients have the right to expect of them, some interesting consequences are inevitable. Many of the diseases of women will in time disappear, as the students trained in these hospitals put into effect the lessons they have learned, and every community is provided with at least one physician who is capable of recognizing and correcting all the consequences and complications of childbirth before they become chronic and wreck the individual's health.

A maternity hospital managed on modern principles will afford its surgeons much the largest clinical experience to be obtained in many of the diseases of women.

Take, for example, complete tears of the perineum through the sphincter. We had last year 15 such operations, mainly from our large out-patient department and other sources. This winter we have already had 12 at all periods after the original injury, and shall have at least 20 before the season is over. It is the same, in larger proportion, with all the injuries of the genital canal. Such things as displacements of the uterus, injured coccyges, diastasis of the recti muscles, the pelvic inflammations of puerperal origin, neoplasms of the birth canal complicating parturition,<sup>1</sup> we naturally have in larger num-

<sup>1</sup>In one clinic hour this year we showed a hysterectomy for fibromyoma in a case sent to the hospital as one of pregnancy; the removal of a fibromyoma of the round ligament in the groin as large as an infant's head, which grew in pregnancy and was removed two weeks after delivery, and a large fibromyoma of the anterior uterine wall, obstructing labor, requiring a forceps delivery before the class and a myomectomy later in the puerperium.

bers than any other sort of clinic could provide, from our indoor and out-door services, and from physicians who refer patients to us.

The effect of this broader legitimate and necessary work of our modern maternity hospitals upon specialization in American surgery is interesting food for speculation.

There are at present three kinds of specialists in America competing for the surgical treatment of the diseases of women: the general surgeon, the surgeon who limits his work to the treatment of diseases of women, and the surgeon who is trained in obstetrics as well as in the diseases of women. To which of these specialists will the work eventually gravitate? Will it be to the general surgeon who lacks special training in pelvic diagnosis, maneuvers, and technic? Will it be to the surgeon who lacks training in half of the science of gynecology, all practical knowledge of the relations of the diseases of women to childbearing, though every one of them must be considered in that relation in the woman's past, present or future history, and experience with the incipency of most of the diseases of women? Or will it be to the specialist who has had adequate training in both branches of gynecology; who must recognize and treat all of the diseases of women in all their stages; whose work

demand a training in abdominal and pelvic maneuvers, diagnosis and treatment of every kind?

The future will answer these questions for America. They have already been answered in the Teutonic, Scandinavian and Slavonic countries of Europe, as I believe they will be answered here. Some of the Latin countries alone, particularly France, have the same system that we have had, but I doubt if we will continue to imitate them in this respect.

## SOME PROBLEMS OF PREVENTIVE MEDICINE.<sup>1</sup>

BY

BURNSIDE FOSTER, M.D.,

of St. Paul, Minn.

President Minnesota State Sanitary Association; Editor St. Paul Medical Journal.

Preventive medicine is the one branch of medical science with which the medical profession, unaided, is utterly unable to cope successfully; on the other hand preventive medicine, in the light of our present knowledge, with the enthusiastic cooperation of an educated public, acting under the guidance of a thoroughly organized medical profession, offers greater possibilities for good to the whole human family than any other branch of the healing art, or than any other department of human knowledge. It is the purpose of this essay to set forth in plain language the acknowledged facts concerning "that branch of medical science that aims to prevent or ward off disease by properly directed hygiene, personal and public."<sup>2</sup> The subject will be discussed under two chief heads: I. The relation of the general public to preventive medicine. II. The relation of the medical profession to preventive medicine.

### I.—THE RELATION OF THE GENERAL PUBLIC TO PREVENTIVE MEDICINE.

Patriotism and national pride are qualities which, more than any other, are inborn; and if we except that small band of perverted individuals who travel beneath the red flag of

<sup>1</sup>Read before the Minnesota State Sanitary Association at its annual meeting in St. Paul, December 18, 1902.

<sup>2</sup>Gould: Illustrated Dictionary of Medicine.

anarchy, we may say without fear of contradiction that practically every sane citizen of the United States is imbued with a spirit of national pride, and glories in all that contributes toward the greatness of our country. Before the summit of national greatness can be achieved the summit of national health must be surmounted. This lesson the people must learn, and having once learned it, we shall have every intelligent citizen enlisted in the cause of preventive medicine. When we consider the enormous amount of sorrow and anguish which comes into millions of homes each year through sickness and death due to preventable diseases, it would seem an easy matter to enlist under the same banner those who bear the largest portion of the grief—the wives and mothers. Once teach them how they can help, and they may surely be depended upon to do their share.

Education of all the people concerning the rudiments of public and private hygiene must be the first step in our battle against preventable disease. Those who have in charge educational affairs must see to it that in every public school and in every university in the land certain facts concerning preventive medicine are taught. Opinions will doubtless vary as to the amount of such instruction that should be given, but there can be but one opinion concerning the value of some such teaching.

It is my opinion that in schools for children between the ages of 10 and 16 it should be taught that certain diseases are contagious, and what those diseases are; that physicians know how to prevent these diseases from spreading and that absolute obedience to their directions will keep others from contracting the disease. It might further be taught that nature's weapons against contagious diseases are sunlight, fresh air and pure water, and that these weapons are freely furnished in ample quantity to every one. A few simple lessons along these lines with object lessons in personal cleanliness, insisting upon clean hands and faces, and neatness of dress, explaining the reasons therefor would be sufficient for children. Older students in the last year of the high schools and in colleges should be given more detailed instruction. They might be taught something about the microorganisms of disease, the difference between contagious diseases such as smallpox and scarlet fever, and communicable diseases such as tuberculosis and typhoid fever, and the different kinds of precautions necessary to prevent the spread of these different kinds of preventable diseases. The older students should also be taught something about the history of the great epidemics which have occurred in former times, and how rare they are under the modern system of inspection and quarantine; they should be taught the history of the discovery of vaccination, and the history of smallpox before and since its general introduction; something, too, of municipal and national sanitation, and how important it is to public prosperity and to private happiness. I would suggest also that it should be taught that the science of medicine, while not an exact science, is a true science, just as chemistry or astronomy are and that it has no secrets, and that all who claim to possess secret knowledge of medicine, knowledge not possessed by or inaccessible to legitimate practitioners of medicine, are charlatans and quacks and are trying to cheat the public.

If a liberal education included such instruction as I have outlined it would do much to abolish quackery, which is one of the worst enemies of preventive medicine. Let us pause for a moment and see what we might expect of our citizens and our legislators if their education had included a knowledge of these things. Recognizing the possibilities of public hygiene, and realizing its importance, not only to the general prosperity, but to the welfare of each individual, the people would demand that the National government as well as each State and municipal government should conduct the affairs of their health departments under the direction of the leading sanitarians in the country. A Department of Hygiene with a secretary of Public Health in the President's cabinet would be recognized as a necessity and demanded by the people. Every State and every municipal health department, while consisting of an independent and complete organization, should be under the authority of and subordinate to the National Department of Hygiene. There should be a national laboratory at Washington, and every State and every municipal health department

should have its own laboratory, each having the necessary equipment, and each under the direction of skilled bacteriologists. Each community should have its isolation hospital for the care of the more dangerous contagious diseases, such as scarlet fever and diphtheria, and its special smallpox hospital. These hospitals, if provided with all the comforts and conveniences needed for the care of the sick, would be self-supporting, and those who so desired could be cared for by their own physician. Thus an ideal machinery for fighting communicable disease would be set in motion, and at a comparatively insignificant cost. The contagious disease hospital in communities educated up to the importance of having all cases of scarlet fever and diphtheria taken there for treatment would undoubtedly in a very short time cause epidemics of these diseases to cease to occur.

An exceedingly important function of the Department of Hygiene would be the general supervision of matters concerning medical education and the issuing of licenses to practise medicine. A common standard for entrance to and for graduation from all medical schools should be established, and no medical school should be permitted to exist which did not come up to this standard. License to practise medicine should be issued only to those who could demonstrate their fitness to the proper authorities, and once having received his license the physician should be permitted to practise in any part of the country. The educated people would realize that it is as dangerous to allow uneducated persons to practise medicine as to practise law; they would no more permit lives to be entrusted to unlicensed so-called doctors than to unlicensed engineers or pilots, and they would demand that all licenses should be based on a common standard of knowledge. The educated people would appreciate the evils which threatened the community in the persons of antivaccinationists and the antiscientists in general, and would realize that freedom of speech and action must be denied to such individuals on account of their hostility to the cause of preventive medicine, just as such freedom of speech and action must be denied to anarchists on account of their hostility to all government.

The educated people would demand that dishonest, suggestive and indecent advertisements which at present appear boldly in nearly all newspapers should be suppressed on the ground that they are offensive to good morals as well as dangerous to the public health. Physicians might then with perfect propriety and with no loss of dignity advertise their names, addresses, and office hours in the newspapers, which would make up to the latter what they would lose from the quacks, and would also be a convenience to the public. The newspapers, no longer afraid to offend their most liberal patrons, the quacks, would then be free to discuss fearlessly and intelligently medical subjects and they would undoubtedly have qualified medical men connected with their editorial staffs, who would handle these topics in such a manner that the newspapers would become most valuable aids to the cause of preventive medicine.

Another important problem of preventive medicine will be solved by the educated people: the problem of inherited disease. The time will surely come when the people will demand that the insane, the epileptic, the syphilitic, the habitual criminal, and the habitual drunkard, shall be refused the legal right, now freely given them in all communities, to marry and hand down their diseases. This will be a delicate problem to handle, but the question of the regulation of marriage is one which at the present time is being seriously studied by many thoughtful persons, and I confidently expect to see some steps taken toward the elimination of at least some of the more strongly hereditary diseases in the not distant future. There will always be in every large community a comparatively small number of people from whom we may expect that the cause of preventive medicine will receive an immense amount of assistance. People of great wealth who possess at once the desire and the means to contribute something toward diminishing the suffering and increasing the happiness of their fellow beings will begin to realize that it is a greater benefit to mankind to help to prevent sickness and pain than it is to contribute to its cure or its relief. The possibilities of preventive medicine being fully appreciated, the rich will begin to understand that they can help to transform these possibilities into realities by

the generous endowment of special institutions for medical research and for the encouragement and assistance of those individuals who possess the inclination and the ability but who lack the means to spend their lives in the study of the various scientific problems in connection with the prevention of disease which still remain to be solved. It is not possible to estimate the immense advances in our knowledge of the causes and means of preventing preventable disease which will be accomplished by the large numbers of enthusiastic and earnest students who will be given the opportunity to carry on direct scientific investigations through these endowed institutions for medical research.

From the foregoing, which is but an outline of what may be expected from the educated people, it will be seen that both as private citizens and as legislators the relation of the general public to preventive medicine is a most important one, and that the possibilities of this branch of medical science will never be achieved without the intelligent and hearty cooperation of the people. Let the people be made to appreciate thoroughly these possibilities and there need be no fear that their full cooperation will not be forthcoming.

## II.—THE RELATION OF THE MEDICAL PROFESSION TO PREVENTIVE MEDICINE.

It will, I think, be conducive to clearness and order if we take up the more important preventable diseases separately, and discuss the methods by which they may be prevented, methods for the most part quite familiar to all physicians, but which cannot always be carried out without the intelligent cooperation of the people.

The following diseases will be discussed very briefly:

Tuberculosis,	Measles,
Smallpox,	Cholera,
Typhoid fever,	The plague,
Yellow fever,	Cholera infantum,
Malaria,	Leprosy,
Puerperal fever,	Syphilis and the venereal diseases,
Diphtheria,	Parasitic diseases of the skin.
Scarlet fever,	

This list does not by any means include all the preventable diseases, but it includes the most important, and if the close of the twentieth century can foreshadow the extinction of epidemics of diseases in this list, a possibility by no means visionary, the century will go down in history as the grandest of all the ages.

*Tuberculosis.*—This is the most important, since it is the most prevalent and the most fatal of the preventable diseases. Not a contagious disease in the ordinary sense of the word, tuberculosis is communicable only by the direct transference of the tubercle bacilli from one individual to another or by the inhalation or the ingestion of the bacilli which have been either deposited on the ground with the sputum of an infected individual, and having dried have been inhaled with the dust of the air, or have gained entrance to the mouth through the contamination of some article of food or drink. The extinction of tuberculosis is to be brought about by destroying the tubercle bacillus and by so treating tuberculous patients that close contact between them and the well is avoided. Quarantine is not essential, although whenever practicable the treatment of persons suffering from tuberculosis in sanatoriums is strongly recommended. It must be borne in mind that a very large proportion of cases of tuberculosis, recognized in the very early stages of the disease, are curable if properly treated. The ideal treatment is rest, forced feeding, and life out of doors in a proper climate. When expense is no object this treatment may be carried out in home surroundings, but to the majority this will be impracticable, and to the very poor impossible, hence the necessity for large sanatoriums in every community. The sanatorium not only cures, but it restrains the individual from being a menace to others, and it educates him and his friends in the manner in which a tuberculous individual should care for himself and should be cared for, so that the danger of communicating the disease will be reduced to a minimum.

An important preventive measure against tuberculosis, which every large community should adopt, is the maintenance of an accurate census of all cases of the disease and a careful

record of their geographic distribution. This, not for the purpose of quarantine, but in order that the local health department may have knowledge of the prevalence of the disease and may communicate, either directly or through their physicians, to the patients instructions as how to avoid spreading it. Tuberculosis is without doubt frequently acquired by passengers in railway coaches, especially in sleeping-cars, and the railroad companies can do much to aid the cause of preventive medicine by adopting thorough methods of disinfection after each trip.

One other matter concerning the prevention of tuberculosis must be alluded to, although space will not permit of its extended discussion, and that is the relationship of bovine to human tuberculosis. I believe that there is sufficient evidence to prove that occasionally at least, bovine tuberculosis has been transmitted to human beings, and that therefore the inspection of all dairy herds is imperative, as is also the inspection of all cattle slaughtered for the market. There is at present a fairly efficient system of government inspection of meat, but owing to recent doubts which high scientific authority has cast upon the likelihood of the communication of bovine tuberculosis to man local inspection, at least in some localities, has become lax. This is unfortunate, and it seems to me to be the urgent duty of the health officers to see to it that the most rigorous inspection of dairy herds is maintained.

*Smallpox.*—Of all the contagious diseases smallpox is probably the one which the properly applied principles of preventive medicine could most easily stamp out of existence. Compulsory vaccination in infancy and revaccination at the beginning of school life; isolation of patients suffering from the disease and subsequent thorough disinfection of the premises and of all articles which have come in contact with the patient—these simple measures would banish smallpox in a single generation. The opposition of many persons to vaccination is due partly to ignorance of the history of smallpox before and after its introduction and partly to the unfortunate accidents which have occasionally followed improperly performed vaccinations. It is the duty of physicians to educate their patients and the public generally concerning the relations between vaccination and smallpox and it is their further duty to see to it that every vaccination is performed under absolutely aseptic conditions and that the site of the vaccination is properly protected afterward. Badly inflamed arms and infected vaccination wounds never follow a vaccination properly performed with fresh lymph and when the vaccination wound has been kept perfectly clean. While there exists practically absolute unanimity of opinion among medical men as to the immunity to smallpox conferred by vaccination there is at the present time some diversity of opinion on the subject of the best method of vaccination and as to what is the best method of preparing and dispensing vaccine virus. I believe that the subject is of sufficient importance to warrant the appointment by Congress of a special commission of experts to take evidence and to deliberate upon the subject of the proper technic of vaccination and to issue a report upon the subject. If there existed a Minister of Public Health this matter would come directly within his jurisdiction. Failing the appointment of such a commission by Congress the American Medical Association would do well to appoint a special committee from its members to investigate and report upon this subject. Although of late years smallpox has become a much milder disease than it formerly was, whether on account of an inherited immunity due to successive generations of vaccination, or whether due to an attenuation of the virus itself, it is not possible to speak positively; it is still a disease greatly to be feared, and as it is one against which we possess such perfect weapons, it is surely not too much to hope that it will become extinct in the not distant future.

*Typhoid Fever.*—This would seem to be a disease very easy of prevention since we know that the germs of the disease always enter the body with articles either of food or drink. An individual who drank no liquids that had not been boiled and who ate no food that had not been thoroughly cooked would never contract typhoid fever, since we know that the germs are destroyed by boiling and cooking. Practically the problem of the prevention of typhoid fever is more difficult than it appears at first sight. It is perfectly possible for every large city to

furnish a supply of pure water to its inhabitants, although there are numerous conspicuous instances of large cities where this is not done and where as a consequence at certain seasons of the year typhoid fever is very prevalent. Given the pure water supply we have only partially solved the problem, since there is always a large population on the outskirts of every city which does not have access to the city water and must depend on wells or streams or lakes. Then, too, even those whose water supply is above reproach are exposed to the danger of drinking milk which has stood in cans which have been washed with typhoid infected water, or of eating raw vegetables or fruits which have been contaminated before they reached the market of the consumer. Physicians have a very important duty to perform in regard to the prevention of typhoid fever and a duty which is too often neglected. They must see to it that all the feces and all the urine of every typhoid fever patient is disinfected before it is thrown where it may contaminate the soil and the surface water. In this way only can typhoid fever be stamped out. It has been demonstrated that the urine of typhoid fever patients may contain the typhoid bacilli for many months after the apparent recovery of the patient, and it has been further demonstrated that there are drugs which administered internally will destroy the bacilli in the urine; hence the urine of every patient must be examined and the patient must be given the proper remedies until the bacilli of typhoid fever can no longer be found. The local health officer should be notified of every case of typhoid fever, so that he can see that the proper precautions against the spread of the disease are taken.

A most important function of preventive medicine which may properly be discussed at this time relates to the management of soldiers, particularly when in the field. It is well known that in every campaign more soldiers perish from preventable diseases than from the bullets of the enemy. Typhoid fever is the most prevalent and the most fatal disease among soldiers, and it should be the easiest to prevent. The first essential, in order that the medical department of an army may be brought to its highest efficiency and may be able to accomplish the greatest amount of good to the men under its care, is that the status of the medical officers in regard to rank, privileges and emoluments should be such that the best men in sufficient numbers will be attracted to the service. The second essential is that the medical department should be an entirely distinct organization, and should be supreme in its authority in all matters pertaining to the management of its own affairs. These conditions do not exist at present, at least in the United States Army.

The prevention of typhoid fever in armies is entirely possible, and at a comparatively trifling cost; trifling, at least, in comparison with the cost of epidemics of the disease. Let us see what a properly organized medical corps could do toward the prevention of typhoid fever among soldiers in the field. In the first place, all camps would be selected by the medical officers; a great step in advance, for many epidemics of typhoid fever are the result of improperly selected camps. In the next place, having its own transportation equipment, the medical department would furnish and transport with its baggage a sufficient number of portable incinerators to destroy all the feces and urine of every soldier in the army, so that none of it could reach the ground. This has been demonstrated to be perfectly practicable and much less expensive than the present cost of epidemics of typhoid fever, which would be prevented by these precautions. Facilities for boiling all water used for drinking purposes should be provided, although this would cease to be necessary if contamination of the ground and of the surface water was prevented, and if all camps were selected with reference to their water supply. Emergencies would occasionally arise as the result of which the incinerators would not be available for use and when contamination of the ground would be unavoidable, and under such circumstances all drinking water should be boiled. All soldiers should be taught by their medical officers the reasons for and the importance of the above-mentioned precautions against disease just as they are now taught the importance of using their first-aid packages, when wounded, as a precaution against septic infection.

The wellknown agency of insects, especially flies and mosquitos, as carriers of disease germs, has not been alluded

to, and in every camp precautions should be taken to protect the food from flies so far as possible, as well as to protect the men from mosquitos.

It is the poorest kind of economy for a government to attempt to economize at the expense of the health of its soldiers, and the prevention of typhoid fever alone would have saved many millions of dollars more than it would have cost in any of the campaigns of modern times.

*Yellow Fever and Malaria.*—These two diseases are grouped, not because there is any direct relationship between them, but because recent investigations have suggested, if indeed they have not demonstrated, that the same methods are indicated for the prevention of both diseases. According to the views of those who have spent much time in studying this subject, the pathogenic organisms of yellow fever and of malaria need for their complete development an extra corporeal existence, the intermediary host being a certain species of mosquito, and according to this theory these diseases are communicated from man to man by mosquito bites. While falling short of absolute demonstration, there is a mass of evidence which seems almost conclusive that this theory is correct, and that when these diseases have suddenly appeared at a long distance from where they are endemic, they have been carried by infected mosquitos. Accepting this theory the extermination of the pathogenic mosquito should result in stamping out these diseases. The experiences of those having charge of the sanitary affairs of Cuba since that island has come under American control have been most interesting and most convincing on this subject. In the *British Medical Journal* of January 11, 1902, will be found a quotation from a private letter written to Major Ronald Ross by Major W. C. Gorgas, chief sanitary officer of Havana, in which the latter says:

The work here has been much more successful than I had hoped when we started. There seemed to me very little prospect for accomplishing much when we commenced in February of 1901, but as you will see from our reports, our results have been most positive. For the first time since the English occupation, 1762, we have had an October free from yellow fever, and malaria decreased more than one-half. Mr. Le Prince, directly in charge of mosquito work, estimates that mosquitos have been decreased 90% by the work as compared with this time last year. Of course this is a difficult statement to substantiate. It is a matter so much of individual opinion. But I have convinced myself that they have been greatly decreased. My own quarters on the bay front, where they have always been very bad, have had none practically for the last six months, and I know many other localities where similar positive statements can be made. But this is certain, that last October we had 74 deaths from yellow fever, this year no deaths and no cases, and from malarial fever last year 25 deaths, this year 19. This, I am convinced, is entirely due to the mosquito work. The disappearance of yellow fever, however, I think is almost altogether due to the killing of infected mosquitos at the infected point. We do this by burning pyrethrum powder in the infected house and all the neighboring houses. It has been extremely gratifying to see how promptly the focus of infection is stamped out in this way, and it has been likewise surprising to me. I knew that some mosquitos must escape from the most careful mosquito hunt, but we have apparently entirely controlled the disease this year by this method when the conditions were exceedingly favorable for its spread. It must be that there are only a few infected mosquitos in each individual case, and that they remain pretty close to the point of infection. And this probably is rendered greater, if we consider that it takes a mosquito 15 or 20 days after biting before he himself is able to transmit the disease. If 50 mosquitos bite a yellow fever patient, it seems to me quite probable from natural causes that only four or five would survive the 18 or 19 days required to render them dangerous.

If later investigations, which are being vigorously carried on in various parts of the world, confirm the theory that yellow fever and malaria are communicated to man by the mosquito, and in no other way, the extinction of these two diseases will be comparatively easy, at least in all well organized communities.

*Diphtheria, Scarlet Fever, and Measles.*—Although occasionally occurring in adults, these three diseases are essentially diseases of childhood, and they occasion either directly or through their sequels a great many deaths and much suffering each year.

These diseases are typical contagious diseases, and are to be combated by rigid quarantine during the attack, and complete and proper disinfection of the premises occupied by, and of all

articles which have been in contact with, the patient during the illness.

The most effective means of prophylaxis against these diseases will lie in the establishment in all communities of properly equipped isolation hospitals, where both rich and poor may go, and where those who can afford it may be cared for by the physician of their choice. These hospitals must be made attractive and comfortable, and so arranged that the mother may stay there with her child if she so desires. So soon as the people appreciate that not only do their children stand a better chance of recovery in the isolation hospital, where skilled medical attention and gentle nursing is at hand during every hour of the day, but that by removing the source of contagion at once from the home the danger to the other children is reduced to a minimum, the prejudice against these hospitals will rapidly disappear and it will become the rule, rather than the exception, for children suffering from these diseases to be taken there for treatment. It will be seen that such hospitals will be easily self-supporting, and that the income derived from those who can afford to pay will be sufficient to defray the expense of caring for the poor as well. When the majority of all cases of diphtheria, scarlet fever, and measles are cared for in the isolation hospitals, epidemics of these diseases will cease to occur. In the case of diphtheria we possess an antitoxin which is of great value not only in the treatment of the disease itself, but as a means of warding off the disease in those who have been exposed. An immunizing dose of antitoxin will in a large proportion of cases confer immunity upon a child who has been exposed to this disease.

Concerning the method of origin and the extra corporeal existence of the pathogenic microorganisms of diphtheria, scarlet fever, and measles we as yet know but little, although we may assert quite positively that their development will be prevented whenever we substitute cleanliness, sunshine and fresh air for dirt, darkness and bad ventilation.

*Cholera Infantum.*—This is a very dangerous disease, quite prevalent in crowded communities during the summer season, and is readily preventable. It is an acute poisoning caused by the toxins produced by bacteria developing in the milk which is fed to infants. The disease would be prevented by a proper supervision of the milk supply in large cities, a duty which every municipality owes to its citizens, and a proper handling of the milk after it reaches the consumer. I believe that it should be laid down as a general rule that all milk which is obtained from a public dairy supply should be either sterilized or pasteurized before it is fed to infants. Many dairies pasteurize the milk before it is sent out and dispense it in sealed bottles; when this is properly done the milk is perfectly safe. The Walker-Gordon laboratories, in some of our larger cities, have done much to reduce the number of cases of cholera infantum. Any intelligent mother can protect her infant from this disease by a proper care of the milk and by using a proper nursing bottle.

*Puerperal Fever.*—This disease, which formerly made the lying-in period a time approached with fear and trembling, and which caused so many deaths, is an instance of a preventable disease which is now prevented.

Puerperal fever, like sepsis following surgical operations, is nowadays considered a reflection upon the technic of the physician or nurse who attended the patient. This is not strictly just, because occasionally we may have an autoinfection from a source not under the physician's control, as, for instance, a suppurating fallopian tube which ruptures during parturition; but this is rare, and in the vast majority of cases proper conduct on the part of the physician will insure an afebrile convalescence after labor.

*Cholera and the Plague.*—These two diseases, which at various periods in the world's history have been the cause of the most fatal and disastrous epidemics of which we have any record, and which even at the present time exist and cause many deaths in certain parts of the world, are excellent examples of preventable diseases which modern methods of sanitation and quarantine are able to and do prevent. It is not at all likely that we shall ever see any extensive invasion of the United States of America, or of any of those countries where modern scientific methods of quarantine prevail, by either of

these diseases although occasional cases may be introduced from those countries where they are still endemic. In regard to the plague, the interesting fact has been quite conclusively demonstrated that rats are very susceptible to the disease and it is more than likely that rats, which commonly infest the holds of trading ships, carry the disease from an infected port and thus introduce it to a country previously uninfected. The disease is probably conveyed from the rats to man by fleas or other parasites which abound on the skin of the former. Extermination of rats, which has been an unsolved problem in all large cities for centuries, thus becomes a very important matter in connection with prophylactic measures against plague. A modern "Pied Piper of Hamelin" would be as welcome a visitor in a plague threatened community as he was in the town of Hamelin, in Brunswick, by the river Weser, and doubtless he would be much better paid. The discoverer of a ready method of ridding houses, ships and wharves of rats will indeed be a public benefactor from more than one point of view. Simpson in speaking of the basis of preventive measures against the plague, which he says must depend upon the knowledge of the disease, urges the importance of establishing, as a part of the sanitary defenses of a nation, special laboratories for organized research and inquiry into the nature and spread of the disease. When a nation is threatened with invasion by an enemy from abroad it not only relies for protection upon its army and navy as individuals, but it sees to it that this army and navy are well supplied with all the necessary implements and engines of war, and it also sees to it that, in times of peace, these materials as well as these individuals are kept in condition for immediate use when needed. No less vital to a nation's welfare is it to protect its people from the invasion of disease, and for this purpose it must rely upon the medical and scientific men who compose its sanitary protective army; but this army in order to be efficacious must be supplied with the necessary implements, and these, too, must be kept in constant readiness. The most important weapon in the hands of science in its battle against disease is the bacteriologic laboratory, and these laboratories should be supported by the government as zealously as are its other coast defenses.

This applies not to cholera and the plague alone, but to all communicable diseases.

*Leprosy.*—This disease, in former times much more prevalent than at present, is still indigenous in certain parts of the world, and occasionally cases are from time to time imported into the United States; indeed, since the annexation of the Hawaiian Islands and the acquisition of the Philippines we have acquired some of its favorite breeding places. The pathogenic organism of leprosy is well known, as is also the fact that under suitable conditions it is communicable from man to man, but concerning the exact method of its communicability there is still difference of opinion. The remarkable feature of the disease is its very long period of incubation, varying from many months to many years. The disease is undoubtedly communicated to those predisposed to it by prolonged, close personal contact, and probably by using utensils or other articles which have been in contact with infected individuals, and its spread is apparently favored by unclean and careless personal habits. The disease is incurable, although in a certain small proportion of cases it seems to be self-limited, and the patient may recover after a long time, having suffered certain disfiguring mutilations, as the loss of fingers, toes, or even limbs (*lepra mutilans*). The problem of stamping out leprosy, so far as our present knowledge of the disease goes, is only to be solved by the segregation in colonies of all lepers, and by absolutely prohibiting contact with uninfected persons. These leper colonies exist in various parts of the world, and their maintenance will probably in time result in the extinction of this horrible disease. Certain climatic conditions apparently exert an influence upon the communicability of leprosy. This is indicated by the fact that along our southern coast, where the disease has been introduced, it has spread to some extent, but in the northwestern States, where there exist a number of foreign-born lepers who have come from the Scandinavian countries, the disease shows no tendency to communicability. As the result of the recent acquisition of territory where leprosy exists to a considerable extent, the United States of America must now

concern itself actively in the leprosy question, and the matter of establishing a leper colony somewhere on this continent is already being discussed. The matter should be thoroughly investigated by a commission of experts, and the necessary steps taken to prevent leprosy from reaching our shores, and to segregate such cases as are already here and such as may subsequently develop.

*Syphilis and Venereal Disease.*—The problem of dealing with these diseases, which have been pandemic since human history began, has puzzled the sanitarians and statesmen of all ages.

Syphilis, it must be remembered, is the least venereal of all the venereal diseases, it being very frequently acquired by accidental contact either with an infected individual or with some infected object. Ophthalmia of the newborn, which is such a common cause of blindness, is often the result of gonorrhoea in the mother, and the innocent, helpless infant must bear the cross through life. In regard to the prevention of these diseases, science has no definite rules to lay down, the problems being very different from those which concern the other preventable diseases. The subject is far too broad to be more than alluded to in this essay even if I had, which I have not, any solution to offer. Undoubtedly the most powerful weapon against venereal diseases lies in a knowledge of their nature, of their prevalence, and of their danger. The majority of individuals grow up in entire ignorance of the whole subject, an ignorance which is cultivated by most educators, in the belief that the matter is one unfit for discussion before young people. I take a very different view, and believe that a certain amount of instruction, given in the proper manner concerning sexual physiology and venereal diseases, should form a part of general education. This knowledge would, without doubt, be a powerful safeguard to the individual, and hence to society against these diseases, although their extinction is hardly compatible with the frailty of human nature. As was stated at the outset, the problem of freeing society from preventable diseases can only be solved by concerted action on the part of the medical profession and of the people, but especially is it true that for the control of the venereal diseases and of alcoholism, which should also be included in all broad discussions on the subject of preventive medicine, the sanitarian, the educator, the moral philosopher, the philanthropist, and the legislator must all join hands without prejudice and meet on a common ground for a common purpose.

*Parasitic Diseases of the Skin.*—Indispensable to the comfort and convenience of modern civilized man is the barber, and equally indispensable to the comfort and convenience of the modern woman is the hairdresser, but barbers and hairdressers are responsible for a very considerable portion of the cases of parasitic affections of the skin and scalp. Barbers and hairdressers in all communities should be licensed and their places of business should be from time to time inspected by health officers, who should instruct them in the very simple precautions necessary to prevent the spread of contagious scalp and skin diseases, and the carrying out of these instructions should be made obligatory. An excellent plan would be to have certain rules concerning cleanliness, the washing of hands between customers, the care of razors, scissors, hair brushes and shaving brushes, the application of face powder, and the treatment of razor cuts, and so forth, printed in bold type and hung in a conspicuous place in all barber and hairdressing establishments. The patrons of such places would read these directions and would soon realize their importance and see that they were carried out. The proper sanitary regulation of barbers and hairdressers after the manner thus briefly described would undoubtedly result in a great diminution in the number of cases of contagious skin diseases, and these diseases while not dangerous to life are apt to be the cause of very great discomfort as well as mental distress to most persons.

[To be concluded.]

*Antispitting Regulation.*—The Select Council of Philadelphia has passed an ordinance imposing a fine of \$1 for each offence upon any person convicted of expectorating upon the floors of any public buildings or institutions. The mayor has promised to approve the measure, and physicians will see that it is enforced.

**8.—Modification of the Connell Suture.**—R. C. Turck has found work on the dog a more severe test of sutures than work on the living human, as the former is peculiarly predisposed to peritonitis from leakage or infection. Conditions being equal sutures passing through all the coats are better than those including only the outer tunics. With the Connell suture properly applied in which all the knots and ends are on the inside of the bowel the mortality at the Postgraduate Laboratory, directly traceable to the anastomosis *per se*, is nil. Criticisms are due to lack of understanding of the technic. Turck has modified tenaculum forceps which do away with tension sutures and a ligature carrier which simplifies the tying of the last knot. He illustrates each step of the operation by cuts. When the suturing is complete the ligature carrier is inserted from one-half to three-fourths of an inch away from the point where the long suture ends emerge and is brought out exactly in the small opening between these ends, which are then threaded in the carrier and the latter is then withdrawn. The suture ends are pulled entirely out through the place where the carrier entered, tied tightly together, the ends cut short and the bowel gently rolled between the fingers until the knot slips through the sutured edges, and the gut regains its normal contour. [H.M.]

**9.—Improvement of General Anesthesia: Anesthol.**—W. Meyer discusses Schleich's theories as to the relation of the boiling point of a narcotic to the body temperature with reference to absorption into the blood and ease of elimination. The temperature of the lungs being 100.4° F. and the b. p. of chloroform 149, the superamount cannot be eliminated by the lungs. The heart, kidneys and liver are called into action. This explains the after-effects on those organs. The b. p. of sulfuric ether is 93.2° F. It demands an absolutely intact lung for its elimination. By mixing narcotics the b. p. can be changed at will. Weidig has found that ether and chloroform enter into chemic combination according to their molecular weight. This product is called a "molecular solution." Analysis has shown that in the administration of Schleich's mixtures the anesthetic was adapted to the temperature of the body at the beginning of narcosis only; soon after narcosis was continued with one of a higher boiling point. Meyer aimed to find one that would contain neither petroleic ether nor free ether and yet have a boiling point corresponding with the body temperature. Various mixtures of M. Smith's ethyl chlorid were tried and one of these, anesthol, adopted. This has a boiling point of 104° F., and is really a chemic combination, for in evaporation a "solution of components" discharges and does not leave a final residual chloroform as in Schleich's mixtures. Any one can prepare it as it is not patented. It should be administered by the drop method. Too large doses affect the respiratory not the circulatory center. In consequence of the equilibrium

between addition and loss the reflexes are not always completely lost unless administration is preceded by a hypodermic of morphin. This has worked well. Salivation and mucous rales never occur. There is no cyanosis. Awakening is quick, subsequent vomiting and malaise are rare, bronchitis and pneumonia unknown. Affections of heart, lungs and kidneys are not contraindications to its use. [H.M.]

**10.—Fever of Doubtful Nature in Infancy.**—According to J. L. Duenas, in Cuba fevers occur with extraordinary frequency during infancy and childhood. Up to 20 years ago the tendency was to diagnose as malaria those cases in which a cause could not easily be found. Often the fever is caused by the same infectious diseases which have been described by observers of other countries. As a rule these pyrexias have a tendency to reveal a similar clinical expression during early stages of life. Hence diagnosis is extremely difficult and requires minute and wide information of a clinical, etiologic, epidemiologic and experimental order. Most of these fevers come from intestinal infection. The writer divides them into the septicemic or rapid, and the enteroseptic or slow type, according to the predominance of the symptoms of auto-intoxication of the organism, or whether more or less extensive inflammatory lesions on the mucous membrane of the intestine are produced. [H.M.]

**11.—Pathologic Histology of Syphilitic Ethmoiditis.**—J. L. Goodale reports a case in which he was able to make histologic examination at an early stage of the disease. The tissue changes consisted essentially in a proliferative periostitis, with a new formation of bone in the form of irregular excrescences, with a proliferation of connective tissue and of the endothelial cells of the arteries, leaving in places an obstruction of their lumen. These changes partake of the character of a granulation tumor rather than a gumma, belonging to the class termed syphiloma. Antisyphilitic remedies established the diagnosis beyond question. [H.M.]

1. A Research Into the Means of Controlling the Blood-pressure. GEORGE CRILE.
2. On Routine Determinations of Arterial Tension in Operating-room and Clinic. HARVEY CUSHING.
3. Cyto-diagnosis: A Study of the Cellular Elements in Serous Effusions. A Preliminary Report. PERCY MUSGRAVE.
4. Intestinal Obstruction Below the Ileocecal Junction. THOMAS H. MANLEY.

**1.—Research Into the Means of Controlling Blood-pressure.**—George Crile, after painstaking investigation on the lower animals, comes to the following conclusions: Surgical shock is an exhaustion of the vasomotor; neither the heart muscle, the cardioinhibitory center, the cardioaccelerator center, nor the respiratory are other than secondarily involved. Collapse, on the other hand, is a sudden suspension of the function of the cardiac or vasomotor mechanism. In shock therapeutic doses of strychnia are useless, physiologic doses are dangerous or fatal. If not fatal increased exhaustion follows. There is no practical distinction to be made between external stimulation of this center, as in injuries and operations, and internal stimulation by vasomotor stimulants such as strychnia. Each is sufficient to produce shock. Stimulants of the vasomotor center are contraindicated. In shock stimulants and intravenous infusion have a limited range of usefulness, and may be injurious. In collapse they may be effective. The blood tolerates but a limited dilution with saline fluid. Adrenalin acts upon the heart and bloodvessels, raises blood-pressure in the normal animal in every degree of shock, even when the medulla is cocainized and the animal decapitated. Its effects are fleeting and it should be given continuously, probably best in saline infusion. By this means the circulation of a decapitated dog was maintained 10½ hours. In excessive dosage there is marked stimulation of the vagal mechanism. The pneumatic rubber suit provides an artificial peripheral resistance without injury and gives control over the blood-pressure to a considerable extent. By combined use of artificial respiration, rhythmic pressure on the thorax, and adrenalin injected into the jugular

vein animals which were apparently dead for 15 minutes were resuscitated. [A.B.C.]

**2.—Routine Determinations of Arterial Tension in Operating-room and Clinic.**—Harvey Cushing believes the crude method of estimating arterial tension by the palpating finger should be superseded by mechanical apparatus, which gives relative precision. The sphygmomanometer in some form, he believes, will in time occupy a place alongside the clinical thermometer and the watch in clinical work. He has found the Ravi-Rocci instrument, or some modification thereof, the most practical. It consists of a distensible cylinder or tire of thin rubber covered with a linen jacket. This cylinder, while encircling an extremity, preferably the arm, is inflated by means of a double cauter bulb until the pulse-wave, distal to the point of application, becomes imperceptible. Inserted into the lumen of the rubber tubing, which connects the bulb and tire, is a simple upright mercury manometer which records the pressure of the air in the cylinder necessary to obliterate the pulse. Many conditions are cited by the author in which an accurate knowledge of vascular tension would be of inestimable value, such as the physiologic testing of the circulatory stimulants and sedatives among drugs; effects of recumbent posture in many conditions of high arterial tension; in many operative procedures, as where fluids or tumors are removed, thus affecting vascular tension; differences in effect of different agents for general anesthesia; effects of subarachnoid injections and the trauma to or division of nerve trunks; investigations in the splanchnic vascular territory, etc. The paper should be read in full. [A.B.C.]

**3.—Cyto-diagnosis: Cellular Elements in Serous Effusions.**—P. Musgrave confines himself in this paper to the cellular elements found in pleural effusions. The liquid obtained by paracentesis is placed in centrifuge tubes to obtain the sediment, which is spread on cover slips by the loop. The writer reviews the cytologic formulas of Descos and recent classifications of pleuritis according to the predominant character of cell elements and reports the findings in a number of cases. He believes after more thorough study this procedure will be of clinical value. [H.M.]

**4.—Intestinal Obstruction Below the Ileocecal Junction.**—T. H. Manley calls attention to the great mortality following operations for malignant disease in this region, particularly if the patient has stercoremia and there is emaciation. Rectal cancer may be accompanied by hemorrhoids and every examination for the latter should be extended to a search for the former. Enterostomy is the safest method of relieving fecal obstruction from organic stenosis. The main pathologic causes leading to stenosis of the rectum are, in order of frequency, tuberculosis, cancer, syphilis, and gonorrhoea. The author states that Mikulicz reports 100 cases of carcinoma entering the Breslau clinic during the past 11 years, of which 5 were in the small intestine, 6 in the ascending colon, 7 in the hepatic flexure, 8 in the transverse colon, 12 in the splenic flexure, 4 in the descending colon, 31 in the sigmoid flexure, 20 in the cecum, and 12 in various areas of the large intestine.

### Medical Record.

March 7, 1903. [Vol. 63, No. 10.]

1. Radio-praxis. HENRY G. PIFFARD.
2. Feeding in Early Infancy: Home Modification of Milk. JOSEPH E. WINTERS.
3. Plastic Artificial Vitreous in Mules' Operation. E. L. OATMAN.
4. Clinical Results With Antistreptococcus Serum in Scarlet Fever. LEWIS FISCHER.

**1.—Radio-praxis.**—H. G. Piffard states that 25 years ago he employed sunlight, concentrated by glass lenses, in the treatment of lupus and similar skin affections. The lens practically, as now known, excluded the ultraviolet light and caused merely a cauter action of the concentrated light. Since other agents could be used equally well, this was abandoned. Finsen found that the ultraviolet light possessed therapeutic value, and a similar property belongs to the Röntgen rays. The author gives a review of the historic data and the literature of radiotherapy, and discusses its promising future. The Röntgen rays and the ultraviolet rays differ in the following particulars:

X-RAYS.

1. Cannot be reflected, refracted, or polarized.
2. Can penetrate and traverse many bodies that will not permit the passage of luminous rays, *e. g.*, wood, aluminum, etc.
3. Will readily traverse the superficial tissues and influence the nutrition of the deeper ones.
4. Will traverse a thick book.
5. Have no appreciable effect on the vitality of bacteria.
6. Will discharge an electro-scope either positively or negatively electrified.
7. Will excite bright green fluorescence in Willemite, and induce *white* phosphorescence in calcium polysulfid.
8. Rock salt is *opaque* to x-rays.

ULTRAVIOLET RAYS.

1. Can be reflected, refracted, and polarized.
2. Will not traverse many bodies that are perfectly pervious to luminous rays, *e. g.*, glass.
3. Will not influence the deeper tissues, nor even the superficial ones, unless they are deprived of their usual blood content; that is, dehematized.
4. Will be stopped by a single leaf of the same book.
5. Will rapidly destroy the vitality of bacteria.
6. Will discharge an electro-scope if electrified negatively, but not positively.
7. Will excite bright green fluorescence in Willemite, and induce *blue* phosphorescence in calcium polysulfid.
8. Rock salt is *transparent* to ultraviolet rays.

[A. B. C.]

2.—Feeding in Early Infancy.—J. E. Winters affirms

that for a newborn child there is but one perfect food, the milk of a healthy mother, because her milk at the beginning of lactation is rich in readily absorbable proteids; and no analysis or synthesis can provide a substitute having the composition and properties of mother's milk at the beginning of lactation—a food adapted to the undeveloped and functionless state of the digestive organs. Lactation for a short period after childbirth stimulates uterine contractions and the necessary resolution and subinvolution of that organ. During this early period the child should be permitted to nurse until sated, and then placed in a quiet, dark room to sleep. Nursing by clock and scale is an absurdity. For two months the mother's milk is a perfect food for the growing child, then the proteids diminish and artificial feeding should begin in addition and as a preparation for weaning, which may take place any time after the second month, and should not be delayed beyond the eighth or ninth month. The only good substitute is a proper modification of cow's milk, and formulas are given for the proper modification of milk from the first week of artificial feeding until the end of the eighth or ninth month. The food for the first few weeks should be prepared from cream separated from cow's milk by gravity, not by centrifugal action, as the latter does not leave sufficient proteids in the cream. Destitution of vitalized mineral and proteid is insuperable in manufactured food, and a substitute for milk is as impossible as artificial blood. [W.K.]

3.—Plastic Artificial Vitreous in Mules' Operation.—

E. L. Oatman has substituted a ball of paraffin for the glass ball in Mules' operation with fair success, some of the paraffin escaping but healing eventuating. Two other cases are cited with results similar to his own. Conclusions based on so few cases are: Paraffin used for this purpose is prone to produce fistula by softening and getting between the lips of the wound, or into the track of a suture. This can be avoided by using paraffin that will not soften at body temperature; also by so suturing the scleral wound that no aperture remains. Paraffin will adapt itself to any inequalities on the surface of the glass shell, and ulceration from pressure is not apt to occur. Paraffin beads are easily prepared and may be used in special cases in which glass beads of the required shape or size are not obtainable. [A. B. C.]

4.—Antistreptococcus Serum in Scarlet Fever.—

Lewis Fischer discusses the Aronson serum with its immunizing and healing properties and power of agglutination, and tabulates Baginsky's cases treated by injections. He also reports two cases of his own in which the results were striking. The effect on temperature shows that it inhibits bacterial products. The necrotic membranes after the fourth day disappeared, almost melting away. The temperature came down by lysis. The author advocates further use of the serum. [H.M.]

New York Medical Journal.

February 28, 1903. [VOL. LXXVII, No. 9.]

1. Notes on Plague as Observed by the Health Authorities of Sydney, New South Wales. G. FRANK LYDSTON.
2. Cases of Intestinal Resection, with End-to-end Union. C. S. HAMILTON and W. D. HAMILTON.
3. The Diagnosis and Treatment of Contracted Pelvis. WARREN R. GILMAN.
4. Hypodermoclysis: Experiments, Technic and Clinical Uses. ROBERT COLEMAN KEMP.

1.—Plague in Sydney.—Lydston gives some notes on plague as observed by the health authorities of Sydney. The epidemic of 1900 comprised 303 cases, 293 whites and 10 Chinese. The mortality was a trifle less than 34%, but the mortality rate among the Chinese alone was 80%. The 1902 epidemic comprised 141 cases. The proportion of Chinese and the mortality rate were not widely different from the 1900 epidemic. The study of plague in Sydney has established the fact that the bubonic and septicemic forms, at least, are not contagious. That this is not true of primary plague pneumonia is probable, and great caution is to be observed here. The bubonic type was the prevalent one in Sydney, a few cases only of the septicemic form being noted. The patients were treated at the hospital with the Yersin-Roux antiplague serum, and the contacts were inoculated with the Haffkine prophylactic serum if they so desired. The health board concludes that the value of the prophylactic serum is doubtful, and that its use is attended with obstacles which make it almost impracticable, irrespective of its intrinsic merit. The Yersin-Roux serum is thought of doubtful value as a specific, although its action as a temporary "reviver" or cardiac stimulant seems to be demonstrated. The conveyance of plague by fomites—mediate contagion—is utterly disproved by experience in Sydney. Ingestion of the germ in pure culture does not convey the disease to animals. Animals—rats, especially—fed on the viscera of animals or man dead of the disease do, however, succumb. With the probable exception of the primarily pneumonic type, plague is never communicated from the sick to the well save via skin atria of infection. This is brought about by such media as fleas, and by wounds and abrasions, which subsequently become infected. This method, it is asserted, cannot prevail save when bacilli are in the circulation of the skin of the donor of the infection, as in the septicemic form, or within 24 hours of death in the bubonic form. The first case in Sydney was preceded by an epizootic epidemic among the rats, which proved to be plague, and it was shown by many experiments that the flea was the most probable medium of contagion. Points are suggested by a study of the clinical history of the disease as presented by Thompson, of the health board, and plates shown from specimens prepared by Tidswell. [C.A.O.]

2.—Intestinal Resection.—This article includes the histories of 12 intestinal resections with end-to-end sutures. In the 12 cases operated upon there were 8 recoveries and 4 deaths. The ages of five of the patients varied from 61 to 73, with three recoveries and two deaths. As to methods of resection employed, they were by suture, by the Murphy button, and by the Robson bobbin. In the past year the authors have been using for intestinal suture Pagenstecher's thread, a linen thread coated with celluloid, which they claim offers many advantages. [C.A.O.]

3.—Contracted Pelvis.—Gilman calls attention to a few practical points in pelvimetry and the management of cases with contracted pelvis. Contraction of the pelvis exists in from 4% to 6% of all obstetric cases. The author says that in ordinary city practice we may expect from 1% to 2% of all obstetric cases to present pelvic deformity of a character and degree which render operation of some sort necessary. The physician should know the size of the pelvis in every obstetric case before labor begins, the primipara should be examined before the eighth month. If the conjugate diameter is 9 cm. (3½ in.) forceps or version may ordinarily be expected to bring labor to a successful termination whenever the progress of the head is arrested. When the conjugate is 7.5 cm. (3 in.) forceps or version may occasionally be successful. When the conjugate is 7 cm. (2¾ in.) or less, the choice of operation lies between induced labor and cesarean section. [C.A.O.]

4.—Hypodermoclysis.—Kemp gives the results of some

experiments with hypodermoclysis. The first experiment shows that in 3½ minutes after the subcutaneous injection of saline solution into the groin of a dog the reaction in the urine was noted and the renal secretion increased. Another experiment shows the specific action of normal saline solution in promoting renal secretion. In a third experiment he produced renal congestion artificially in rabbits by the injection of serum, and then found that when this was followed later by a hypodermoclysis of normal saline solution renal congestion was much lessened. The author gives in detail the technic and precautions to be observed. He suggests the ilio-lumbar region, the space between the crest of the ilium and the twelfth rib, as the most convenient site. The author quotes Hilderbrand as stating that one dram of normal saline solution in proportion to one pound of body weight is the maximum quantity that will be taken care of by the kidneys every 15 minutes. If the fluids tends to remain *in situ*, enteroclysis with normal saline solution at 122° F. increases the heart's action and aids absorption. In some cases, in oliguria or in uremia, frequently repeated injections of moderate amount seem to promote the excretion of toxins better than the employment of a single large volume of saline solution; there is also less strain on the kidneys. In an adult from six ounces to a pint is indicated in uremia and allied conditions; from one pint to one quart if there is shock or hemorrhage. A temperature of 110° F. should be employed with a needle of moderate size, and a temperature of at least 115° F., or even 120° F., with a small or very fine needle. [C.A.O.]

#### 1.—Periduodenal Abscess from Ulcer of the Duodenum.

—W. S. Bainbridge reports the case. The patient was a man of 54. The symptoms are detailed, and a diagnosis was made prior to death but the patient's condition precluded operation. Autopsy confirmed the diagnosis. There are, including the author's case, 26 on record, and 22 of the patients died without the diagnosis being made. In 2 an operation was performed and the diagnosis made at the time that the abdomen was opened. A cure resulted in one (Moynihan). In another, diagnosis was accurate, operation performed, but patient subsequently died from the disease (Lowson). The purpose of the paper is to give an epitome of the literature on the subject, to stimulate a fuller record of cases, and to urge a more general recognition of the possibility of this disease in daily practice. In but 12 of the reported cases (including the author's) are the reports considered by him of value. These are rehearsed. [A.B.C.]

#### 2.—Mosquito Extermination in New York City.—G. A.

Soper advocates careful observation of times and places of breeding with identification of species. He considers separately *Culex pungens*, which is most apt to give trouble indoors at night, *Anopheles maculipennis*, the malarial agent, and *Culex sollicitans*, the salt marsh mosquito. The first develops in stagnant water near habitations. Engineering works, like the underground railway, natural pools and swamps, and a want of proper neatness about dwellings furnish the breeding places. The most objectionable breeding places are those near thinly-settled districts which are passing from country to city. Here the malarial mosquito occurs. Public works, new streets, railways, etc., leaving "sunken lots," create places in which stagnant water accumulates. The salt water mosquito occurs almost exclusively near the tide meadows. The number of people near the edges affected by these is considerable. In 1902 extensive biologic and sanitary surveys were made and steps taken toward legal remedies. War is to be waged against all responsible for stagnant water. Useless receptacles should be destroyed, old barrels should be broken up for firewood. There should be no rubbish heap. Cisterns should be stocked with

goldfish or screened. Cesspools and manure pits should be covered with kerosene. Pools should be filled up or drained, brook margins should be sharp and clean. When drainage is impossible, kerosene, lime or carbolic acid should be used. Many districts by suitable drainage could be made healthful and valuable. Small ditches about the meadows would reduce the number of mosquitos. The thinning of foliage about dwellings often secures relief. [H.M.]

3.—Mosquito Extermination in New Jersey.—H. C. Weeks emphasizes the importance of cultivating the anti-mosquito habit by persistent agitation. The inducements to action lie in improved healthfulness, lessening of time lost from work, increased land values, and public comfort. He believes the mosquito can be exterminated from the whole State and every acre reclaimed could be profitably utilized. The Passaic basin forms the greatest menace as a fresh breeding area. This whole section could be relieved by State action with great economic benefit. There are about 300,000 acres of tidal marshes, one-eighth of the farmland, whose fertility would add 20% to farm products. [H.M.]

4.—Sanitary Aspect of the Mosquito Question.—J. B. Smith discusses various species of mosquitos and the life history of *Plasmodium malariae*. For hibernation the anopheles select houses or barns and preferably cellars. In a house kept at 75° they will become active and may bite. Winter development of malaria is not unknown. Winter fumigation of cellars in malarial districts is therefore a precaution of the highest value. Equally necessary is thorough treatment of persons with malarial fevers who are the source of infection. We might ignore the mosquito altogether could we protect all patients from bites till thoroughly cured. Smith has never found the anopheles in really foul water and rarely in woodland streams, but aside from that there is scarcely a bit of sheltered water in which they will not occur. Thousands breed in the salt marshes. They will fly half a mile over level country. He found their larvae in every square laid down on the New Brunswick map. There is no reason why breeding pools should be allowed in any city. No larva lives in any ripple area in any body of water. The day is not distant when the shore mosquito will be only an exceptional occurrence. [H.M.]

1.—Tropical Parasites.—C. Kieffer says the nematode worms are common to the tropic and temperate zone. *Trichuris trichuria*.—Excepting in deteriorated conditions the parasite does not cause any clinical symptoms; its normal habitat is the cecum, although it may be found in other portions of the colon or lower ileum. This parasite is not expelled by the ordinary anthelmintics; the only reliable remedy is mechanical dislodgement of the worms by high enemas, or their destruction by antiseptics. *Ascaris lumbricoides*.—Even though this worm produces no symptoms the accidents which it may occasion indicate prompt attempts at removal; for this purpose santonin combined with purgative doses of calomel is to be highly lauded. *Uncinariasis*, due to different varieties of uncinaria, is a parasitic disease of the small intestine, the chief symptoms of which are severe anemia, abdominal pains, asthenia without emaciation and edema. In Egypt this worm is found in nearly every postmortem. Harris has found it in Georgia and Florida, and believes it is the common cause of the severe anemias of the southern United States that have hitherto been regarded as malarial. In conditions of great deterioration in the half-starved or ill-nourished, in acute or chronic dysentery, the presence of only a few of these parasites may be sufficient to act as a very dangerous complication. There is no leukocytosis, but there is a relative increase in the

eosinophiles ranging from 3% to 30%. The definite diagnosis is made by the identification of the ova. In the treatment of uncinariasis male fern and thymol are of value; the latter is the more effective, being administered in 30 grain doses, given in capsule or emulsion with acacia; repeated in two hours for an adult. [F.C.H.]

**2.—The Ductless Glands.**—C. E. de M. Sajous details the deductions of the results of investigations of the ductless glands as organs of the first importance in vital functions and their relationship as such to disease and therapeutics. When in the course of time we were brought to study the literature of the ductless glands the marked affinity of the suprarenal secretion for oxygen could not but attract our attention. The following are the conclusions which Sajous reached as a result of these investigations, each of which is elucidated: 1. When the venous blood reaches the pulmonary alveoli the marked affinity of the adrenal secretion in the plasma for oxygen causes it to absorb this gas from the alveolar air. The carbonic dioxide in the blood is thus forcibly replaced by oxygen and expelled with corresponding vigor. The red corpuscles after this operation bathe in an oxygen-laden medium and their hemoglobin becomes converted into oxyhemoglobin. 2. The physiologic function of the internal secretion of the adrenals is loosely to combine the oxygen in the lungs and to endow the blood plasma with its oxidizing properties. A concomitant study of the experimental physiology of the pituitary body and of the ultimate effects of sympathectomy and a rather extensive research into the pathogenesis of acromegaly and other disorders of the pituitary, having likewise pointed to phenomena directly ascribable to functional disturbance of the adrenals, it became clear that the governing center of these organs was found and that the following conclusion was warranted. 3. The anterior pituitary body governs the functional activity of the adrenals and is directly connected with these organs through the cervicothoracic ganglia, the splanchnic nerves, and the semi-lunar ganglia of the sympathetic system. 4. All general symptoms witnessed in disorders in which the blood is invaded by a poison of any kind are in reality manifestations of over-activity, insufficiency or inactivity of the adrenals. 5. The thyroid gland, the anterior pituitary body and the adrenals are functionally interdependent and constitute a system. 6. Neutrophile leukocytes ingest proteids and certain hydrocarbons, sugar, and starch in the digestive canal and convert these into peptone, myosinogen and fibrinogen granules. 7. Eosinophile leukocytes elaborate hemoglobin from the proteids, bilirubin, and iron ingested by their parent-cells, the neutrophiles. 8. Lecithin is the active constituent of the myelin of nerves. The axis cylinder contains plasma, the adrenoxin of which, by combining with the lecithin, liberates nervous energy. 9. Basophile leukocytes convert fats derived from intestinal foodstuffs into myelin granules. 10. The greater part of the trypsin of the organism is formed in the splenic vein. 11. The splenopancreatic internal secretion is represented by the trypsin, which reaches the portal vein by way of the splenic vein. 12. The main function of the splenopancreatic secretion, trypsin, is to protect the organism from the effects of bacteria, their toxins and all toxic albuminoids, including vegetable poisons and venoms. 13. The posterior pituitary body, as the general center of the nervous system, was found to be the anterior pituitary body's cocenter in sustaining the cellular metabolism of all organs. 14. Adrenal stimulants will often prove inadequate if the alkaline salts are not administered simultaneously, while the use of alkaline salts without adrenal stimulants will prove unavailing, though perhaps beneficial for a time. 15. The power of the organism to antagonize the constitutional effects of pathogenic germs, their toxins and other poisons, is directly proportionate, all else being equal, to the functional efficiency of the adrenal system. 16. When a favorable reaction does not follow the use of saline solution, it is because the adrenal system also requires direct stimulation, such as that afforded by strychnin, digitalis, etc., administered subcutaneously. [F.C.H.]

**3.—Gangrenous Destruction of the Pituitary Body.**—E. Wasdin details a case of gangrenous destruction of the pituitary body, with disintegration of the blood, following a fracture of the sphenoid bone and subsequent infection as illus-

trative of the influence which the integrity of the pituitary body exercises upon the integrity of the blood through the adrenal glands. The patient was a male of 24, who died 22 days after receiving the injury. The anatomic diagnosis made was fracture of the lower jaw opening into the buccal cavity, fracture of the body of the sphenoid through the sella turcica with infection resulting in localized gangrene of the contents of sella, the lobes of the pituitary body and general intoxication. The skin was a deep bronze yellow, the right half of the face was greatly discolored and edematous, the right eye protruded to overdistention of the swollen lids, between which the edematous conjunctiva protruded. Upon postmortem the cerebral tissues normal except the right crus as it overlaid a gangrenous area on the base of the skull. In the left midfossa there was a dark green mass near the carotid opening of the petrous bone involving the gasserian ganglion, and which, passing backward, involved all the contents of the sella turcica, then as a slender greenish line it passed along the right cavernous groove into the orbital cavity. The middle and posterior clinoid processes were necrotic, and the pituitary removed showed a fracture through the body. [F.C.H.]

**4.—Surgical Affections of the Biliary Tracts.**—John B. Deaver details at length the surgical affections of the biliary tracts. The following are the indications for medical treatment: (1) Acute obstruction of the common duct. Morphine for the pain during the acute stage. Should symptoms of obstruction return after apparent relief, indicating a fixed position of the stone, operation should immediately be advised; (2) hydrops of the gallbladder, due to an infection and not to calculus obstruction of the cystic duct; (3) mild attacks of colic without any inflammatory symptoms, unless chronic invalidism is threatened. Such cases are markedly benefited by the Carlsbad treatment; (4) in cases of marked obesity or on account of diabetes, heart, lung, kidney or liver disease in which the shock of operation would result fatally; (5) carcinoma of the biliary apparatus, unless the obstruction requires a palliative operation. The indications for surgical treatment are: (1) Chronic obstruction of the common duct. The operation of choice is choledochotomy; (2) chronic obstruction of the cystic duct from an impacted gallstone with infective cholecystitis. The operation to be performed is cholecystectomy; (3) hydrops of the gallbladder from an impaction of a gallstone in the cystic duct. Cholecystectomy should be performed in most cases; (4) chronic calculus cholecystitis without jaundice and with or without enlargement of the gallbladder; (5) abscess either in or about the gall ducts or in the liver; (6) infective and suppurative cholangitis; (7) acute phlegmonous cholecystitis and gangrene of the gallbladder; (8) chronic catarrh of the gallbladder and bile-ducts associated with stones in the gallbladder with persistent infection by growing microorganisms; (9) for the sequels of cholelithiasis, and particularly adhesions; (10) malignant disease. [F.C.H.]

## CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

### EDITORIAL COMMENT

**Sea-sickness.**—Despite speculation extending through ages and the experience of millions, we are as much in the dark as to the true cause of sea-sickness as ever. Nor is its treatment any more efficient today than it was when the bold Phœnician sailor passed through the Pillars of Hercules into the tempestuous Atlantic. Secret and other remedies in countless numbers have been vainly vaunted as cures. One enjoying considerable vogue at the present time is an English preparation called "Yanatas," a name formed from the initial letters of the words in the sentence, "You are now able to avoid sea-sickness." A study of this preparation made by Professor C. Binz, of Bonn, has shown that it is essentially a 1% watery solution of chloral hydrate. Binz,<sup>1</sup> in his report upon this preparation, reviews the more recent

<sup>1</sup>Zent. f. inn. Med., February 28, 1903.

writings upon the subject of sea-sickness. O. Rosenbach considers *mal de mer* a kinetosis, for which he makes intra- and interenergetic (intermolecular) disturbances responsible. To quote his luminous (?) phraseology, the phenomena of a kinetosis ensue when particularly strong and unusual impulses—*e. g.*, the movements of the ship—so endanger the artificial internal equilibrium of the entire organism, or of its parts, which is maintained through a special form of surface tension, that the existing reactive forces (the latent surface energy) are not capable of restoring the normal relations of the constituent parts. W. Janowski attributes sea-sickness to a mild form of oft-repeated cerebral concussion. C. Schwerdt considers that the disease is due to a rapid exhaustibility of the nervous and muscular elements, as well as to an augmented irritability of the center of equilibrium. He believes that on board ship the function of the diaphragm is inhibited in its upward and downward movement, causing diminished gaseous exchange in the lung and the accumulation of blood and lymph in the abdominal cavity. This brings about a double source of CO<sub>2</sub> accumulation in the system. A careful observation of suffering fellow-travelers has led Binz to formulate another theory; namely, that sea-sickness is dependent upon an acute anemia of the brain. The first symptom of the affection is a marked pallor, bordering upon that of chlorosis; then come nausea, retching, and vomiting. Binz believes that, inasmuch as the external carotid, which supplies the blood to the face, derives its vasomotor impulses from the same sympathetic source as the internal carotid, which supplies the blood to the brain, anemia in the territory of the external carotid doubtless means anemia in the distribution of the internal carotid. To prove this, he has made the following experiment: He trephined the skull of an albino rabbit; and, with a loup, observed the exposed portion of the brain, while an assistant kept in view the animal's ear. It was found that the vessels of the latter and those of the surface of the brain dilated and contracted synchronously. It is admitted by Binz that this does not permit of conclusion that during the rocking motion on ship the same thing occurs in man, and that the condition of the parts supplied by the external carotid must correspond with that of those supplied by the internal; but there is still less proof for the opposite view. In the animal experiments it was not possible to produce vascular spasm by long-continued rocking. Cerebral anemia causes nausea and vomiting, as may at times be observed in conditions of slow hemorrhage. It has been noted during sea-sickness that after the retching act there is a momentary feeling of relief. This Binz attributes to the increased afflux of blood during the straining, which counteracts the cerebral anemia. His view of the causation of the disease is also borne out to some extent by the fact that experienced travelers that are subject to sea-sickness assume a horizontal posture as soon as they come on board the ship, even before the harbor has been left. Binz sums up his observations in the following conclusions: 1. The rocking of the ship produces a contraction of the arteries of the head and therefore an acute anemia of the brain. 2. This acute local anemia has as its consequence nausea and vomiting. 3. The movements in the abdominal press produced by the retching and vomiting force a large amount of blood into the brain, remove the anemia for the moment, and thus interrupt the malaise. 4. The stomach in sea-sickness plays only a passive role. The vomiting act is centrally excited, whether the stomach is full or empty. 5. Everything that tends to increase the flow of blood to the brain acts prophylactically, amelioratingly or curatively upon sea-sickness. In the last instance, however, we have as yet no explanation of why the rocking of the ship causes contraction of the vessels of the head, but this is no stranger than the contraction and dilation of the cephalic arteries during

strong emotion. For the treatment of the disease there is in the first place the horizontal posture, then remedies that cause dilation of the vessels of the brain. Among these may be mentioned chloral hydrate, which may be taken in doses of 0.3 grams (5 grains) three or four times within a few hours, and amyl nitrite in doses of two or three drops by inhalation. Potassium bromid and anti-pyrin in not too small doses have also been recommended and theoretically at least appear to be of value. R. Heinz advises rapid breathing, which, as is well known, has a tendency to lessen ordinary nausea. Binz also recommends that a full meal being taken before boarding the ship.

#### REVIEW OF LITERATURE

**The Fatsplitting Ferment of the Stomach.**—In a previous paper Volhard<sup>1</sup> has shown that a fine emulsion of almost neutral egg and milk fat removed from the stomach of man after from 1 to 2½ hours of digestion is removed not as neutral fat, but as free fatty acid. Almost 70% of it is found thus. In another paper he demonstrates that this digestion takes place when fat is brought in contact with gastric juice in the test-tube; he demonstrates the process to be one of fermentation, since the fatsplitting agent is capable of passing through an earthen filter impassable to bacteria. The gastric juice after passing through filter possessed the fat digesting property to the same degree as before. The ferment was contained in a glycerin extract prepared from the gastric mucous membrane of a pig, and was found in larger quantities in the glands of the fundus than of the pylorus. In the present paper he publishes experiments which demonstrate (1) that the fatsplitting ferment of the gastric juice is very sensitive when acted upon by an alkali, much more so than that of a glycerin extract of the gastric mucous membrane; (2) the former is much more resistant against hydrochloric acid than the latter; (3) the gastric juice contains the fatsplitting ferment, the extract its zymogen; (4) the digestion of the fat through the ferment apparently does not increase proportionally with the time, but is performed in irregular intervals; (5) the reaction is incomplete independent of the absolute amount of neutral salts present, only a certain percentage is acted upon; (6) in achylia the secretion of this ferment is diminished, as well as that of rennin and pepsin; (7) high degrees of hyperacidity interfere with the digestion of fat in the stomach. [E.L.]

**Physical Degeneracy as a Result of Change of Environment.**—Janson's<sup>2</sup> observations are based mainly upon a study of the peasant and his offspring from certain mountainous parts of Norway. He speaks of their diet, physical characteristics and freedom from disease, and contrasts them with the conditions present in those people as found in the United States. In the same generation there is loss of buoyancy and elasticity of gait, the hair becomes dry and alopecia results, digestive disturbances and constipation become common, and following the latter many disorders, especially in the female, entirely unknown in their native land. Nervous disorders are frequent. In the second generation are found decaying teeth and an alarming frequency of the so-called scrofulous diathesis. Particularly important is the prevalence of tuberculosis in its various manifestations, this being the disease upon which most stress is laid in connection with these victims of change of environment. It seems to make up for the time lost by the past immunity of the race, and the mortality is high. What applies to the Norwegians applies equally to other Europeans who have lived among simple and secluded environments. [A.G.E.]

**Achondroplasia.**—Vargas<sup>3</sup> reports the case of a female child 6 months old exhibiting the condition to which Parrot and others have applied the term achondroplasia. The condition is characterized by the combination of a normal head and body with short, thickened extremities. Radiographic investigation of the limbs shows that the bones are much thickened, especially at the ends, and are wanting in the epiphyses and

<sup>1</sup> Zeitschrift für klinische Medizin, Vol. xliii, p. 397.

<sup>2</sup> Northwest Medicine, January, 1903.

<sup>3</sup> Monatschrift für Kinderheilkunde, November, 1902, Bd. i, No. 2.

centers of ossification normally found at that age. The child shows no signs of rachitis or cretinism. Vargas reviews the literature on the subject and gives a list of reported cases. The etiology of the affection is not known. The specific changes are found only in the long bones, in which ossification occurs by means of epiphyseal cartilages. The broad bones, which develop from membranes and such bones as the sternum, patella, etc., which may remain in a cartilaginous state for several years, are usually not affected. Microscopically, it is observed that all the characteristic appearances of normal epiphyseal bone formation are absent. The arrest of development must have taken place between the third and sixth months of pregnancy, through some nervous influence on the vascularization of the epiphyses. Achondroplasia is regarded as a condition quite distinct from fetal rickets or myxedema. [B.K.]

**Dysphasia or aphasia as an initial symptom of tuberculous meningitis** is discussed by Sinclair,<sup>1</sup> who insists that the occurrence of aphasia, even of transitory character, in a person already suffering from any form of tuberculous disease, should be looked upon with the gravest suspicion and regarded as the probable precursor of further meningeal trouble. [A.O.J.K.]

**The Causation of the Crescendo Murmur of Mitral Stenosis.**—In this paper E. M. Brockbank<sup>2</sup> replies to Samway's criticism of his views, restating the latter. The crescendo murmur is the terminal portion of the so-called presystolic murmur. Its three characteristics are ascending pitch, crescendo force, and abrupt termination by an accentuated first sound. The ascending pitch is caused by blood being forced through a gradually narrowing orifice. The crescendo character is produced by the gathering force of the ventricular systole; the abrupt termination by the sudden closure of a rigid valve. The auricle frequently produces by its contraction a murmur at the stenosed valve, but this can have no crescendo character, as the force is either uniform or decreasing. The auricular systolic murmur occurs during ventricular diastole. It is highly improbable that the force which closes the valve in health should be changed to another in disease, and the auricle, moreover, is unable to provide this force, since in the majority of cases of mitral stenosis it is dilated and unable to raise the pressure high enough to close the stiff valve. The author explains the replacement in some cases of the uniform systolic murmur of regurgitation by a crescendo murmur or by only an accentuated first sound within a few beats of the heart as follows: So great is the force required to close the rigid valve that when the patient is lying down and the ventricle beating quietly the valve resists closure and the ordinary systolic regurgitation murmur is heard, but when the patient sits up and contraction is more forcible the resistance to closure is overcome and a crescendo murmur is heard; when the patient walks about and the ventricle contracts more forcibly still the resistant valve is forced to close almost at once and only an accentuated sound is heard. [H.M.]

**True Nanosomia, with Demonstration of a Case.**—Von Hausemann<sup>3</sup> presents a case of true nanosomia in a man of 22. He has a beard and pubic hairs but his testicles are undescended. His thyroid cartilage stands out as it does in a properly developed man. His body is proportionately developed. The measurements are given. No pathologic condition exists with the exception that his fingertips are club-shaped, and his hands are hyperemic yet ice-cold. He is intelligent and can speak three languages. The Röntgen rays show that his long bones have no epiphyses. At birth he weighed one pound. His mother gave birth to three other dwarfs and to eight normal children. The three dwarfs died in infancy. Von Hausemann says dwarfs are either proportional or disproportional. The latter form is seen in rachitis chondrodystrophia, congenital defects in the osseous system and cretinism. In the proportional variety the condition is physiologic and not pathologic. When the size is so small as to cause functional disturbances the condition is called nanosomia. There are two forms

of the latter. In one variety the child is normal at birth but ceases growing in infancy or early childhood (nanosomia infantilis). In the other form the child is small at birth, matures but always remains undersized (nanosomia primordialialis). [W.E.R.]

**Problems in the Laboratory Study of Diphtheria.**—Wesbrook<sup>1</sup> refers to the work of the Massachusetts committee for the study of diphtheria bacilli in well people, and compares it with some work done by the Minnesota State Board of Health. From the results of the latter that are at present available, it appears that (1) the percentage of infection of the nose and throat of well people with diphtheria bacilli varies within wide limits; (2) the types of bacilli characteristic of clinical diphtheria are not so abundant in well people as was expected; (3) the infection is much higher where well people have been exposed to clinical diphtheria. Experiments along two lines are now in progress, (a) to find a means of changing one type of diphtheria bacillus into another, and (b) observations on daily cultures from the throats and noses of clinical cases in hospitals. [A.G.E.]

## GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### REVIEW OF LITERATURE

**Report of a Case, with Autopsy.**—L. A. Sanders<sup>2</sup> gives the following findings at autopsy upon a child who suddenly died within 12 hours after he was called in to attend it. The child was a female, 6½ years of age, who a few minutes previous to death drank almost a glassful of milk. Upon opening the abdomen there was found a considerable quantity of thin, watery fluid, together with milk curds. Examination of the stomach revealed a perforation or tear of that organ on the anterior surface near the lesser curvature and a little nearer the cardiac than the pyloric opening; this perforation would easily allow the passage of the index finger into the stomach, and was as clean cut as though done with a knife. The stomach was dilated to such an extent as to reach down to the bladder. The entire anterior wall was very thin, pale, and almost transparent. The posterior surface was not so thin and had more color. The spleen, almost the entire small intestine, including portion of the caput coli, with the vermiform appendix, had passed through an opening in the diaphragm into the left thoracic cavity, occupying it almost entirely; the left lung being atrophied or compressed to about the thickness of one's hand, and had apparently not been dilated. The right lung was considerably increased in size, so much so that more than one-half the size of the liver was below the free border of the ribs. The heart was in the right side of the chest, occupying relatively the same position which it should normally have done in the left, and was apparently normal in size. [F.C.H.]

**The Value of Rest as Effected by Operation in Diseases of the Alimentary Canal.**—A. E. Maylard<sup>3</sup> notes that it is in overstimulation and undue activity that we find the most fruitful source of almost all gastrointestinal diseases. There are probably no diseases peculiar to the esophagus unaccompanied by inflammation. Efforts at deglutition, even with regulated diet, tend to increase this. Gastrostomy gives the needed relief. The result is striking. Maylard does the Kader-Senn operation under skin cocaineization, completing it in 12 minutes. He advises gastrojejunostomy for hyperchlorhydria, chronic gastric catarrh and nonobstructive dilation of the stomach if a year's treatment by ordinary methods has failed. Considering the stomach as a storehouse it is easy to understand how many derangements are originated and augmented. An opening between the lower part of the stomach and the bowel will remove any possibility of the contents being retained, thus putting the stomach at rest. When gastric ulcer requiring operation is so situated that it cannot be excised gastrojejunostomy is indicated. With a patent pylorus the opening becomes ultimately so reduced that the digestive func-

<sup>3</sup> Glasgow Medical Journal, November, 1902.

tions of the stomach are normally restored. He has successfully treated chronic ulcerative colitis and dilated colon by an artificial anus in the right iliac or lumbar region, and rectal disease by a sigmoid anus. [H.M.]

**Spinal Hydatid Cyst Causing Severe Compression Myelitis.**—Tytler and Williamson<sup>1</sup> report the case. The patient was a woman of 27 who was suffering from paralysis of both legs. Some three or four years previously she had developed a painful tumor in the back, to the other side of the lower angle of the left scapula. The tumor was removed and found to be a hydatid cyst. She remained well about two years and then began to suffer from pain in the middorsal region and at the base of the right lung. The pain continued for three weeks, then disappeared, and no trouble was noticed until two weeks before the authors first observed her. She then noticed weakness of the legs, which gradually increased until she was unable to walk. Pains existed in the legs, and she lost control of the bladder and rectum. She was operated upon and fifteen extradural spinal hydatid cysts were removed. The patient gradually improved. There is complete recovery of sensation and control of the bladder and rectum. There is marked recovery of motor power in the legs, though they remain somewhat spastic. The patient is able to walk with the aid of a stick. Hydatid cysts causing compression myelitis are usually external to the dura, and in the majority of cases they are on the posterior surface of the dura. Early removal is almost imperative if degeneration of the nerve filaments is to be prevented. In most of the cases symptoms of compression of the spinal nerve root, such as radiating pains, have occurred first and later paraplegic anesthesia and bladder and rectal symptoms have developed. The onset of paraplegia is usually gradual. [A.B.C.]

**Cholelithiasis.**—After a detailed investigation of the subject, especially in regard to treatment, Djakonoff<sup>2</sup> gives the following conclusions: 1. Gallstones are comparatively very rare in Russia. 2. The pressure of a stone in the gallbladder, as well as in the common or in the cystic duct, is fraught with danger and is a constant menace to the patient, owing partly to the mechanical obstruction, and in part to the probability of inflammatory complications. 3. The diagnosis of gallstones is often extremely difficult, but much is to be expected in the future from the improved utilization of the Röntgen rays. 4. In every case of demonstrated gallstones operative interference is unequivocally indicated. 5. The choice of operation lies between cholecystectomy and cholecystostomy. Simple cholecystostomy should be altogether abandoned, while choledochotomy and cysticotomy are indicated in exceptional instances when the stone has been definitely located in the common or in the cystic duct. The most radical and plausible of all these operations is undoubtedly cholecystectomy, and it should be more frequently performed than has hitherto been the case. [L.J.]

**Suprapubic Cystotomy in Tumor of the Bladder.**—From a study of the statistics of this operation C. B. Lockwood<sup>3</sup> notes how much safer it is when the urine is acid and the tumor removable. If shock and hemorrhage were prevented, and he believes they could be, the mortality would fall within very reasonable proportions. The statistics show the extreme danger of the operation when the urine is septic and the tumor irremovable. It is then not justifiable. Now and then a survivor experiences some relief from the horrors of the disease, but this is not worth attempting when the attempt entails a mortality of 50%. Irremovable tumors are almost invariably malignant and accompanied by hemorrhage, which may be fatal, and in any case predisposes to septic cystitis, and indeed to general sepsis. Owing to the proximity of ureters, kidneys, peritoneum, pelvic veins and cellular tissue sepsis has unusual opportunities of doing harm. The largest proportion of bladder tumors are malignant. The thickness of the pedicle is not a trustworthy guide to the character of the growth. The high mortality attending suprapubic cystotomy can be greatly lessened by operating before the growth is too extensive for removal and before sepsis is established. Early diagnosis could be achieved by systematic use of the endoscope after

sudden spontaneous hematuria, the earliest symptom of tumor. [H.M.]

**Retention of Urine Caused by Ischiorectal Abscess.**—Bartenstein<sup>1</sup> reports a case of retention of urine occurring in an imbecile infant 10 months old. On catheterization the instrument met with considerable resistance at the sphincter vesical. Rectal examination at first revealed nothing but accumulated hard feces, the removal of which did not relieve the retention of urine. Five days after the first appearance of retention an ischiorectal abscess was discovered and opened. The following day spontaneous urination occurred for the first time. Notwithstanding this relief, the child finally died of sepsis. The retention of urine is not explained through the mere mechanical presence of the abscess or fecal impaction, as the course of the disease will show. The probable explanation is that the inflammatory process in the ischiorectal fossa set up an irritation of the inferior hemorrhoidal nerve, which passes through that space, and thus caused a reflex spasm of the neck of the bladder. The spasm lasted for some time after evacuation of the abscess, as the irritation was not due to mechanical pressure, but to inflammatory processes in the neighborhood of the nerve. [B.K.]

**Operation to Correct Undue Prominence of the Ears.**—A. MacLennan<sup>2</sup> reports a case operated on under Schleich's local anesthesia. Owing to the sensitiveness of the tissues and the impracticability of getting the solution through the cartilage there was considerable pain. An incision was made behind, freeing the ear from its attachments to the mastoid region. A crescentic piece of skin was removed from the edge so as to leave a raw surface on the skull for about one-third of an inch. A similar piece was removed from the ear, including the underlying concha and antihelix, but without buttonholing the skin in front. Removal of the cartilage allowed the ear to be brought in contact with the skull without having much tendency to spring back. Silkwormgut sutures were used. The helix was not interfered with, as an interruption of its continuity might spoil the contour of the ear. A cut illustrates the results. [H.M.]

**Liver Abscess in a Child Two and One-half Years Old.**—Arnott<sup>3</sup> reports the case. The child gave a history of a neglected attack of dysentery. The lungs gave evidence of beginning tuberculosis, the general aspect was tuberculous and anemic. Open-air treatment was instituted and improvement followed, though at the end of ten days the temperature still ranged from 100° to 104°. The abdomen was distended and the liver was tender and enlarged to two fingers' breadth below the ribs and to the same extent upward. There was slight fulness in the contour of the right side of the hepatic region, respiration was thoracic. An exploring trocar and cannula were inserted in the tenth interspace in the anterior axillary line. Pus escaped, and an incision was made in the tenth interspace, and 12 ounces of pus evacuated and drainage instituted. The child was progressing fairly well when about the fifth day convergent strabismus was noticed, and a day later the hydrocephalic cry of tuberculous meningitis was noticed. The child died on the sixth day after the operation. [A.B.C.]

**Echinococcus of the Pleura.**—Springer<sup>4</sup> reports the case of a boy of 11 years who had an unrecognized echinococcus cyst of the liver for five years, at the end of which time a rupture occurred into the right pleural cavity. The nature of the disease was then diagnosed by examination of the fluid obtained by aspiration of the chest. Resection of two ribs was performed and the cavity drained for eight days. Then it was packed rather firmly, in the hope of causing a sequestration of the echinococcus membrane. This end was accomplished eight days later, when the sac became loosened and was removed *in toto*. The case is remarkable on account of the favorable outcome, which is very rare in rupture of a hydatid cyst into the pleura, and also on account of the manner in which the sac was spontaneously discharged as a whole. [B.K.]

**Lysiform.**—F. W. Tunnicliffe and R. T. Hewlett<sup>5</sup> describe

<sup>1</sup> Monatschrift für Kinderheilkunde, November, 1902, Bd. 1, No. 2.

<sup>2</sup> Glasgow Medical Journal, November, 1902.

<sup>3</sup> British Medical Journal, January 24, 1903.

<sup>4</sup> Centralblatt für Kinderheilkunde, January, 1903, viii, No. 1.

<sup>5</sup> Medical Press and Circular, October 29, 1902.

<sup>1</sup> British Medical Journal, February 7, 1903.

<sup>2</sup> Chirurgia, January, 1903.

<sup>3</sup> Medical Press and Circular, November 26, 1902.

lyosform as a formaldehyd soap. It is a viscid, colorless liquid, superficially similar to glycerin. Its unirritating qualities render it valuable for skin disinfection. It is a powerful, rapid deodorizer. It can be used as a gargle or irrigating fluid for mucous cavities. The typhoid bacillus is killed by a 5% solution in 5 to 10 minutes, *Bacillus coli* in 10 to 20 minutes, and *Staphylococcus pyogenes aureus* in a little over an hour. The formaldehyd compound it contains has a very low toxicity. As a mouth or nose wash it should be used in the proportion of one to three teaspoonfuls to a pint; as a vaginal or uterine douche, four to six teaspoonfuls; for abscess cavities, sinuses, etc., six teaspoonfuls or stronger; for disinfecting hands or instruments, six to twelve teaspoonfuls to the pint; as a deodorant, half to one ounce to the gallon; to disinfect discharges, half an ounce to the pint should be used. [H.M.]

**Perforations and Lacerations of the Gallbladder.**—To determine whether it is possible in cases of traumatic perforations and lacerations of the gallbladder to close the wound by inserting portions of peritoneum and abdominal muscle, Baldassari and Gardini<sup>1</sup> performed experiments with dogs. They were performed under rigid antisepsis and were successful in every instance. Dogs were killed at various intervals after the operation and absolute closure of the wound with adhesions to surrounding liver found. They advise the use of this method of closing such wounds in man, especially in cases in which a loss of substance would follow ordinary suture. [E.L.]

**Concerning Blood-pressure in Man During Ether and Chloroform Narcosis.**—Blauel<sup>2</sup> reports comparative observations of the blood-pressure of 139 patients operated on for different surgical conditions; 100 were anesthetized with ether, and 39 with chloroform. He sums up his results in the following manner. Ether used as an anesthetic elevates the blood-pressure greatly, doing this not only in strong, healthy persons but also in constitutions weakened through long illnesses. It maintains high pressure throughout the entire narcosis, and only toward the end a slight decline takes place gradually. A sudden unexpected fall in the blood-pressure never occurs. After narcosis the ether curve declines slowly and gradually. Chloroform lowers the blood-pressure considerably, even small doses possessing this action. The fall occurs suddenly with the onset of the narcotization and increases until the end; even after this the pressure continues to fall in every case, sometimes suddenly and without warning. These sudden falls vary in degree between harmless differences of a few millimeters, and others reaching such a depth as to be below the level, apparently necessary for the continuance of life. They resemble syncope attacks in every way. As these sudden remissions occur in every case they cannot be considered individual peculiarities. In every case, even where chloroform is given in very small quantities, these remissions occur without the slightest sign to announce their coming, and many come on even in cases where the anesthetic has been stopped for some time. He therefore concludes that ether is an adjuvant to the circulatory mechanism assisting it to do its best work, while chloroform on the other hand is harmful in every way. He advises the use of ether as an anesthetic in every case where it can be used, stating that at Tübingen it is given the preference always. [E.L.]

**Value of Modern Methods of Renal Diagnosis.**—Bryson<sup>3</sup> details cases to illustrate the value of cystoscopy, segregation of urines, cryoscopy, and the phloridzin test. His method of using the Harris segregator is minutely described. Conclusions are: (1) Urinocryoscopy in association with the separation of the urines is of distinct value, especially in connection with hematocryoscopy; (2) the phloridzin test is a very delicate and valuable one for the investigation of the functional capacity of the kidney, is not difficult of application, and should be made whenever possible before doing an operation on the kidney; (3) until further observations the freezing and phloridzin tests should be made separately. The polyuria often caused by the injection of phloridzin may modify the freezing point of the urine from the healthy kidney; (4) these tests should be regarded only as aids to diagnosis and as in no way taking the place of well established means of clinical reckoning. [A.G.E.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Placenta Prævia.**—Whitling<sup>1</sup> was summoned to attend a woman who had been three hours in labor with alarming bleeding. The patient, a multipara, aged 40, was usually quick in labor. Examination showed a presenting placenta, membranes intact, and the fetus lying to the right with limbs to the left, and vertex right occipito anterior. It being found impossible to reach the edge of the placenta and rupture the membranes without introducing the whole hand through the os, he determined to tear through the placenta and deliver. After a douche of izal and water at 115° F., and an injection of five grains of aseptic ergotin hypodermically into the gluteal muscle, fixing the fetus externally with the left hand, with the other he tore through the placenta, felt the head presenting, introduced the forceps and delivered the fetus in 3½ minutes, bleeding ceasing for the first time when traction began. Without delay the placenta was removed manually, the membranes dragging after. The aperture in the placenta was almost exactly in the center. Two hot intrauterine douches of the izal solution were given, the uterus contracting well, and no further hemorrhage occurred. The child, as was expected, was dead, but the mother had a normal recovery. [W.K.]

**Milk Secretion Replacing Menstruation.**—The case reported by Gauthier<sup>2</sup> is that of an unmarried woman of 25, who had had two previous suppressions of menstruation, each of three months' duration. At the time of the third suppression there appeared an abundant secretion of milk in the breasts. The menses did not reappear for seven months, during which time, and for several months afterward, there was an almost continuous lactation. For four or five days at the time of the month corresponding to the menstrual period the secretion was quite abundant, and became scanty during the rest of the month, without stopping altogether. The sexual organs were found to be normal. The cause is ascribed to a neurosis. [B.K.]

**Effects of Vaccination During the Menstrual Period.**—E. Rumley Dawson<sup>3</sup> reports the case of a woman, robust and healthy, who had been vaccinated in infancy, but was revaccinated at the age of 29. She fainted at the operation, which occurred on the second day of her menstruation. She lay down for two hours, arose, felt dizzy and again fainted. The menstruation ceased and did not return again. The vaccination took well, but she did not quite regain her usual health and her menses practically ceased for six months, her symptoms being those of a premature menopause. At the expiration of this time she began to feel tired and heavy, fainted and vomited several times in the course of two days, and finally she brought up two full pints of very dark-looking blood and was put to bed. The doctor made a diagnosis of gastric ulcer. But soon after being put to bed menstruation came on as profusely as before her revaccination. After this, the first normal menstruation since the vaccination, she gradually recovered her former health and menses returned at normal intervals. Dawson considers the accepted causes of hematemesis, gastric ulcer, cirrhosis of the liver, and cancer of the stomach, all of which are excluded by the history of this case, and evidently thinks that the hematemesis in this instance, if not a vicarious menstruation, was at least in some way connected with it, and claims that the lesson of the case is that it is not advisable to vaccinate at or during the menstrual period except under circumstances of great emergency. [W.K.]

**Tuberculosis of the Female Genitalia in Children.**—Bruening<sup>4</sup> reports the case of a girl of 4, of healthy antecedents. She had been ailing slightly since her second year, but the illness which preceded her death was of but a few weeks' duration. There was slight fever, progressive emaciation, abdominal distention and tenderness, occasional vomiting, dullness over the bladder and cecum, enlargement of spleen, red-

<sup>3</sup> Medical Bulletin of Washington University, January, 1903.

ness about umbilicus, etc. A diagnosis of peritonitis was made, and that the condition was a tuberculous one seemed certain on account of the enlarged lymph glands, dry rales over the lungs, etc. The primary seat, however, could not be determined. The autopsy showed general glandular tuberculosis, perforation of tuberculous intestinal ulcers, perforative tuberculous peritonitis, cheesy endometritis, and salpingitis, miliary tuberculosis of pleura, peritoneum, spleen and other organs. He searched the literature for similar cases and was able to collect 43 which occurred between the ages of seven months and 15 years. They are noted especially between the first and fifth, tenth and fifteenth years. Genital tuberculosis is usually secondary (75% of his cases) and may be either ascending or descending. The primary process may be everywhere, but is oftenest found in lungs or peritoneum. The fallopian tubes are affected in nearly all cases of genital tuberculosis, often other parts are affected with them. The ovaries are rarely the only diseased portion. A diagnosis during life is but rarely made, but were the uterine discharges examined more frequently for tubercle bacilli there is no doubt that a proper diagnosis would be made oftener. The prognosis is bad. [E.L.]

**Operations for Myoma.**—Freund<sup>1</sup> reports three cases illustrating three methods of operating under varying conditions. In the first a uterine myoma was removed by vaginal amputation, the greater part of the fundus and of the uterine body being retained, so that the woman after her recovery continued to menstruate regularly without pain. The second was a case of uterine myoma complicated with carcinoma, and a radical abdominal operation was performed, the diseased organ with appendages was removed, the broad ligaments cleaned out, and uterine arteries ligated. The patient recovered. In such cases Freund thinks any less radical procedure entirely inadequate if the case is operable at all. The third was a uterine myoma complicated with inflammatory adnexal tumors. In such condition he employs and recommends the supravaginal transverse incision as possessing many advantages over the median incision. [W.K.]

**Surgery in Tropical Lands.**—Ziemann<sup>2</sup> reports a case in which the patient recovered after a cesarean section had been performed on her by a midwife under very unfavorable circumstances. The patient, the wife of a missionary in West Africa, was so situated that a doctor could not be obtained. No narcotic being at hand, the operation was done without anesthesia. A transverse incision was made with a small vaccination lancet. The uterus was incised in its transverse axis. After the placenta had been removed the uterine walls contracted so strongly that suturing was not attempted. The edges of the uterine wound were tightly locked, one upon the other. The abdominal wound was closed with catgut sutures. The operation lasted 45 minutes and was accompanied by considerable loss of blood. Only a few artery forceps were obtainable. The patient was removed three times to dry beds in the first 31 hours. In the next 14 days the temperature rose only once to 37.9° C. The woman became perfectly well. The child died six months later from dysentery. Ziemann reports another remarkable case in which a negro was badly injured by a buffalo. The abdomen had a wound 16 cm. long, through which the coils of intestines protruded. The bowels and omentum had been lying in the dust and leaves for 36 hours. The intestines and abdominal cavity were washed on account of a beginning fibrinous peritonitis. No suppurative peritonitis developed and the patient recovered. [W.E.R.]

**Drainage After Laparotomy.**—Olshausen<sup>3</sup> divides operative cases into four classes: 1. Cases in which during operation pus or fetid material has proceeded from the operative field. 2. Cases in which partly extirpated tumors with raw surfaces remain behind. 3. Cases with perforated injuries of intestines or bladder. 4. Cases unclean through much soiling of the abdominal cavity with cyst contents, old blood, etc. Because of the large proportion of cures in these four classes, recovering without drainage, he concludes that drainage is

superfluous and reprehensible. Sippel, however, does not accept this conclusion. While he would not drain in the last two classes, in the second he might drain with tampons according to Mikulicz, and in the first he advocates ordinary drainage as the more certain method. One cannot say with certainty of any case that the patient will die without drainage or will live if drainage is employed. Much depends upon the sterility or virulence of the pus, also upon the resisting power of the abdominal surfaces and their power of absorption. But he thinks no convinced advocate of drainage would abandon the feeling of certainty which it gives for the risks of the opposite method in critical cases. Sippel also advocates abdominal irrigation for cleansing purposes and in his experience has never seen it cause shock or check heart action, though he has often seen it have a distinctly favorable influence upon the pulse. [W.K.]

**Cesarean Section and Ovariectomy on Account of Impacted Tumor.**—G. van der Briele<sup>1</sup> gives a detailed account of a woman of 30, multipara, in whom delivery was so obstructed by the presence of an impacted tumor as to render cesarean section necessary. In his closing remarks he says that each case must be a law unto itself, the method of treatment depending upon the different topographic and anatomic conditions existing. In the case reported there was an absolute indication for cesarean section, since the tumor lying in the birth passage was so firmly adherent that it could not be pushed aside, and therefore must of necessity be removed. [W.K.]

**A New Genus of Teratopagus.**—Marcel Baudouin<sup>2</sup> reports having found in the Museum of Pathological Anatomy of the Faculty of Medicine of Paris a specimen of teratopagus which constitutes a new genus. It is essentially characterized by the peculiarity that the union, instead of taking place between the umbilicus and xiphoid, in other words, at the level of the epigastrium, extends from the umbilicus to the prepubic region; or to that corresponding to the hypogastrium; wherefore he proposes for this monster the name of *hypogastropagus*. This type of teratopagus is viable. An hypogastropagus is evidently intermediary between a xiphopagus and an ischiopagus, which is a new proof of the fact that in the teratology of double monsters it is possible to find all transitions between the most widely separated types. [C.S.D.]

**The Importance of Determining the Leukocytes in Gynecologic Diseases.**—Weiss<sup>3</sup> reviews 23 illustrative cases taken from Chrobak's clinic in Vienna, and from these concludes that the determination of the number of leukocytes forms in gynecology a substantial aid in differential diagnosis in that constant leukocytosis with a number above 16,000 shows the presence of a suppurative process. If the process is of some duration, the number generally diminishes although noticeably high when medical advice was first sought. In cases of long-standing leukocytosis fails under any circumstances, and the physician in these cases must direct his treatment according to general principles determined by the general subjective condition of the patient and the objective condition of the genital tract. A negative condition of leukocytes in an acute illness or illness of short duration entirely excludes any suppurative process. [W.K.]

**Heterotopia in the Histologic Structure of a Fibrous Uterine Polyp.**—Pollak<sup>3</sup> reports the removal of a uterine polyp from a woman aged 37, gives an illustrated description of its histologic structure, showing many small patches of fatty tissue; and then discusses different theories to account for the presence of these fat cells, whether congenital or heterotopous in origin. As the patient had some years previously been cured, he concludes that the uterus was perforated at that time and that the opening extended to a part of the omentum which in a previous gonorrhoeal attack had become adherent and thus closed the perforation. At first the fatty tissue belonging to the omentum became the nucleus of the polyp formation, and secondly the efforts at separation and expulsion were answerable for the continuance of the polypus growth. **TREATMENT**

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPELMAN

**REVIEW OF LITERATURE**

**Massage in Cutaneous Therapeutics.**—G. Beauchef<sup>1</sup>

reviews the physiologic action, indications, and uses of massage in the treatment of cutaneous diseases and draws the following conclusions: 1. Massage is too often neglected in the treatment of cutaneous diseases. Its effects on the skin may be summed up as follow: (a) It frees the skin of epithelial debris, renders it supple, facilitates absorption, and cleanses the excretory ducts of the glands which it contains; (b) it increases the circulation of the blood and lymphatics of the skin, facilitating the nutritive changes and provoking increased phagocytosis; (c) it elevates the local temperature; (d) it facilitates the resorption of extravasated liquids, whether they be normal or pathologic; (e) it exerts a characteristic action on the cellular elements, increases their development and multiplication, and therefore plays an important part in the reparation of the epidermis; (f) moreover, it favors the excretion of the glandular products and stimulates the glands, for it increases the number of specific elements and especially the water eliminated; (g) finally, it influences remarkably the nerves of the skin, producing anesthesia of the sensory filaments, stimulating the motor, vasomotor, and trophic filaments. Through this it has an action on the entire nervous system. 2. The indications for massage are numerous: (a) To overcome thickening, and to facilitate resorption in chronic inflammations of the skin; (b) to stimulate secretion and to facilitate excretion in affections of the sebaceous glands and the sweat glands; (c) to combat circulatory disturbances in varicose ulcers, telangiectasis, etc.; (d) to combat pruritus and pain; (e) to improve trophic disturbances and to combat cutaneous pigmentation; (f) to stimulate the vitality of smooth areas in certain forms of alopecia. 3. Massage is useless or counterindicated in extensive acute inflammations, bulbous lesions of the skin, purely parasitic diseases, acute dermatoses due to general infection. 4. All the manipulations employed in massage may be used in treating the skin. They must always be begun gently and produce their effects according to the energy of application. [L.F.A.]

**The Cerebrin Treatment of Epilepsy.**—Lion<sup>2</sup> reports the results of Poehl's cerebrin treatment in 15 cases of epilepsy. In 2 cases there were no more attacks after the first dose of the drug; 5 patients were very much improved; in 7 patients the attacks became fewer and lighter; in 1 patient their number apparently increased, but their character changed from grand mal to petit mal. All of these patients were suffering from grave types of the disease. The extract is given either in tablet form or as subcutaneous injections. Each tablet corresponds to 4½ grains (0.3 gram) and he gives as many as 6 tablets daily after the patient has been under treatment for 3 weeks. After the desired result is attained he orders 6 tablets twice weekly. The injections are given every second or third day, depending on the case. [E.L.]

**Neoarsycodile.**—Neoarsycodile or sodium methylarsenite<sup>3</sup> is an organic compound of arsenic, analogous to the cacodylates, but distinguished from them by its permanency, which enables it to be employed by the mouth, even in relatively large doses. It is used with excellent results in tuberculosis and in nontuberculous affections of the respiratory tract, particularly in asthma and grip. It has also been employed in the treatment of anemia, in malarial fever, and in other affections in which arsenic is indicated. Neoarsycodile is administered in doses of from 2 to 9 centigrams (¼ to 1½ grains) for a period of five days, and then withdrawn for five days, continuing in this way until the patient recovers. It is rarely given in doses of more than 6 cg. (1 grain). The drug should be stopped if intolerance is manifested by the phenomena of congestion, breathlessness, or elevation of temperature. [L.F.A.]

**A Soluble Salt of Theobromin.**—Solacolu<sup>1</sup> calls attention to a soluble salt of theobromin, agurin, prepared by Impens, of Brussels. Agurin is a double salt of sodiated theobromin and sodium acetate. It is soluble in water and occurs as a white deliquescent powder, alkaline in reaction. It is precipitated from its solutions by organic and mineral acids. Solacolu employs it in beginning doses of 0.5 gram (7½ grains), gradually increasing it until 3 or 4 grams (45 or 60 grains) are being taken. It is usually given in cachets. In all the cases in which agurin was administered it caused an increase in the urine, which reached its maximum at about the fourth day of treatment. This diuretic effect persisted for several days after its administration was stopped. Slight increase in arterial pressure was noticed after its use. [L.F.A.]

**Theocin as a Diuretic.**—Minkowski<sup>2</sup> recently employed theocin as a substitute for theobromin with good results. Theocin is an isomer of theobromin. It is more soluble than the latter, more stimulating to the nervous system, and more rapid of action, even in smaller doses. The changes produced in the pulse rate and arterial tension are not more marked than by the use of theobromin. Theocin causes a greater increase of the urine than is caused by digitalis, diuretin, or agurin. Edema and ascites disappear rapidly. In some cases the ingestion of theocin is followed by vomiting, or by irritation of the stomach and loss of appetite. Minkowski combats this by suitable drugs and appropriate dietetic precautions. [L.F.A.]

**Kephyr.**—Duprat<sup>3</sup> has found kephyr an excellent substitute for milk in all conditions in which the latter is indicated. Kephyr is cow's milk which has undergone fermentation by the addition of kephyr grains. It contains, in addition to the usual constituents of milk, the new chemical elements and active substances which have produced fermentation. Kephyr owes its therapeutic results to the influence of each of these elements. It is very valuable in dyspepsia due to a deficiency of hydrochloric acid and pepsin; when the patients cannot take milk, kephyr is often well borne, and is more tonic in its effects. In tuberculous patients and in those whose nutrition is faulty, kephyr acts as a general stimulant and permits of suralimentation without trouble. It has also been employed successfully in the treatment of acute gastroenteritis and dyspepsia in children. Equally good results have been obtained from its use in chronic enteritis of children. In these cases it does good by acting as an antiseptic, diminishing the tendency to vomit and acting as a stimulant to the mucous membrane of the gastrointestinal tract. [L.F.A.]

**FORMULAS, ORIGINAL AND SELECTED.**

**Ointment for Chapped Hands.**<sup>4</sup>—Steffen is credited with the following formula in the *Journal de Médecine de Paris*:

Menthol . . . . .	3 parts
Salol . . . . .	4 parts
Olive oil . . . . .	4 parts
Lanolin . . . . .	100 parts

To be applied twice a day. It is said that the pain disappears, the skin softens, and the fissures heal promptly.

**THE PUBLIC SERVICE**

**Health Reports.**—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 7, 1903:

SMALLPOX—UNITED STATES.			Cases	Deaths

Changes in the Medical Corps of the U. S. Army for the week ended March 7, 1903:

MANSFIELD, ELMER E., contract surgeon, will proceed to Camp Monterey, Cal., for duty.

TWEEDIE, H. V., contract surgeon, is granted leave for one month.

MCANDREW, First Lieutenant PATRICK H., assistant surgeon, having reported his arrival at San Francisco, Cal., will proceed to Jefferson Barracks for duty.

AMES, ROGER P., contract surgeon, now at New Orleans, La., will proceed to Fort St. Philip for duty, to relieve Contract Surgeon Oliver H. Buford, who will proceed to his home, Cartersville, Ga., for annulment of contract.

KARLSON, IVAN N., hospital steward, now at Rock Island Arsenal, Ill., is relieved from further duty at Jefferson Barracks and assigned to duty at his present station.

HAUGHEY, PATRICK, hospital steward, is relieved from further duty at Rock Island Arsenal, Ill., and will proceed to San Francisco, Cal., and will report for duty aboard the first transport leaving San Francisco for the Philippine Islands.

WILLIAMS, CHARLES F., contract surgeon, will proceed to his home, Yorkville, S. C., for annulment of contract.

HULL, A. R., contract surgeon, leave granted for twenty days is extended ten days with permission to apply for a further extension of ten days.

The following changes in the stations and duties of officers are ordered: Captain Henry Page, assistant surgeon, is relieved from duty at Fort Monroe and will proceed to Fort Mason for duty to relieve Captain George J. Newgarden, assistant surgeon. Captain Newgarden will proceed to Fort Harrison for duty. First Lieutenant James R. Church, assistant surgeon, is relieved from duty at the U. S. General Hospital, Washington Barracks, D. C., and will proceed to Fort Trumbull for duty, to relieve Captain Irving W. Rand, assistant surgeon. Captain Rand will proceed to Fort Wright for duty. First Lieutenant John D. Yost, assistant surgeon, is relieved from further treatment at the U. S. General Hospital, Presidio, and will report for assignment to duty in the office of the attending surgeon and medical superintendent, Army transport service, San Francisco, Cal., to relieve Contract Surgeon William P. Banta (appointed first lieutenant, assistant surgeon), who will proceed to Fort Sam Houston for duty.

Orders of February 27 relating to Contract Surgeons Roger P. Ames and Oliver H. Buford are revoked.

AMES, ROGER P., contract surgeon, will proceed from New Orleans, La., to Fort Barrancas for duty, to relieve Contract Surgeon Dwight C. Powell, who will proceed to his home, Logansport, Ind., for annulment of contract.

BYRNE, JOHN G., contract surgeon, now at Fort Flagler, is relieved from duty in the department of the Columbia and will proceed to his home, Chicago, Ill., for annulment of contract.

ENDERS, WILLIAM J., contract surgeon, leave granted September 18 is extended twenty-four days.

VANE, PATRICK P., hospital steward, Manila, P. I., will proceed to San Francisco, Cal., and will report to the commanding general, department of California, for assignment to duty.

Changes in the Medical Corps of the U. S. Navy for the week ended March 7, 1903:

BIDDLE, C., surgeon, detached from the Naval Hospital, Philadelphia, and ordered to the Navy Yard, League Island—February 28.

BOGERT, E. S., surgeon, detached from the Recruiting Rendezvous, Buffalo, and ordered to the Philadelphia Naval Hospital—February 28.

BYRNES, J. C., surgeon, detached from the Navy Yard, New York, ordered home and granted three months' sick leave—February 28.

DEHL, O., surgeon, detached from Navy Yard, League Island, and ordered to the Oregon, sailing from San Francisco, Cal., March 19—February 28.

COOK, F. C., passed assistant surgeon, detached from Naval Hospital, Newport, R. I., and ordered to the Nevada—February 28.

HOLCOMB, R. C., passed assistant surgeon, detached from the Naval Hospital, New York, and ordered to the Naval Hospital, Newport, R. I.—February 28.

DEAN, F. W. S., assistant surgeon, ordered to the Naval Hospital, New York—February 28.

SUTTON, R. L., assistant surgeon, ordered to the Naval Hospital, Washington, D. C.—February 28.

MEARS, J. B., acting assistant surgeon, ordered to the Naval Recruiting Station, Buffalo, N. Y.—February 28.

RIGGS, C. E., assistant surgeon, ordered to the Naval Hospital, Philadelphia, Pa.—March 3.

ORVIS, R. T., passed assistant surgeon, detached from the Michigan, and ordered to duty with marine detachment at Culebra—March 4.

FOSTER, T. G., acting assistant surgeon, ordered to the Michigan—March 4.

Changes in the Public Health and Marine-Hospital Service for the week ended March 5, 1903:

CARTER, H. R., surgeon, to proceed to Morgantown, W. Va., for special temporary duty—March 5, 1903.

GUITERAS, G. M., surgeon, to report at Washington, D. C., for special temporary duty—February 28, 1903. To proceed to Eagle Pass, Texas, for special temporary duty—March 2, 1903.

WERTENBAKER, C. P., passed assistant surgeon, to proceed to El Paso, Texas, for special temporary duty—February 28, 1903.

ROSENAU, M. J., passed assistant surgeon, detailed to represent service at meeting of special committee on diphtheria antitoxin at Philadelphia, Pa.—March 7, 1903.

OAKLEY, J. H., passed assistant surgeon, granted leave of absence for seven days from March 1, 1903—February 28, 1903.

DECKER, C. E., assistant surgeon, granted fourteen days' extension of leave of absence on account of sickness from February 20, 1903—February 28, 1903.

LUMSDEN, L. L., assistant surgeon, relieved from duty at San Francisco Quarantine Station, and directed to proceed to Los Angeles, Cal., and Phoenix, Ariz., for special temporary duty—February 28, 1903.

KERR, J. W., assistant surgeon, to proceed to Nogales, Tombstone, Tucson and Phoenix, Arizona, for special temporary duty—February 27, 1903. Bureau order of February 27, 1903, directing Assistant Surgeon J. W. Kerr to proceed to points in Arizona, suspended, and directed to assume temporary command of the Service at New Orleans, La.—February 28, 1903.

GIBSON, R. H., pharmacist, granted leave of absence for seven days, under the provisions of paragraph 190 of the regulations—March 2, 1903.

Promotions.

VON EZDORF, R. H., assistant surgeon, commissioned as passed assistant surgeon, to rank as such from March 4, 1903.

ANDERSON, J. F., assistant surgeon, commissioned as passed assistant surgeon, to rank as such from March 18, 1903.

PUBLISHED WEEKLY AT 1321 WALNUT STREET, PHILADELPHIA, BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. V, No. 12.

MARCH 21, 1903.

\$5.00 YEARLY.

The attitude of the public press of San Francisco toward all those who maintain the demonstrated truth about plague has not abated any of its former virulence. A recent editorial in one of these newspapers calls upon the California representatives at Washington to explain why the United States Treasury Department was not prevented from notifying other American republics of the existence of plague in San Francisco. Attack is made indiscriminately upon any and all who express belief in the past or present existence of plague. Even *American Medicine* has been attacked in approved yellow journal style in San Francisco on account of an editorial in our issue of February 21. Our friends assure us, however, that Drs. Williamson, Buckley, Baum, and Lewitt have developed heroic strength under a steady downpour of such atrocious billingsgate, and that whatever is good for men of their mettle is also good for *American Medicine*. The contest is waged not alone for truth and publicity in matters of public health, but at stake is the liberty of sworn officials to do their duty. There is always the saving remnant who count honor and courage more than expediency or than dollars and cents. At their hands the reputations of the defenders of our professional faith will receive eventual vindication, and with them the pleaders for "peace at any price" and the prophesiers of smooth things must reckon.

**The Plague Condition in California.**—Three recent manifestos from as many responsible sources offer us comforting assurance concerning plague politics and conditions. These are the resolutions of February 2 by the San Francisco Mercantile Joint Committee, the published statement by Dr. Vincent P. Buckley on February 9, and the telegram of Surgeon-General Wyman on February 22. Examined in the light of concurrent events, not alluded to in official correspondence, each of these utterances loses part of its earnest of good things. The resolutions of the Mercantile Joint Committee were in part signed by the Governor of the State, the Mayor of San Francisco, the City Health Officer, the only member of the State Board of Health, the Surgeon-in-charge of the United States Public Health Service, and by the presidents of seven commercial bodies, as follows:

"WHEREAS, Competent medical authority has declared that bubonic pest has existed to a limited extent in the restricted

area known as Chinatown in San Francisco, the last case having been reported December 11, 1902, and although the health authorities have exercised sanitary supervision over this section in the past,

"Nevertheless, this undersigned joint official statement is promulgated in accordance with the resolutions adopted at the Conference of State Health Officers, held at Washington, D. C., January 19, 1903, as an assurance that there is no present or future danger from that disease, inasmuch as complete and harmonious action by all health authorities concerned is hereby assured, and will be maintained."

These resolutions did not make it clear whether the signers did or did not mean to admit the existence of plague. The doubt has been resolved by Mr. L. M. King, secretary of the Mercantile Joint Committee, the proponents and publishers of the resolutions. In the March number of *Merchants' Association Review* Mr. King prints a long article, in which he says:

"It would be as presumptuous for the Association to admit the existence of a thing it knows nothing about as it would be dishonest to deny its existence if it knew plague were here. It is not a health board, and has never considered itself competent to decide a question of pathology on which doctors disagree. Hence it cannot reasonably or decently be called to account for refusing to make an admission that would add nothing to the controversy." (Italics ours.)

Mayor Schmitz did not mean to admit by his signature the past or present existence of plague. Quite the contrary. How shall we discover the meaning of the resolutions as understood by the other signers? Which of them holds the neutral position of the commercial bodies? Do any of them agree with Mayor Schmitz? Have any of them the conviction that plague is or has been present in California? Have these joint resolutions any meaning? These same commercial bodies published in May, 1900, a resolution to the effect that "the city, State, and federal authorities have declared that there is no case of plague in existence" in San Francisco, and "the directors of the Association declare that there has not been in the past and is not at the present time any occasion for alarm." This earlier resolution is now said by Mr. King to have neither admitted nor denied the existence of plague.

**The "Harmony" of Scientific and Commercial Interests in California.**—Dr. Buckley is one of the five courageous medical men who have upheld the good name of the City Board of Health of San Francisco against a continuous storm of abuse during the past

three years. About February 8 Dr. Buckley prepared a memorandum on the progress of plague. Four newspapers obtained copies of this statement, but not one of them printed it in full. It was no accident that the four offices were unanimous as to what part of Dr. Buckley's "copy" should be printed. This is what appeared:

"During the past 60 days no case of bubonic plague has been discovered in this city, and at no time during that period has the Board of Health, of which I am a member, published or recorded any case of that disease. In view of this fact vessels clearing from this port are given clean bills of health. It is with great pleasure that I make this statement and at the same time denounce as false any and all statements contrary to what is herein contained."

We know nothing about the suppressed matter, but the printed statement consists apparently of two fragments which can hardly have been intended by Dr. Buckley to appear in juxtaposition. The printed statement contains nothing to provoke denial from any quarter, and it seems probable that Dr. Buckley's denunciation of falsehood would have been immediately understood if his communication had been printed in full. On February 22, 1903, Surgeon-General Wyman, of the United States Public Health and Marine-Hospital Service, telegraphed to Mr. Symmes, Chairman of the Mercantile Joint Committee, in part as follows: "No case of plague has been discovered since December 11, nearly two months and a half ago, and then only one case. Official reports show that the national, State, and city authorities are working in thorough harmony under the leadership of the federal officers." It will be remembered that one of the resolutions of the conference at Washington on January 19 named as a condition necessary to the safety of the country that "a competent City Board of Health and a competent State Board of Health in cooperation with the United States Public Health Service" must be "jointly and severally in the free exercise of their lawful powers." Until the middle of February, 1903, the sickness and death inspections in Chinatown were made by physicians appointed by the Gage Board of Health to conceal plague. For nearly three years detectives have been constantly employed to shadow the movements of United States Public Health officers and of all other persons who were known to be honestly looking for plague. By such methods the work was so well done that in 1901 an interval of 93 days passed without the discovery of a case of plague. Good men are now engaged in the inspections, but we are not informed whether the detectives are still active. The State Board of Health of California should be included in a "thorough harmony." There is no State Board of Health. Governor Pardee has withdrawn from the Senate those appointed by ex-Governor Gage and has not as yet named their successors. The State Board of Health of California now consists of one man, Dr. Matthew Gardner, chief surgeon to the Southern Pacific Railroad, a corporation whose immense power has from the first been exerted to suppress the facts and to crush the truth-telling officials of the city, State, and nation. The only sign of a change of heart manifested by the Southern Pacific is the fact that Dr. Gardner confessed in Washington his belief

that plague existed in San Francisco. The "harmony" of the City Board of Health of San Francisco is turbulent. Five physicians appointed by the mayor, with the chief of police and the president of the Board of Public Works, constitute the City Board of Health. Up to January 8, 1903, of the five physicians four, Drs. Williamson, Buckley, Baum, and Lewitt, stood firm for the truth about plague, and with the aid of the chief of police were enabled to make a good fight against both plague and commercial obstruction. On January 8 the term of Dr. Williamson expired, and he was succeeded by a pronounced partisan of Mayor Schmitz's antiplague views. The chief of police notified Dr. Buckley that he could no longer vote with the "stalwarts," because he had been notified by Mr. Newhall, police commissioner, that he must do the mayor's bidding or lose his office. Dr. Buckley published his own affidavit to this bit of history. Unexpected aid came to the "old guard" in the person of the other exofficio member, who has a political grievance and for the present votes against the mayor. Early in February Mayor Schmitz proposed at the General Assembly a bill to prevent the courts from restraining the mayor of San Francisco in the exercise of his power to remove city officials. This bill has passed both House and Senate, and is now in the hands of Gov. Pardee. The most active worker in its behalf was William F. Herrin, chief counsel for the Southern Pacific Railroad. Its confessed intent is to enable Mayor Schmitz to oust Drs. Buckley, Baum, and Lewitt from the City Board of Health, and the newspapers are now gibing at the "expiring wriggles of the bubonics." On February 20 the mayor instituted *quo warranto* proceedings for the purpose of removing Drs. Buckley, Baum, and Lewitt. The complaint cites the allegations made in the mayor's original letter of removal, dated March 25, 1902:

"Following is the cause for which you are removed, to wit: Continued injury and injustice to the people of the city of San Francisco and of the State of California, and to their commercial and financial interest, in declaring, proclaiming, and publishing under your official sanction, and without proper foundation or justification in fact, that bubonic plague exists in San Francisco, and that it has existed therein since March 6, 1900."

Under such conditions as are here set forth no one can believe that the national, State, and city authorities are "jointly and severally in the free exercise of their lawful powers," and it seems most difficult to reconcile such circumstances with the statement that the national, State, and city authorities are "working in thorough harmony under the leadership of the federal officers."

**The Fight Against Tuberculosis in Germany.**—According to the Imperial Health Office in Berlin the deaths from tuberculosis are about one-tenth of those of all diseases. In 1899 the number of patients treated in hospitals in the Empire was 226,000. According to the latest statistics there are at present 57 public sanatoriums for the tuberculous in Germany, of which 34 are located in Prussia, 6 in Bavaria, 2 in Saxony, 1 in Wurtemberg, 1 in Hessen, 1 in Sachsen-Weimar, 1 in Thuringia, 1 in the Reichsland, 3 in Baden, 2 in Brunswick, and 5 in the Hansa cities. Besides these there are 4 institutions

near the sea, namely, Nordeney, Wyk, Gross-Müritz, Zoppot. There are also 23 public sanatoriums nearly completed, among these being Buch, near Berlin. The city of Berlin has at the present time 3 public sanatoriums, namely, Malchow, Blankenfelde, Gütergotz. There are also 20 private German sanatoriums, and 1 in Davos (Switzerland). In the 78 sanatoriums for tuberculous there are 7,000 beds. If we calculate that each bed is used by 4 persons in the course of a year, we find that about 30,000 tuberculous annually enjoy the benefit of treatment in the sanatoriums. The efforts made in the German Empire to combat tuberculosis, both by direct regulations and by general preventive measures, are being actively carried on. In particular, the Imperial Government, the governments of the different States, the executive authorities, the national insurance institutions, and the municipal governments are seriously and actively participating in this work. The result of these efforts, which have now been carried on for some years, is already noticeable in a decrease in the number of deaths from tuberculosis, which in the future will be still more marked. Success in combating tuberculosis depends, in the first place, upon the proper disposal of the sputum. It would be interesting to know if the statistics show a rise in the pneumonia mortality, almost in proportion to the fall in tuberculosis—a fact which seems to be pretty well established in this country. The significance of this fact seems to be insufficiently appreciated by us.

**The Crime of Encouraging Beggary.**—Mr. Benjamin C. Marsh has been making a study of criminal charity as illustrated in the support and encouragement of beggary in Philadelphia. He found that the Wayfarers' Lodge is avoided by the beggars. There were 110 empty beds at the Lodge. In the popular religious and other lodging-houses, missions, etc., there was indecency, dirt and sham, while laziness and beggary were encouraged. Applicants were actually told where to go to beg for tickets which had been sold to the "charitable" at the rate of ten for \$1. These tickets are exchangeable for drinks at the neighboring saloons. "It's a disgrace to work in Philadelphia when you can get along so easily without doing a stroke." This was said by a "five-cent flopper," *i. e.*, one of hundreds who are allowed to sleep on the floors of some of the cheap lodging-houses for five cents. Mr. Marsh begged \$1.15 in an hour, as a test. "Most ministers are dead easy blokes," said a comrade. "By an ironical propriety," says Mr. Marsh, "the lodging-houses in Philadelphia are under the supervision of the Inspector of Nuisances. There are 106 cheap ones in the city, accommodating 4,643 lodgers." He heard one superintendent of a mission deliver a tirade against "selfish wealth." At the Sunday Breakfast Association there were about 800 in attendance who had come, as the leader said, for "spiritual food." The filth, mental, moral and physical, of the conditions at the places liked by the beggars were in glaring contrast to those of the Wayfarers' Lodge, with its 110 empty beds. But here a work test is asked of those who are able. That selfish and lazy charity is an expensive luxury is a truth Philadelphians

appear slow to learn. In Baltimore recently the blind, lame, armless, and crippled beggars were brought in by the police, and all were suddenly transformed into seeing, sound, whole, and healthy scalawags.

**"Patent Medicines," "Bitters," and Nostrums as the Cause of Alcoholism, Etc.**—We would like to call the attention of the *New York Weekly Witness* (see our issue of January 2, 1903, page 2) and also of many other saintly defenders of their nostrum advertisers, to an article by Dr. Lewis D. Mason in the *Journal of Inebriety* for January, 1903. Dr. Mason divides these nostrums into two classes:

*First.*—Those advertised for the relief of various painful affections, such as neuralgia, rheumatism, gout, etc., the basis of which is opium or its alkaloids, or a class advertised as "tonic," the basis of which is alcohol in some form.

*Second.*—Patent medicines advertised as "cures" for the liquor or opium habit, the basis of which is frequently in the former case *alcohol*, and in the latter *opium* or its alkaloids.

To illustrate "the way of the world," the following example of the concoction and history of a nostrum is given:

"Make the basis whisky; put in some opiate; disguise the whole with a bitter tincture; get high-sounding testimonials or indorsements, and especially give it an attractive, 'taking' name. Then extensively advertise it from 'Dan to Beer-sheba' and the thing is done. The young man got up such a preparation, called it 'Scotch Oats Essence'; and secured indorsements and testimonials of a high character and advertised extensively. He spent over \$40,000 on the investment. A friend of mine analyzed the preparation, published the formula, showing it contained morphin. As a result the sales fell off, insolvency and financial ruin followed. Then the proprietor drank himself to death, mortified at his failure and public exposure."

It is one of the saddest facts that American legislatures will permit this horror to go on indefinitely. That the alcohol and morphin "cures" contain the very drugs themselves they are hypocritically supposed to overcome is diabolism run mad. When we become civilized the first evidence will consist in laws making it a highly punishable offense to sell any patent medicine containing alcohol, opium, or other narcotic, unless the label shows the exact constituents.

**"Institutional Quackery."**—In 1893, according to Dr. Lewis D. Mason (*Journal of Inebriety*, January, 1903), the New York Academy of Medicine

*Resolved*, That it is the sense of this meeting that all institutions for the care and treatment of those addicted to the use of alcohol, opium, or kindred drugs, should be under the supervision and inspection of a State commission, which should consist of experts in these specialties, and which should exercise its duties, under the same privileges and opportunities as are now extended to a similar commission consisting of experts on insanity, whose duty it is to supervise and inspect the care and treatment of the insane in the various insane asylums of the State.

For ten years the abuse which this resolution was designed to prevent has been growing at an astounding rate. The greatest dignitaries of the land, as we illustrated editorially page 994, December 27, 1902, now support institutions devoted to the treatment of various forms of inebriety by secret methods. At the meeting of the Society for the Study of Inebriety held in Boston December 18, 1902, it was again

*Resolved*, That we reaffirm and indorse a resolution passed at a meeting of this society held March 23, 1893, in reference to the licensing and proper inspection of all institutions for the care and treatment of inebriates, morphia habitués, or other forms of narcomania.

Why should such institutions wish really to cure their patients? The longer their victims stay and the more frequently they relapse and return the better for the owners and stockholders. This is the sole argument needed against the support of institutional quackery. The State should assume the oversight of these places and as the first step in reform abolish secrets in the treatment of the patients.

**Penalizing the transmission of venereal infection** has been a measure we have often advocated. What greater absurdity is there than making it a crime for one suffering from smallpox, etc., knowingly to expose himself to others, and to allow those with venereal disease surely to infect others with the most loathsome of all afflictions, perhaps to kill them—all for a moment's gratification. A sense of this revolting illogicality, it seems, has made itself evident in Paris, where an important judgment has recently been delivered by the Tribunal of the Seine, by which the transmission of syphilis by persons knowing themselves to be affected, even though they do not willingly transmit the disease, becomes a penal offense, for which an indemnity can be obtained by the recipient. In the case before the court a man suffering from syphilis had sexual intercourse with, and infected, a girl aged sixteen, who had previously been perfectly healthy. The court granted her substantial damages to the extent of 12,000 francs. This, we hope, is the beginning of the end of the hideous injustice by which libertinage has been free to pollute and murder multitudes of innocent wives and children, and to shove upon the community the terrible economic burden of the millions of hopelessly diseased and good-for-nothing sufferers. We have before demonstrated that the venereally diseased are not worth their keep. They become a dead weight upon the profession and the benevolent, a curse to themselves and the world, and all because we stupidly refuse to penalize the crime that keeps it up.

**Chicago's drainage canal and sewer system**, if we may judge from the reports of the latest Bulletin of her Health Department, are dismal failures. "Untreated hydrant water" is earnestly advised against, and the warning given that there is imminent danger of another outbreak of typhoid fever. "The city sewer system is outgrown." Mayor Harrison recently asked the Comptroller's office for an opinion on these subjects and the Comptroller replied that until a branch is constructed to connect the canal with the Calumet district, Chicago will not get the benefits for which so much money has already been expended. Nine-tenths of Chicago's drainage has been diverted from Lake Michigan to the canal and thence to the Mississippi, but the remaining one-tenth is able to make almost as much trouble as the entire lot. The Calumet district, which has been increasing greatly in population, drains into the Calumet river, and it, in turn,

empties into the lake. There is the whole trouble. "The use of great sums of money in the building of the sanitary canal was a political crime, unless the Calumet district were included," declares the Comptroller. We should hesitate to quote the following passage were it not taken from the Health Department's Bulletin itself: "Chicago's head may be among the stars, as a recent writer claims, but her feet are in the mire, and the mire grows deeper and deeper year by year." Have the two cities yet settled the question, Can bacteria voyage successfully from Chicago to St. Louis via the drainage canal?

**The duties and responsibilities of physicians as to preventive medicine** has been a constant theme of *American Medicine* since its foundation, but we have nowhere seen a better summary and a more enheartening plea concerning the matter than that of Dr. Burnside Foster, concluded in our forelying issue. We trust every subscriber will read every line of it. Among many subjects illuminated by Dr. Foster there is one which has been frequently urged in these columns—a more thoroughgoing and businesslike saving of their money by insurance companies through preventive medicine as applied to their policy-holders. At present they are paying out vast sums of their money because of needless and premature deaths. Periodical examinations of policy-holders, in order to detect the early symptoms and to prevent the ripening of subtle diseases, are strangely omitted by the companies. A capital suggestion is that urged whereby these organizations should insert in every policy the conditions that nostrum-taking or nontreatment, as, *e. g.*, by the eddyite and other quack methods, shall invalidate the contract. Why should an insurance company pay out its money and needlessly raise the rates to all others because of the hastened deaths of the foolish at the hands of the nostrum syndicates and of criminal ignorance?

**The Responsibility of Accident Insurance Companies as to the Results of Infection.**—The conclusion reached by insurance companies that the suicide clause is an insufficient defense is now followed by a further admission that contested claims do the companies more harm than good. This conclusion will be put beyond further doubt by a recent legal decision in Great Britain which defined a policy-holder's right to recover under an accident contract in cases where death results from disease weeks after the injury has been received. The patient died of septic pneumonia following and caused by erysipelas after a simple scratch on the leg. In the decision of the justice it was said if it was once agreed that the same scratch broke the man's skin and introduced into the wounded surface the germs which eventually poisoned him, the conclusion was irresistible that the morbid condition of the illness which was ultimately fatal was directly and solely caused by the wound. Suppose a man was bitten by a mad dog and died of hydrophobia, the court should say that the death resulted from the bite, although the actual destruction of life resulted not from the bite but from the poisoning set up by the bite. The professional verdict upon this decision must be that it is sound, scientific, and just.

The right to do as one pleases about himself and his health, urged by Mark Twain and other social pseudo philosophers, is getting its "everlasting no" at the hands of disease and in the interests of the common weal. More tyrannical, but more justly so than any tyrant is democracy when it comes to consciousness and realizes the pathologic power of the foolish or selfish individual to work harm to all by his folly and selfishness. The question now is not "Am I my brother's keeper?" but, rather, Is he mine? By a recent act of the Ithaca Board of Health it is a made a misdemeanor punishable by \$50 fine or fifty days in jail for any one to drink unboiled water or to furnish it to others for that purpose.

EDITORIAL ECHOES

**Education and Tuberculosis.**—To break the nefarious trade of the man who deals in "sure and infallible" pulmonary tuberculosis remedies, to stop the practice of the man and woman who claim to be able to diagnose and treat pulmonary tuberculosis by letter, the Christian scientists, the faith curists, who ridicule preventive measures and the laws of cleanliness and hygiene—which are the laws of God—but who, as a token of faith, demand their fees in advance, we have but one weapon, and that is education—education by a conscientious press, the clergyman, and the teacher.—[*Dr. S. A. Knopf.*]

**The Nostrum Traffic.**—There are also nostrums which promote and intensify the very condition which they pretend to cure. These are composed largely of alcohol. Most of the so-called "bitters" come under this classification. The annual report of the Massachusetts Board of Health for 1896 is a classic on this subject. It contains analyses of sixty-one kinds of bitters, tonics and sarsaparillas then in vogue, some of the most notorious of which are still on the market, and many of which have been advertised as "purely vegetable," "free from alcoholic stimulants," "not a rum drink," etc. Parker's tonic, "recommended for inebriates," was found to contain 41.6% of alcohol. Ayer's Sarsaparilla contained 26.2%, Hood's Sarsaparilla 18.8%, and Paine's Celery Compound 21%. A lot of "blood purifiers" were found to contain iodid of potassium, which is classed among poisons by nearly every writer upon toxicology. "It is not uncommon," says the Massachusetts report, "to find persons who have used continuously six, eight, or ten pint bottles of one of these preparations." They can usually be identified by their pale, sallow complexions. There is another class of nostrums that may be called unmitigated swindles, as where bread pills are sold for the price of costly drugs. An instance of this kind was given in the Massachusetts report, where "Kaskine," a much-vaunted remedy, which sold at \$1 an ounce, was found to consist of nothing but granulated sugar.—[*N. Y. Evening Post.*]

**On the Existence of Arsenic in Animals.**—G. Bertrand communicates a note on his researches which tend to demonstrate the presence of minute quantities of arsenic in marine animal organisms—in other words, in creatures living far from all possible contaminations which might result from more or less direct contact with modern industries. These researches have been carried on in animals of the greatest diversity, and establish the fact that arsenic is not characteristic of certain groups of beings, but is found throughout the entire animal series. This metalloid exists in all the tissues, and appears to be one of the fundamental elements of protoplasm. A. Gautier, commenting on the report of Bertrand, states that from his researches on domestic and wild animals, arsenic appears to be exclusively localized in the ectodermal organs.—[*La Semaine Médicale*, November 19, 1902.]

AMERICAN NEWS AND NOTES.

GENERAL.

**Cholera in the Philippines.**—It is reported that since the present outbreak of the epidemic of cholera in the Philippine Islands not fewer than 25,810 cases have been reported. The disease is still exceedingly epidemic in the Moro country and in Misamis. In the latter locality many natives are dying daily. One American surgeon and two assistants are in charge.

**Smallpox in Trinidad.**—Dr. Bridger, who has been commissioned by the authorities of the Island of Barbados to investigate the eruptive fever prevailing in the Island of Trinidad, reports that it is a widespread and rapidly increasing epidemic of smallpox. He bases his statement on evidence obtained and on observations made. The Trinidad medical board, however, declares that smallpox does not prevail there epidemically, and that the eruptive fever referred to is not smallpox.

**Hospital Benefactions.**—LOWELL, MASS.: Frederick F. Ayer, of New York City, has made a gift of \$100,000 to the Lowell General Hospital and has promised to give \$5,000 additional toward the floating debt provided that the debt is raised immediately. CAMBRIDGE, MASS.: Miss Agatha Schurz and Miss Marianne Schurz, of New York City, have given \$3,000 to establish the Herbert Schurz Memorial Fund for the care of needy students at the Stillman Infirmary. BOSTON, MASS.: Under the will of the late Jacob H. Hecht the Massachusetts General Hospital and the Boston Lying-in Hospital each receives \$5,000, the Industrial School for Deformed and Crippled Children \$500, and smaller amounts are given to various other hospitals and similar charities.

**Miscellaneous.**—PHILADELPHIA, PA.: On March 11 William B. Atkinson completed his fiftieth anniversary as a practitioner of medicine in the city of Philadelphia, he having graduated from the Jefferson Medical College March 11, 1853. In this class there were 223 members, and Dr. Atkinson with only five more members of the total number survive. The doctor on the date mentioned held a reception at which many people assembled to offer congratulations and good wishes. Many letters and telegrams were received expressing the same sentiments. NEW YORK CITY: Dr. George L. Mylan, of Boston, has been elected adjunct professor of physical education and medical director at Columbia University, and will enter upon his new duties next fall. Dr. D. S. D. Jessup, one of the teaching staff in the New York College of Physicians and Surgeons, has been appointed medical visitor to Columbia University.

**Decrease of Lepers in Hawaii.**—According to the report of Governor Dole to the Legislature, leprosy has decreased greatly in the Hawaiian Islands during the past 12 years. This decrease is attributed to the rigid enforcement of the law requiring the segregation of those afflicted with the disease. Governor Dole's message contains the following statement: "Since 1887 the law has been vigilantly carried out. The number of admissions in 1888 was 579, in 1889, 308, and in 1890, 202, and from that year to the present time the admissions have decreased in number, though not regularly from year to year, but taking the 12 years beginning with 1890 and ending with 1901, in sections of three years each we find the admissions to be as follow:

1890 to 1892 inclusive.....	454
1893 to 1895 inclusive.....	445
1896 to 1899 inclusive.....	350
1899 to 1901 inclusive.....	254

Several bills which have been recently introduced into the Hawaiian Legislature are of interest. One repeals all laws pertaining to leprosy; another permits all persons to treat leprosy, and a third prohibits persons afflicted with leprosy or tuberculosis from remaining in the territory.

EASTERN STATES.

**Cleaner Street Cars.**—A set of resolutions has been submitted to the Cambridge Board of Health, asking that they be made a part of the municipal law. According to them at the end of each day every car in the service of a street railway must be thoroughly fumigated and during the time any car is in use the ventilators must be kept open at least one inch, and at the end of each trip ventilators and doors must remain open until the car goes out on the next trip. A copy of the resolutions is being placed in each car and in each car house. The penalty for violation is \$100.

NEW YORK.

**Glanders in New York.**—Officials of the Health Department of New York have concluded from investigations that glanders is more prevalent than was formerly supposed. Active measures are being taken to combat the disease and orders have been issued for the destruction of all horses that are found to have glanders. In a stable in which the disease was discovered to be epidemic the health department representatives found that within the past three months 13 horses had died and 7 others had been killed or removed.

**Typhoid in West Seneca.**—Dr. Walter Green, health commissioner, and Edward Clark, his deputy at Buffalo, have been sent to Seneca as representatives of the State Department of Health to combat the typhoid epidemic now prevalent there. There are now about 170 cases of typhoid in West Seneca, and there have been many more.

**Trachoma in School Children.**—In spite of the fact that physicians of the Health Department continue to inspect the schools, trachoma is still giving as much trouble as when the crusade against it was first instituted. The disease is confined almost exclusively to the lower East Side of Manhattan. This is probably due to the fact that a child who has been treated and cured is reinoculated by parents or other persons in the family. Since the establishment of a hospital and a dispensary for the treatment of trachoma in the old Gouverneur Hospital early in December, there have been treated from 400 to 700 cases daily up to the present time.

**Armstrong Bill for Trained Nurses.**—Representative trained nurses and representatives to the number of 30 from the New York Presbyterian Hospital, and from training schools in Utica, Buffalo, and Rochester, have appeared before the Senate Judiciary Committee at Albany in support of the Armstrong bill, establishing the degree of trained nurses, to be conferred by the Board of Regents upon such as pass the required examination and have had the previous necessary training. The only opposition to the bill is based upon the requirement that the examining board shall be nominated by the Nurses' Association. It is believed the bill will pass.

**Rev. Dr. Parkhurst and Eddyites.**—In a sermon on "Sin," the Rev. Dr. Parkhurst is quoted as having used the following language with reference to the eddyites: "I should not want to stand sponsor for all the methods and teachings of Jonathan Edwards, but if there could sweep over this city that same tidal wave of heart-searching and intense moral self-conviction such as was started by his handling of the Bible, and his address to the conscience, there would not be left a christian science edifice in the city. They would all be built over into apartment houses, or, more likely, into Christian churches, for the promulgation of God's truth, and the priests and priestesses of this unctuous fantasy would fall upon their knees alongside of the poor publican and cry: 'God be merciful to me, a sinner.'"

**Proposed Sanatorium for Tuberculosis.**—The Committee on the Prevention of Tuberculosis of the Charity Organization Society has submitted plans for the erection of a sanatorium in the Adirondacks to Dr. Lederle, of the New York Health Department. The Board of Health will endeavor to obtain from the Board of Estimate a sufficient appropriation to begin work on the institution, which as proposed will accommodate 480 patients and will probably be the largest of its kind in existence. The cost of erection, aside from obtaining the necessary site, is estimated at \$530,000. The urgent need of a special institution to care for the tuberculous of New York City is emphasized. It has been found that there are about 30,000 cases of tuberculosis in the city, and the general hospitals are unequal to the task of caring for these sufferers, and it is therefore argued that the only way to treat the disease successfully is in appropriate institutions especially devised for the purpose. The plan provides for a group of structures, the general arrangement of which will be fan-shaped, with the administrative building at the center and the pavilions projecting like the sticks of a fan, thus giving each pavilion a maximum of light and air. The pavilions are to be two stories in height, and connect with each other and the administrative building by covered corridors. A bill has been introduced into the Legislature which enables the health department to acquire lands at any point in the State for the purpose of erecting such a sanatorium, and effort will now be bent on securing the necessary appropriation for its erection.

#### PHILADELPHIA, PENNSYLVANIA, ETC.

**Smallpox in Philadelphia.**—During the week ended March 14 there were 44 new cases of smallpox reported to the health department. During the previous week there were 17 new cases. This increase is probably only temporary, but it shows that the disease has still a strong hold on the city.

**Ostracism or Vaccination.**—The Bristol Board of Health at a special meeting decided to procure or erect a building for the care of smallpox patients. A house-to-house visitation by vaccine physicians was also ordered for the purpose of vaccination, and the town was divided into seven districts with a physician for each district. Social ostracism is planned for those who refuse to avail themselves of the free inoculation offered by the board, as the physicians are instructed to report daily the names of those vaccinated and also those who refuse. The names of the latter are to be published in the local papers. The local association of mill owners has decided to cooperate with the Board of Health in the effort to stamp out the smallpox that has prevailed there without cessation for 15 months. During that time there have been 60 cases, 9 of which have resulted in death.—[*Philadelphia Press*.]

**Eddyites and Smallpox.**—In the columns of last week's issue of *American Medicine* we reported the case of a Philadelphia eddyite who after suffering for a week with a virulent type of smallpox and refusing to call a doctor, though constantly surrounded by members of his own family and others, was forcibly taken to the Municipal Hospital for treatment. The sequel to the above is exemplified in the fact that since our last publication two other members of the same family have been stricken with smallpox and sent to the Municipal Hospital.

**Army Canteen Substitute.**—A plan adopted by officers at a certain post is likely to be followed at other posts when it can be done with safety. It is learned that at the post referred to the commanding officer and his subordinates secretly arranged with a civilian for the establishment of a first-class place immediately outside of the government reservation. It was agreed that the place should be run in a practically similar manner to the "post canteen." The rooms were light and airy, were kept clean, and strict order was preserved. A reading-room, well stocked with reading matter, was provided for the men; pool and billiard tables were available for use to a charge of one cent a cue, and each man was limited to six bottles of beer per day, at eight cents a bottle, while in the low "joints" the men had been patronizing they were charged 12½ cents a cue for the use of the table and exorbitant prices for the vilest quality of liquor. Each man was limited to \$5 credit per month, and the officers saw that each man's indebtedness to the proprietor was met. At this particular post during the month immediately prior to the establishment of this "canteen," 75 courts-martial occurred, and the officers were almost in despair because of their inability to maintain discipline. During the first month the place was running there were only five courts-martial.—[*Public Ledger*.]

**The State Sanatorium Committee of the Pennsylvania Society for the Prevention of Tuberculosis,** composed of Dr. Guy Hinsdale, chairman; Dr. Benjamin Lee, secretary of the State Board of Health, and Dr. M. Ravenel, of the University of Pennsylvania, with the president of the society, Dr. Howard S. Anders, met recently at Harrisburg in advocacy of the bill appropriating \$500,000 for two sanatoriums for indigent consumptives, to be under direct governmental initiative and control, and for reasons of salubrity and economy to be located within the forestry reservations upon sites selected by a commission of five to be appointed by the Governor, the expenses of the commission not to exceed \$5,000, and the work of same to consist also of planning methods of construction, character of equipment, administration, etc. After being received by Governor Pennypacker in the afternoon the four were heard by the Appropriations Committee of the House of Representatives. Dr. Anders at both hearings appealed for direct State control because of the urgent need and the meagerness and uncertainty of private charity to meet it; the analogy of State care of the insane, the blind, and other defectives, numbering altogether less than the tuberculous, and the example of recent history in the action taken by European governments and other States here. Dr. Hinsdale referred to the great natural advantages of the State for the care of consumptives, the feasibility and economy of State forestry camps for large numbers of tuberculous, and strongly emphasized the necessity of the Commonwealth making at least an adequate start in the work. Drs. Lee and Ravenel urged the enormity of the neglect of the tuberculous, the needs of segregation for public safety, and the inability of philanthropy, even with government aid, to cope with the demands. The work at White Haven was commended and its inadequacy pointed out.

#### SOUTHERN STATES.

**Smallpox in Virginia.**—The Secretary of the State Board of Health of Virginia states that the average number of smallpox cases in the State for the past six months was large, over 100, and that at the present time he is confident that there are not less than 200 cases; and that the border counties in Kentucky and Tennessee are likewise suffering from the disease. The epidemic is of a virulent type.

**Law Against Sky-scrapers.**—A new law in the city of Washington requires that hereafter no buildings on resident streets can be over 80 feet high. The new law it is said interferes with several new apartment houses now under construction, and the plans of the builders will have to be modified in accordance. The law permits buildings facing Government parks and triangles to be as high as the wider street at the intersection is wide. This privilege was secured to settle a controversy as to a large hotel which was contemplated on the site of the Hotel Lawrence.

**American Medical Association.**—The Southern Railway announces that for the occasion of the meeting of the Association in New Orleans, May 5, 6, 7, 8, 1903, tickets for the round trip, limited to 10 days will be sold for one fare. By deposit of ticket by original purchaser, and payment of 50 cents, to joint agent, New Orleans, not later than May 12, extension of final limit may be obtained to enable the purchaser to reach original starting point not later than May 30, 1903. Special service trains composed exclusively of Pullman, dining, drawing and state-room, sleeping, library, and observation cars has been

arranged to leave New York at 4.25 p.m., May 2, via Washington, Atlanta, and Montgomery. Time, New York to New Orleans, 39 hours.

**Medical Inspection of Public Schools.**—Commissioner Macfarland will soon appoint 12 medical inspectors of schools in the District of Columbia. The commissioners have heretofore urged a law providing for medical inspection. This year they were successful and Congress made provision for the appointment of 12. The provision reads as follows: "For 12 medical inspectors of public schools, 4 of whom shall be of the colored race, at \$500 each, \$6,000; provided that said inspectors shall be appointed by the Commissioners only after competitive examination, and shall have had at least five years' experience in the practice of medicine in the District of Columbia, and shall perform their duties under the direction of the health officer and according to rules formulated from time to time by him, which shall be subject to the approval of the Board of Education and the Commissioners."

#### WESTERN STATES.

**Pasteur Institute for Hydrophobia.**—It is reported that the Michigan Board of Regents of the University of Michigan has decided to establish a Pasteur Institute at the university for the treatment of cases of hydrophobia. The institute will be in operation after April 1, 1903.

**The Harvey Medical School,** of Illinois, is to be affiliated with the State University, which is represented in Chicago by the College of Physicians and Surgeons. Harvey College admits only night students, and its affiliation with the University will add to its importance and will give it an advantage no other university enjoys, in being allied with two medical colleges, one with day and the other with night classes.

**Necropsy Findings in Dogs Dead From Rabies.**—The Bulletin of the Health Department of Chicago for the week ended March 7, 1903, says: Notes from the municipal laboratory report that postmortem examination of a dog that bit a boy on Garfield boulevard showed the spinal cord congested and the stomach full of grass and sticks. These conditions indicate that the animal was suffering from rabies. Rabid dogs have been killed in several places in the city during the past two months. Postmortem examinations or animal inoculations do not always demonstrate the presence of rabies in its early stages. The public should appreciate the importance of securing a dog that has bitten any one and keeping him alive until it is positively known whether or not it is suffering with rabies.

**Mortality of Michigan During February, 1903.**—The total number of deaths was 2,756, or exactly 100 fewer than the number of deaths in the preceding month. The deathrate was 14.4 per 1,000 population, as compared with 13.5 in January. The mortality was slightly higher than that for February of the preceding year. By ages, there were 559 deaths of infants under 1 year, 175 deaths of children aged 1 to 4 years, and 874 deaths of persons aged 65 years and over. Important causes of death were as follows: Tuberculosis of the lungs, 182; other forms of tuberculosis, 35; typhoid fever, 34; diphtheria and croup, 52; scarlet fever, 16; measles, 17; whoopingcough, 31; pneumonia, 372; influenza, 73; cancer, 126; accidents and violence, 134. There was a decrease in the number of deaths from typhoid fever and scarlet fever, while the number reported from influenza was nearly double the number in January. The deathrate from this cause, however, was not as high as during the same time last year. Pneumonia showed a very slight decrease in the number of deaths reported. There were 5 deaths from smallpox.

## FOREIGN NEWS AND NOTES

### GENERAL.

**Antituberculosis Serum.**—It is stated that Professor Behring, the discoverer of antiphtheric serum, has announced the discovery of a serum by means of which calves can be made perfectly immune to tuberculosis, and which he believes will be equally applicable to human beings. The profession awaits with some interest the outcome of Professor Behring's experiments.

### CONTINENTAL EUROPE.

**The Nestor of Medicine.**—Dr. David, of Montpellier, France, celebrated his one hundred and second birthday February 8, 1903. He is said to be the oldest member of the medical profession now living. He practised medicine until his ninety-eighth year. Dr. David attributes his longevity to sobriety and outdoor life. He has very good health, but is now troubled by failing eyesight.

**Hygiene in Relation to Shipping.**—In opening an official course of lectures on naval and colonial hygiene at the University of Naples, February 4, 1903, Professor Alessandro Pasquale, speaking of the scope and importance of the subject, said that in a country from which there is such an extensive emigration, as from Italy, it is necessary for the universities to

provide instruction on hygiene in relation to the shipping in order that there may be assurance that emigrants and the ships on which they leave may be in a sanitary condition satisfactory to the authorities of the countries to which the emigrants go. Not only is it the duty of the country from which emigrants leave to provide for suitable sanitation on the passage, but means should be taken to keep persons physically unfit from emigrating and to prepare such as do emigrate against the perils of a climate to which they are unused. The course at the university will include instructions in naval construction from a sanitary standpoint, examination of water, air, and food aboard ship, the consideration of air space, disease on board ship, disinfection, quarantine, the examination of personnel, and in short, all subjects in which medicine has a practical bearing on shipping.—[*Public Health Reports.*]

### OBITUARIES.

**William P. Munn,** of Denver, Colo., March 13. He was graduated from the University of Michigan, Ann Arbor, in 1886. He was a member of the American Medical Association, formerly president of the Colorado State Medical Society, member and former president of the Denver and Arapahoe Medical Society and recently chief of the Board of Health of Denver. He was also a former professor of genitourinary and clinical surgery in the University of Denver.

**George Washington Le Cato,** of Richmond, Va., March 12, aged 61. He was graduated from the University of Maryland, Baltimore, in 1864. He first located in New York City and served as a member of the Board of Health. He was one of the most popular and widely known men on the eastern shore of Virginia and had been an influential member of the State Senate since 1893.

**Willard I. H. Mathews,** in Des Moines, Iowa, February 24, aged 38. He was graduated from the Iowa College of Physicians and Surgeons in 1886. He was county physician of Polk county, major and brigade surgeon U. S. V. in the Spanish-American war, and was for a time in charge of the United States General Hospital, Presidio, San Francisco.

**Franklin B. Galbraith,** of Pontiac, Mich., February 21, aged 63. He was graduated from the University of Michigan, Ann Arbor, in 1861. He was a member of the American Medical Association, surgeon to the Fourth Michigan Volunteer Cavalry during the Civil war and served three times as mayor of Pontiac.

**George E. McPherson,** in San Francisco, Cal., February 20, aged 73. He was graduated from the Jefferson Medical College, Philadelphia, in 1855. He served as surgeon in the United States service in the Civil war.

**Frank Brownlie Newton,** in Stafford Springs, Conn., February 19, aged 28. He was graduated from the University of Vermont, Burlington, in 1899 and was a member of the Connecticut Medical Society.

**George C. Gage,** in New York City, February 22, aged 52. He was graduated from the College of Physicians and Surgeons, New York, in 1872, and was a specialist in diseases of the nose and throat.

**A. W. Church,** of Jersey City, N. J., March 13, aged 32. He was a graduate of the Edinburgh University of Scotland and of the medical department of the Columbia University, New York City.

**Joseph A. Jackson,** in Manchester, N. H., February 20, aged 68. He was graduated from the McGill University, Montreal, in 1879 and was a member of the New Hampshire Medical Society.

**George White Sloan,** in Indianapolis, Ind., February 15, aged 67. He was a graduate of the Indiana Medical College and president of the American Pharmaceutical Society.

**Charles Walter Palmer,** of Newhope, Pa., March 9, aged 36. He was graduated from the Jefferson Medical College in 1902. He was also a graduate in pharmacy.

**James Calvin Hall,** in Millerstown, Pa., February 11, aged 48. He was graduated from the Baltimore College of Physicians and Surgeons in 1879.

**Cyrenius D. Spencer,** in Binghamton, N. Y., February 22, aged 77. He was graduated from the Berkshire Medical College, Pittsfield, Mass., in 1849.

**Edward H. Luckett,** in Owensboro, Ky., February 24, aged 70. He was graduated from the Kentucky School of Medicine, Louisville, in 1854.

**Robert H. Romage,** of Carnegie, Pa., February 15, aged 61. He was graduated from the Homeopathic Hospital College, Cleveland, in 1872.

**Henry McQuiston,** at Pasadena, Cal., February 13, aged 65. He was graduated from the Western Reserve University, Cleveland, in 1868.

**Robert M. Means,** at DeHaven, Pa., February 14, aged 35. He was graduated from the Jefferson Medical College, Philadelphia, in 1893.

**John B. Liddell,** in Gadsden, Ala., February 22. He was graduated from the Atlanta (Ga.) Medical College in 1880.

**C. M. Skinner,** of Hartland, Wis., March 14. He was graduated from the Rush Medical College, Chicago, in 1876.

**George Young,** of Pioneer, Ohio, February 15, aged 64.

**Frank Turnbull,** of Goderich, Ont., March 12.

## CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

## THE UNTOWARD EFFECTS OF AN EXCESSIVE DOSE OF HYOSGIN HYDROBROMATE.

To the Editor of American Medicine:—The following case is reported as one of interest on account of the untoward effects of an excessive dose of hyoscin hydrobromate. The administration of the drug was an unfortunate blunder, one placing the patient for several hours in very great danger. From our mistakes we learn, sometimes, as much as from our successes, hence this report.

H. L. M., a male of 23 came to me November 5, 1902, to receive treatment for syphilis of 2½ years duration. Treatment was administered hypodermically, six tablets, 2 mg. ( $\frac{1}{50}$  grain) each, mercuric chlorid, twice weekly.

The solution was made up in the usual manner and injected into the gluteal region. Within five minutes after the administration of the drug the patient complained of some disturbance in the head, chiefly a feeling of intoxication, and directly afterward of blurring of vision, followed immediately by change in the facial expression. The pupils dilated at this time. An immediate investigation revealed the fact that in making up the solution for the injection a bottle containing hypodermic tablets of hyoscin hydrobromate had been substituted for the one containing mercuric chlorid.

The patient had received six of these tablets, each containing .6 mg. ( $\frac{1}{100}$  grain), making in all 3.6 mg. ( $\frac{1}{27}$  grain). Within ten minutes after the administration of the drug the patient became dizzy, this being followed quickly by incoordination of the muscles, affecting especially the lower extremities. This was followed by an inability to stand upon the feet, or to support the body in a sitting posture. Extreme nervousness manifested itself along with the muscular incoordination.

Rigors with chattering of the teeth followed. Later the patient stated that he felt as if a faradic current was being turned through his body. He complained of pain in the head and inability to move the limbs, especially the legs, saying his "legs were too heavy to move."

There was dryness of the mouth, face was flushed, voice was hoarse, and there was some difficulty in articulation. He complained of dyspnea, and pupils were widely dilated. At this stage he was semidelirious part of the time, later becoming wholly so. Eyes were open a part of the time. He would sink into slumber which was not profound, and from which he could be easily aroused. Respiration, which was rapid and labored during the early stage, became slow, full, and regular toward the end. Skin was moist, pulse very irregular with frequent and marked changes, some times weaker than at other times, rate being from 84 to 138. Pulse became slower and more full at the end of three hours.

Six hours after receiving the drug the patient walked three squares to the car. His gait was unsteady during two-thirds of the distance traversed, but improved thereafter. After being put to bed he slept through the night, but continued to talk the greater part of the time. Of this, and the events following the development of the marked symptoms of poisoning, he was unconscious the following day. He complained of some nausea early next morning, but after eating breakfast he experienced no further distress in that way. A feeling of fulness in the head and some difficulty in concentrating the mind was experienced throughout the day.

The treatment employed immediately after the development of symptoms of poisoning consisted in a hypodermic injection of strychnin sulfate 1 mg. ( $\frac{1}{100}$  grain), nitroglycerin .6 mg. ( $\frac{1}{100}$  grain); digitalin .6 mg. ( $\frac{1}{100}$  grain). This was followed by 1.3 cc. (20 minims) of deodorized tincture of opium; this by 8 mg. ( $\frac{1}{8}$  grain) pilocarpin hydrochlorate. Later he received .32 gram (5 grains) of chloral hydrate; later, another 8 mg. ( $\frac{1}{8}$  grain) pilocarpin hydrochlorate.

Pilocarpin and heart stimulants were administered hypodermically, and the chloral and opium by the mouth.

## REPORT OF A CASE OF APPENDICITIS WITH CHOLECYSTITIS OF TYPHOID ORIGIN.

BY

CARL J. HOLMAN, M.D.,  
of Mankato, Kan.

H. W., aged 22, had always been well up to November 19, 1900, when he had an attack of typhoid fever. Two years before his father died of pulmonary tuberculosis at the age of 90. His mother, four brothers and three sisters are living and well. On April 4, 1901, he complained of pain in the abdomen which was referred to the region across the umbilicus; it came on three days before. He had been nauseated for 16 to 18 hours, the

appetite was poor and there was diarrhea. The tongue was coated, abdominal reflex was marked on the right side. He referred the pain to McBurney's point, where there was marked tenderness. A diagnosis of catarrhal appendicitis was made. Rest in bed and bowel feeding in place of receiving nourishment by mouth was advised. He would not consent to this treatment. Three days later he returned to my office complaining of more pain in the lower right abdomen. Pulse was accelerated 86 to 90, temperature was 99.5°, respirations 22. There was increased tenderness over McBurney's point, and some abdominal rigidity. He had been given mild laxatives, and had had free stools. The urine was acid, specific gravity 1.024, with a trace of albumin, but no sugar; urea, 2.5%. The microscope showed a few leukocytes. His weight was 148 pounds. Here were the four cardinal symptoms of appendicitis—pain, tenderness, nausea, vomiting—and associated with these an acceleration of temperature and pulse, and rigidity of the abdominal muscle. Operation was offered and accepted. The following morning at St. Joseph's Hospital the operation was performed under chloroform and ether narcosis. Dr. Billaud gave the anesthetic. The muscle-splitting incision was made. The peritoneal cavity was walled off with gauze and the appendix which was about five inches in length was delivered. The organ was thickened and greatly distended with gas, and the vessels were highly injected. The appendicular artery was tied and at the base of the appendix was placed a buried silk purse-string ligature—the organ was amputated and the base inverted. The purse-string suture was drawn taut and tied, and the ragged peritoneal edges were sewed over with fine catgut. The abdomen was closed with three longitudinal wire sutures, and the wound was covered with silver foil.

Microscopic examination of the hardened cut specimen shows the following: Hemorrhagic distention of Lieberkühn's crypts between the epithelial cells of the mucosa, numerous leukocytes, some diapedesis of erythrocytes, congestion of vessels of mucosa and submucosa and cellular proliferation and desquamation of epithelial cells. Patient made an uneventful recovery and left the hospital on April 23, 1901. He was seen on May 25, and I learned that he had reached his normal weight of 172 pounds.

On June 14 he came to me about 4 o'clock a.m., complaining of severe paroxysmal right epigastric pain, nausea and vomiting with occasional slight chills. His tongue was coated but there was no elevation of pulse, temperature or respiration. He was given a mild laxative, sent home and told to remain quiet, confining himself to a light or liquid diet. He returned July 1, complaining of constant pain in the right upper epigastric region. Tongue was furled and there was nausea. Temperature and pulse were normal. On the morning when seen the pain had been made worse by the jolting of the wagon in which he rode. Examination revealed great tenderness over the gallbladder region.

Urinalysis was negative.

He consulted other physicians; one of them confirmed my diagnosis and wished to drain the gallbladder the following morning. Evidently the patient was not ready to have this done because he returned to me and I placed the organs of digestion at rest by the use of nutritive enemas, giving morphia for the pain. After 10 days of such treatment—during which time there was elevation of temperature and pulse—with no relief, I decided to drain the gallbladder. This was done under chloroform and ether narcosis at St. Joseph's Hospital. The incision was about three and a half inches long, parallel with the right rectus muscle, exposing the gallbladder, which was greatly distended, pearshaped, almost livid, with vessels highly injected. Two traction ligatures were placed at the fundus and the gallbladder was surrounded by gauze. The organ was opened and the escaping bile collected on pads; it contained about five to six ounces of thick, viscid, brownish-black fluid containing flocculi of detritus. The mucous membrane of gallbladder is rough and congested, and considerably thickened yet friable, almost like wet brown paper. Smear culture on agar taken from the bile and gallbladder mucous membrane showed abundant growth at the end of 12 hours. When fixed on coverslips and stained it showed bacilli resembling *B. typhi abdominalis* (Eberth) giving the typical immobilizing effect when added to blood which gives the Widal reaction with typhoid culture. A tube of the inoculated agar was sent to Max Herzog, professor of pathology at the Chicago Polyclinic, and on August 3, 1901, he wrote:

"I finally succeeded in isolating from the last mixed culture you sent me a bacillus which, according to the various tests, proves to be the typhoid bacillus. It appears, therefore, that the empyema of the gallbladder was primarily caused by the typhoid infection, though it now is a mixed infection."

The patient got along nicely for two weeks when the wound was allowed to close, and then the old pain returned, only it was more severe. Thinking perhaps there might be something in the common duct, he was again narcotized, the wound opened and the ducts explored with negative result. The patient gained rapidly in weight and strength and left the hospital some eight weeks after admission. He occasionally complains of left epigastric pain, and in January of this year I saw him. He had intense left-sided epigastric pain, distended epigastrium, tenderness in the left epigastric quadrant, coated tongue, pulse 130, temperature 105°, respirations 36 to 40. Under calomel salines and codein, all the symptoms subsided in three or

four days. Since then he occasionally complains of left epigastric pain.

On July 15, 1902, I saw the patient. He is working as a farm laborer. He feels strong, looks well, weighs 170 pounds and is now free from pain.

This patient had a typhoid infection and later an appendicitis which was followed shortly by a cholecystitis, and later, in all probability, by a pancreatitis.

**LIST OF SURGICAL OPERATIONS, SHOWING WHAT CAN BE ACCOMPLISHED BY STRICT ADHERENCE TO THE ESSENTIALS OF MODERN ASEPTIC SURGERY.**

BY  
F. D. SHEPARD, M.D.,  
of Alntab, Turkey.

Physician in charge of the Hospital maintained by the American Board of Foreign Missions of the Congregational Church.

Following is a list of surgical operations performed by myself during the last nine months, which is of particular interest as showing what can be done by adhering strictly to the essentials of modern aseptic surgery and omitting all nonessentials. The work was done without any of the modern hospital facilities and without skilled nursing in convalescence, but everything was disinfected by boiling except the patient and the operator, and they were rendered as nearly sterile as possible by the use of hot water, soap, and alcohol.

OPERATIONS BY DR. F. D. SHEPARD, NOVEMBER 27, 1901, TO AUGUST 18, 1902.

N, number; S, successes; F, failures; D, deaths.

Of the abscesses, tonsillotomies, actual cauteries, tapping of abdomen and thorax, etc., only those few cases demanding a general anesthetic have been included in this list.

The fatal hernia case was an alcoholic subject. Had an aseptic healing, but died on thirtieth day from hepatitis.

**TREATMENT BY ELECTRICITY.**

BY  
GEO. BROOKS SWASEY, M.D.,  
of Portland, Me.

The cases herein reported may be of sufficient interest to warrant their publication. They are presented not because they represent unique conditions or even rare affections, but with the purpose that they may bear testimony to the assistance which may be obtained from the use of the electric current in cases in which medicinal treatment alone at times fails to bring that relief which physician and patient both desire. A single exception is noted in Case IV.

These cases, taken from my case-book, are not selected to demonstrate the applicability of electricity to a certain class of diseases or conditions, but rather to suggest the usefulness of a remedy in a very large variety of cases.

CASE I.—Mr. H., aged 67, a printer, first consulted me in April, 1898. Some 20 years previous to that date he suffered from an attack of rheumatic fever following exposure, and was sick four weeks. Pain was general over the body, but was most severe in the left hip, extended down the back of the thigh and leg and into the lumbar muscles. Following this attack and during these 20 years he has worked with great difficulty because of pain. This he states has been almost constant, at times very severe, relief only being obtained by lying down, but he cannot lie on the left hip. He limps and uses a cane. His general health has been good. When he came under observation tender points upon pressure existed over the course of the sciatic at its point of exit from the pelvis and down the thigh, but there was no atrophy of the muscles of the thigh or leg.

Treatment consisted in the use of the galvanic current with strength of from 10 to 30 mm. every second day, followed by the positive static spray and sparks over the back, thigh and leg. On May 23 the pain was much less and he could walk with far greater comfort. Treatment was discontinued, and two months later he could walk two miles without discomfort. This patient was seen in the fall of 1901, when he stated that the pain had never returned in the hip or thigh. During treatment

he was given moderate doses of potassium iodid and sodium salicylate, but as he had taken all forms of antirheumatics during his years of infirmity it is fair to presume these remedies had received a thorough trial before.

CASE II.—Mr. S., aged 20, a shoemaker, was first seen November 15, 1898. Nine years ago he had an attack of rheumatism which affected the right hip. He walked with difficulty and was disabled some three weeks. In 1895 he had another attack in both heels, which nearly prevented his walking for a year, the lameness being more troublesome in damp weather. Since September 1, six weeks before coming to me, he had suffered from a recurrent attack which involved the right hip and thigh, rendering locomotion possible only with the use of a crutch and cane. Examination showed the muscles on the back of the thigh to be hard and stiff and somewhat atrophied, the thigh flexed on the pelvis and the leg on the thigh. The top of the left shoulder was tender, the deltoid atrophied, with inability to extend the arm from the body, and the ankle on the left foot was red and swollen. This young man's father was advised to take his son south, but this being impossible electric treatment was undertaken, which consisted of the application of the Leyden-jar current, the feet being placed in one receptacle, the hands in another, every second day, followed by heavy positive spray and sparks on the spine, hip and thigh, milder sparks on the shoulder. At the expiration of four weeks of this treatment he could walk with comparative ease. The right heel was thickened and tender, the left slightly. Fly-blisters were applied to both heels, and after they had healed the Leyden-jar current was again applied to both heels. After ten weeks of treatment, quite regularly carried out, a degree of improvement had been obtained sufficient to warrant cessation of treatment and observation of results. Improvement continued, and three years later he was driving a delivery wagon for one of our grocers. Potassium iodid and sodium salicylate were given, but to my knowledge these remedies had been tried previous to the electric treatment.

CASE III.—Mrs. W., aged 40, housekeeper. In December, 1897, she had an attack of acute rheumatism in the right shoulder-joint. After several weeks of medicinal treatment the acuteness of the attack somewhat subsided. I saw her first on June 30, 1898, when she stated that she had taken medicine since the attack began but was still suffering great pain. Examination showed great tenderness on the anterior aspect of the joint, its movements were much restricted because of pain, with the usual painful and neurotic condition of all the muscles associated in the movements of the joint. The muscles of the corresponding side of the neck were also involved so that any movement of the head was painful. The hand could not be carried to the head, nor the arm across the chest and any movement of the joint was painful. Sleep was much disturbed and her general health was seriously impaired.

Treatment consisted of positive static insulation followed by positive static breeze and very mild sparks every second day. At the expiration of two weeks faradic sedation was added to the above treatment, using the No. 36 wire in the Monell coil. This treatment was continued until August 11, when the patient was discharged greatly improved. Improvement continued and she has remained well since. A preparation of salicylic acid was given with the above treatment, but as she was under the care of one of our most successful physicians from December to June we may believe that these remedies were thoroughly tested.

CASE IV.—Mrs. R., aged 64, a housekeeper, had been well until seven years ago when she had grip and pneumonia. Since that illness she had suffered from a dull pain at the inner edge of the left shoulder-blade. Pain radiates from this point through the back into the arm and right side. Physical examination of the chest was negative. Tender points existed at the lower edge of the scapula. Patient was decidedly neurotic. This woman was under treatment, at different times, from February, 1899, to July 26, 1900, during which time all methods of electric treatment were administered with little or no relief. Temporary relief was several times obtained, but nothing satisfactory.

CASE V.—Mr. H., aged 30, a foreman, consulted me January 1, 1899. He gave the following history: In the summer of 1889 he was gathering seaweed on the beach and carrying it to his father's barn at a distance. While attempting to carry too heavy a load he felt "something give way in his back," and fell on the ground. Being unable to get up and walk home, he crawled on his hands and knees to the house, and was in bed three weeks, suffering greatly. Since this accident there has been almost constant pain, which has been most troublesome at night, and during the day relief can be obtained only by bending the body as far forward as possible and resting the hands on some object. He stated that considerable effort and money had been expended during the 10 years to obtain relief without avail.

Treatment consisted in placing a large negative electrode on the body in front, and two positive electrodes, 4 x 4, over the painful points just above the iliac crests on both sides posteriorly; 20 min. were used for 10 minutes, followed by the positive static spray and sparks; the static roller was also used. Six treatments were given, on alternate days, when the pain was relieved. He has remained well, with the exception of an illness for which he received a few treatments in 1890, until the present date, January, 1903. Medicine was not given.

CASE VI.—Miss S., aged 29, housekeeper, unmarried. The patient commenced to menstruate at 14, and has always had considerable pain attending the function. There has been no irregularity in time or in the quantity of the flow; the pain is most severe after the flow is established and most pronounced in the right ovarian region, also passing down the anterior aspect of the right thigh. She often vomits and is obliged to go to bed. The pain in the right side is never wholly absent, but continues between the periods. She consulted me in May, 1900. Physical examination showed the uterus very tender on pressure, as were also both ovaries, the right more than the left; otherwise the parts appeared normal.

Treatment consisted of placing a negative galvanic electrode, 4 x 4, over the ovarian regions externally and placing a small ball electrode well covered with cotton and moistened with a solution of sodium bicarbonate high up in the vagina against the ovary, as they were treated individually. The current was turned on to a strength of 15 mm., running for 10 minutes, and then reduced slowly and with the greatest care. This was followed by faradic sedation from the No. 36 wire for 20 minutes, which was also very carefully reduced to zero. Treatment was given twice weekly. August 29, 1900, my notes contain the following: "Last two periods have been accompanied with very little pain, the general health has improved, and she has gained nine pounds in weight. The tenderness has very largely disappeared from the ovarian regions, and she feels very much relieved." Medicine was not given. Within the past month, nearly three years after treatment, she tells me she has remained nearly well, having very little pain at her periods.

CASE VII.—Mrs. W., aged 35, housekeeper, consulted me on February 27, 1898. She furnished the following history: During the two preceding years she had suffered from obstruction of the right lacrimal duct, and there had been several very distressing attacks of acute dacryocystitis, with great distention of the sac, and eventually the pus would discharge into the nose. The patient declined treatment until the above date, when, under ether, the canal was thoroughly opened with the probe-pointed bistoury and probes. The usual custom of subsequent probing was carried out with fair results, but the strictures showed a strong tendency to return, as there were two. On August 1 of the same year the following treatment was supplemented. A medium-sized lacrimal probe was selected and covered with a protective coating of shellac, leaving uncovered that section which would come in contact with the strictures when the probe was passed. The probe being attached to the rheophore connected with the negative side of a galvanic battery, a positive pad was securely fastened to the arm. Current strength was from 1 to 2 mm., for two minutes, repeated every fourth day, later once a week, and still later once in two weeks. At the end of three months the canal was patulous, the strictures showing very little tendency to return. Up to the time of this writing, January, 1903, the patient has had no indication of the return of the strictures.

CASE VIII.—Mrs. R., aged 35, housekeeper. This patient was first seen in September, 1900, and her case is so nearly a duplicate of the one last reported that a full report is not necessary. The stricture had existed in the right canal for 15 years, with attacks of acute suppurative inflammation in the sac. The same treatment was carried out as in the above case with the same results. The trouble has not returned.

## ASTHMA OR LARYNGISMUS STRIDULUS.

BY

A. L. BENEDICT, M.D.,  
of Buffalo.

During 1890 and 1891 J. McK., then 35 years old, and in fair general health, was occasionally under my care for asthma. He then, in some way, passed the physical examination for admittance to the fire department, and has been a fireman ever since. He frequently had attacks of asthma, apparently fairly typical but without very acute paroxysms of dyspnea. With the exception of emphysema, such as commonly attends chronic asthma, he has presented no organic lesion so far as I could discover or learn from the history with the exception to be noted; and his general health has remained fair and even the attacks of asthma have seldom incapacitated him for duty. So far as exciting causes are concerned he has never noticed any but exposure to cold and wet, but attacks have also occurred without obvious exciting cause. His habits have been temperate in all respects, excepting for occasional indulgence in alcohol some years before I first saw him.

On November 17, 1902, thinking that general treatment from the digestive standpoint might afford the benefit which direct attention to the asthma had not in the 13 years during which he had suffered, he again placed his case before me. He gave no personal nor hereditary history of gout and none of eczema or other eruption. His liver was contracted, extending by auscultatory percussion from the lower border of the fifth to that of the eighth rib and there were present the dendritic varicosities along the level of the diaphragm that I have previously described as characteristic of portal obstruction. There was no evidence of gastric disturbance, the bowels were regular

though their usual condition was mildly constipated. The urine was normal qualitatively, but urea, uric acid, salines and total solids by specific gravity were reduced to about 50% of the normal. The lungs, beside the emphysema, presented fugacious sibilant and sonorous breathing. Some improvement occurred under eliminant treatment, but I am not very sanguine of success in a case of so long standing.

The point of especial interest to me was this: On December 12 he came to the office during what he considered and what appeared an ordinary attack of asthma with characteristic wheezing. On auscultation the lungs were perfectly clear and the sibilant sound seemed to be absolutely limited to the larynx. There was no dysphonia and nothing of the dyspnea and nervous condition characteristic of laryngismus stridulus. The wheezing was somewhat relieved, subjectively and objectively, by inhaling a solution of menthol and iodine from hot water. Asthma is commonly considered a bronchiole spasm—or is it not rather a congestion of the bronchioles? I was surprised at the apparent location of the sibilant breathing. I am reasonably familiar with asthma from former general practice and from present experience with occasional patients that seek relief for the same reason that led this one to consult me. I have also seen several cases of laryngismus during the spasm, partly through the courtesy of laryngologists and partly through the occasional causation of laryngismus by the stomach tube. I have never before observed a laryngeal spasm in asthmatic cases, and would be glad of information as to the frequency of its occurrence or as to the possibility of conduction of pulmonary sounds so as falsely to give the impression of a constriction at the larynx.

It should be noted that this case does not come under the category of the rare, yet well-known laryngismic "ictus," with an underlying asthmatic or gouty dyscrasia. It may be that I have overlooked accessible references to laryngeal asthma, but on inquiry by telephone of a number of friends in general practice and after reporting the case to the medical section of the Buffalo Academy of Medicine, no information as to the occurrence of this condition has been forthcoming.

### AN IMPROVISED CENTRIFUGE.

BY

D. H. GALLOWAY, M.D.,  
of Chicago.

The centrifuge has become an indispensable instrument in the laboratory of every physician who aspires to do careful and scientific clinical work. The hand machine is the only one whose price is not so high as to make its purchase seem a burden to the physician who has only occasional use for the instrument. The electrical centrifuge is all that could be desired when the laboratory contains a current, and when expense is a secondary consideration. I have devised a centrifuge which has several advantages, and the construction of which is made

Improved Centrifuge.

very plain by the accompanying drawing. I had a small one-eighth horsepower electric motor which has been used for running a small lathe and sewing machine. This motor had cost me \$25.00, and to buy another motor and centrifuge combined would cost \$45.00 more, so I bought what is known as a jeweler's buffing-head, for which I paid \$1.50; for another dollar the machinist put in a special shaft with one end made to fit into the socket in the yoke which carries the tubes on an ordinary centrifuge; I then bought this part of the centrifuge for \$2.50, fastened it to the shaft and the centrifuge was ready for use. Instead, however, of fastening it in the ordinary way to

a table I bolted it to a board and fastened this board against the wall so that the shaft of the buffing-head was vertical instead of horizontal; then connected the motor to the grooved pulley on the buffing-head by a small leather belt about 1/2 inch in diameter. By a little care in starting the motor with the fingers of one hand while turning on the current with the other the machine is readily started without the sudden jerk which would ordinarily spill the liquids. With this I get a speed of 1,200 revolutions per minute. Having the motor, the centrifuge has cost me \$5.00, or, including the motor, \$30.00.

By using a differential pulley I can increase the speed to any number of revolutions within the power of the motor.

### COLCHICUM IN DIABETES MELLITUS.

BY

J. R. CLEMENS, M.D.,  
of St. Louis, Mo.

Empiricism may be defined as the exhibition of drugs in diseased conditions in which the indications are urgent but the causes unknown, and the extension of this definition presupposes two axioms: (1) The full knowledge of the drug given; (2) some indication for its use. Shielding myself behind these two axioms I venture to bring to notice the use of colchicum in diabetes mellitus and my grounds for doing so are as follow:

The most commonly accepted cause (theoretic though it be) of diabetes mellitus is an overactivity of the liver in a pathologic direction and comparable to the paradoxical paralytic overactivity of the heat center in hyperpyrexia. To control this, codeia has been exhibited and some success has followed its use. It has been chosen on account of having less tendency to cause constipation than opium or morphia or their other derivatives.

In acute gout the cause is hepatic overactivity with a resulting overproduction of uric acid in the liver.<sup>1</sup> Therefore the two diseases, gout and diabetes, are the same in kind but differ in degree, inasmuch as the overactivity of the liver in one case produces sugar in excess and in the other uric acid in excess. If we could find a drug that would in a measure control this overactivity of the liver there would be an indication for its use in both diabetes and gout. Such a drug, in my opinion, is colchicum. It is incontestable that colchicum in gout does diminish the output of uric acid in the urine—and more, it diminishes the formation of uric acid in the liver; otherwise if in an acute attack of gout treated by colchicum the diminished excretion of uric acid in the urine did not correspond with a simultaneous diminished production of uric acid in the liver the articular condition of the joint in gout would become worse. Hence colchicum does control liver activity, at least so far as the production of uric acid is concerned, and such being the case, why not sugar production? I am aware that the liver is rather the storehouse than the chief source of production of sugar, but for all practical purposes in therapeutics if its morbid overactivity results in flooding the circulatory system with sugar it may be looked upon as the origin of sugar production, and any measure that lessens its activity, *pari passu*, lessens sugar production. Codeia lessens liver activity and hence its use in diabetes. Colchicum lessens liver activity and hence it should be used in diabetes. Another advantage that colchicum has, paradoxical though it seems, is that it is a powerful cholagogue.

In a case of Arthur P. Luff's (subacute gout) the following is of interest:

Daily elimination of uric acid at beginning of attack.....	0.438 gram
Average daily elimination of uric acid for 14 days under colchicum.....	0.234 gram

Gouty glycosuria, if left to run its course untreated, becomes in time identical with true diabetes mellitus. Therefore colchicum checks a *tendency* to overactivity in a sugar direction, and hence the pertinent question: Why not the sugar production itself?

## A CASE OF UMBILICAL HERNIA.

BY  
RICHARD R. SMITH, M.D.,  
of Grand Rapids, Mich.

Mrs. F. S., aged 24, has always been in good health, excepting that seven years ago she had an attack of typhoid fever lasting eight weeks. At 14 years she weighed 240 pounds. She has a sister of 12 who weighs 178 pounds. One aunt died of tuberculosis; another aunt died after an operation for umbilical hernia. Her father has a double inguinal hernia. The winter following the attack of typhoid fever she noticed a protrusion at the umbilicus. The swelling has grown steadily in size up to its present dimensions. Five years ago she was married and has had five children since that time. Aside from some discomfort and considerable inconvenience she suffers but little. She has made attempts to keep the hernia reduced by various bandages and trusses, but without success. Her digestion is good; she is sometimes troubled with constipation.

*Examination* shows a woman weighing 203 pounds, 5 feet, 5 inches in height. An examination of the thorax reveals nothing abnormal. The pelvis was not examined; urine was normal. The accompanying photograph conveys a very good idea of the hernia. By placing the patient on her back the hernia was easily reduced.

*Operation.*—An elliptic incision about 8 inches in length was made near, but well clear of the sac down to the fascia. The sac and included tissue were partially freed from the fascia; the opening measured about 3 inches transversely and slightly more than that in length. The sac was then opened,

one small adhesion between the omentum and sac broken up, and the omentum and protruding bowels reduced and held in place with a sponge. With a finger inside the sac it was easy to complete the dissection of the sac from the surrounding fascia. After this the sac was cut away, the sheath of the rectus on either side split so as to expose the muscle well above and below the hernial opening. The peritoneum and underlying sheath of the muscles were first brought together, closing the abdomen. The two recti muscles were then sutured in a separate layer. Next the fascia was closely sutured over the muscles, and lastly the skin and superficial fat were united with silk-wormgut. Interrupted catgut was used throughout, except for the outer layer. There was slight suppuration extending apparently only to the fascia. This healed by granulation. It involved only a small portion of the wound. Recovery has been otherwise uneventful. The patient has been kept in bed five weeks in order to bring no strain upon the newly united tissues, and will be sent home with a firm abdominal bandage. It is, of course, impossible to predict the final outcome.

It is interesting to note in this case the marked inherited predisposition to hernia; the abnormal obesity, a condition which is present in the vast majority of those suffering from umbilical hernia; the appearance of the hernia before child bearing, and the rapid growth of the same to an unusual size, due probably to a quick succession of pregnancies.

The indications for operation in cases of adult umbilical hernia are: Relief from a condition which with the best care must be a source of great and lifelong annoyance; probable increase in size and danger from strangulation or sloughing of the sac, and the intraabdominal complications, such as dense

adhesions and even occlusion of the bowel; these make a later operation often a formidable affair.

The prognosis in these cases is, unfortunately, hardly so good as with inguinal hernia. The operations which have been devised for the relief of acquired umbilical hernia are several. Those which seem most rational advocate the bringing of the tissues together in layers, making the line of contact in fascia and muscle as broad and firm as possible. Overlapping the muscles and uniting them with a mattress suture has been done with success, and I believe should be carried out whenever the parts are lax enough to permit it. The same thing should be done with the fascia. Unfortunately this cannot always be carried out without putting too much strain upon the sutures. When this cannot be done a single union with interrupted catgut sutures is perhaps as effective as any other method.

## DEATHRATE FROM SMALLPOX IN VARIOUS CITIES AND STATES.

BY  
M. V. BALL, M.D.,  
President of Board of Health, Warren, Pa.

*To the Editor of American Medicine.*—Is it possible for any one of your readers to tell me why there should be such great differences in the deathrate of smallpox in various cities and States? According to the "Public Health Reports," the last one for instance (November 14, 1902):

Illinois .....	reports 137 cases with	2 deaths
Indiana .....	" 338 "	" 20 "
Massachusetts.....	" 364 "	" 68 "
Minnesota.....	" 1,119 "	" 6 "
New Hampshire.....	" 154 "	" 1 "
New Jersey.....	" 267 "	" 58 "
New York.....	" 213 "	" 54 "
North Carolina.....	" 537 "	" 5 "
Ohio .....	" 2,312 "	" 232 "
Pennsylvania .....	" 1,366 "	" 129 "
Tennessee .....	" 2,228 "	" 67 "
Washington .....	" 1,241 "	" 1 "
Wisconsin .....	" 797 "	" 6 "

## Individual cities:

Lowell, Mass.....	" 22 "	" 2 "
Boston, Mass.....	" 189 "	" 34 "
Cambridge, Mass .....	" 55 "	" 23 "
Newark, N. J.....	" 98 "	" 29 "
Jersey City.....	" 110 "	" 19 "
New York City.....	" 182 "	" 53 "
Cleveland, Ohio.....	" 1,034 "	" 182 "
Cincinnati, Ohio.....	" 162 "	" 1 "
Pittsburg, Pa.....	" 397 "	" 65 "
Philadelphia, Pa.....	" 102 "	" 14 "
Cambria county, Pa.....	" 194 "	" 18 "

I wrote to the Bureau of Public Health in regard to this matter and the reply was that "the figures are exactly as received from the State and municipal authorities. The causes for the differences are not known." Why, for instance, Cleveland should have a deathrate of 18% and Cincinnati .6%, or why Pittsburg should have 16% and Newark nearly 30%, Jersey City 17% and New York City nearly 30%, is not easy to understand unless the diagnosis of smallpox is different in one place than in the other, or the statistics are not correct.

That 1,241 cases should be reported from Washington with but one death is most likely due to incomplete returns. The Bureau of Public Health should take more pains to obtain correct and complete statistics. If possible have a representative in each State instead of depending upon local authorities. To my own knowledge at least seven cases of smallpox in our own county were not reported by our State authorities until I had called the attention of the Bureau at Washington to them. In the last report I also notice that whereas there had occurred in Porto Rico from February 1 to June 15 nearly 1,000 cases of smallpox no report has been given since June 15. Are we to infer that no cases have occurred since then or that none has been reported?

If the mortality rate does actually differ as the reports indicate, upon what does this difference depend? Has vaccination anything to do with it or are different methods of treatment responsible? It seems to me the subject is one for careful investigation by some such authority as the United States Bureau of Public Health.

EXCISION OF THE SUPERIOR MAXILLARY UNDER MEDULLARY NARCOSIS.

BY

A. W. MORTON, A.B., M.D.,  
of San Francisco, Cal.

Professor of Surgery, College of Physicians and Surgeons; Surgeon-in-Chief, Morton's Hospital; Visiting Surgeon, City and County Hospital; Consulting Surgeon, California General Hospital; Consulting Surgeon to German Hospital; Surgeon to the Santa Fe Railroad, San Francisco, Cal.

Mr. G. H., aged 39, entered the City and County Hospital December 3, 1902. His family history is good and personal history free from any disease. He is an excessive smoker of a pipe, and had used alcoholic stimulants freely until five years ago, since which time he has abstained.

Two years ago, while smoking, he received a blow which drove the pipe-stem into his right jaw through the mouth, causing a wound which never healed. Two months later a lump developed, which soon broke down leaving an ulcer; the patient continued to grow worse until September, 1902, when part of the growth was removed (Fig. 1, lower incision). On examination, the entire right jaw was found to be involved with a large mass, which proved to be a carcinoma.

The patient was prepared by removing decayed teeth and the usual mechanical cleansing. Sterile cocain hydrochlorate,

.032 gram ( $\frac{1}{2}$  grain), was placed in the syringe, and the piston, which was attached to a needle that had been placed into the subarachnoid space between the third and fourth lumbar vertebrae, in the center line, was then closed and enough of the cerebrospinal fluid was allowed to pass, as the piston was withdrawn, to fill the syringe two-thirds full. After the cocain was dissolved, the solution was introduced as rapidly as the piston could be pressed. Analgesia was complete in 20 minutes. The pulse during operation varied from 90 to 100; respiration remained normal. The patient was not nauseated, and remained conscious of everything, and expressed himself as free from pain.

The upper lip was divided near the middle line, extending along the side of the nose to about

Fig. 1.

one-half inch below the inner canthus; then along the lower border of the orbital region, beyond the outer canthus; the soft structures were raised and reflected outward, exposing the superior maxillary to its attachment to the zygoma; hemorrhage was controlled by means of pressure and hemostatic forceps; the hard palate and the nasal process was divided by a saw; the back part was separated with forceps and chisel, and the periosteum was separated from the orbital portion. The mass was seized with Lyons' forceps and pried with a chisel, which separated the mass. The hemorrhage was controlled by pressure and the Paquelin cautery; the soft palate was removed and the cavity cauterized. The patient did not swallow any of the blood or allow any to pass into the lungs during inspiration, as he could expectorate or retain it until it was wiped away. Analgesia was so complete when I was removing the right side that when I mentioned that there might be danger of recurrence in the other side, he requested me to remove the other jaw if necessary. Again, just as I was stitching the soft parts I requested Major D. M. Apple to give a talk to the students, and the patient was among the first and last to greet him with a clap of the hands, which would show that he was free from pain. The stitches were removed on the fifth day, with primary union, and he was discharged on the tenth day, with instructions to return if any further disease developed. (Fig. 2 represents the same operation reported in the *Journal of the American Medical Association*, November 8, 1902.)

The method offers many advantages, especially in operations about the buccal cavities:

1. The anesthetic is not in the way of the operator.
2. The danger of blood and secretions entering the

lungs and producing suffocation, or later pulmonary complications is absent.

3. It can be used in acute disease of the heart, lungs, or in kidney complications, when the anesthetic is counterindicated.

4. The shock of the operation is diminished, and there is not the severe disturbances which often follow an anesthetic.

I have used this form of analgesia in 929 cases, 76 for operations above the diaphragm, and many were similar

Fig. 2.

operations to the foregoing, excision of lower jaw, tongue, etc.

The operation and its complications are so simplified that I would fear very much to do a preliminary tracheotomy for administering a general anesthetic in any of the operations about the buccal cavity.

Surgeons are not now so anxious to use this method as they were when it was new. Possibly they have encountered some slight difficulties which they have not tried to overcome by perfecting their technic. Then again we have been educated since the days of anesthetics that it is necessary to have the patient unconscious during the performance of a capital operation. In some cases the surgeon must practise the laws of suggestion, or his patient will mistake tactile sensation for pain.

I have found the analgesia about the mouth as complete as in the lower extremities, and have failed to find any more constitutional disturbances than when the analgesia was used for operations on the lower extremities.

I am satisfied that its greatest field of usefulness is for operations in such locations where there is danger of blood and secretions entering the lungs.

**Medical Aid in Factories.**—A committee representing the German American Alliance will present a bill to the present Legislature of Pennsylvania requiring employers to maintain in their factories, mills, and other places in which help is employed, suitable medical and surgical materials, the object being to supply the necessary assistance and relief to accident cases or any demanding immediate assistance until the patient can be transferred to a hospital.

## ON THE TRANSPORTATION OF CELLULAR EMBOLI THROUGH THE THORACIC DUCT INTO THE LUNGS.

BY

W. G. MACCALLUM, M.D.,

of Baltimore, Md.

Associate Professor of Pathology, Johns Hopkins University, Baltimore.

The occurrence of large phagocytic mononuclear cells in the lymph sinuses of the mesenteric glands and elsewhere in typhoid fever and, indeed, in various other pathologic conditions is quite well recognized, and Mallory has pointed out that these cells may be recognized in the circulating blood as obtained from the ear in patients suffering from typhoid fever. He ascribes to them a considerable role in the production of the focal areas of necrosis in the liver where they act as plugs in the capillaries producing a localized anemia and states that he has also occasionally seen such cells in the vessels of the lung and in the thoracic duct. I have not found any description, however, of extensive affections of the lungs due to this cause nor any mechanical explanation of the process, such as seems to be suggested by the following case:

A young man previously in good health contracted typhoid fever, and after a sickness marked by no especial complications, but characterized by the intensity of the toxic symptoms, died in coma on the nineteenth day of the disease. At the autopsy the usual intestinal lesions were found—deep ulcers, some of which were still covered with sloughs while others were clean. There was no perforation, no peritonitis. There was moderate acute splenic tumor, and the mesenteric lymph glands were much enlarged and softened. The heart muscle was very soft and flabby, but showed no fatty degeneration. The lungs were extremely hyperemic throughout, and there was a patchy fibrinous exudate over the surface which could be easily stripped off, leaving a dull pleural surface with minute ecchymoses. Firm areas could be felt through the pleura in the underlying lung substance. On section these were found to correspond with areas of consolidation rather pyramidal in form which stretched down into the tissue. There were several of these, varying a great deal in form and size, and generally very irregular in outline. The lung substance in general was very deep red in color throughout, and except for the areas described was everywhere crepitant. The consolidated areas were dark greyish-red and surrounded by a zone of somewhat deeper red. Search with the scissors for plugs in the vessels failed to reveal any.

Microscopical sections of the lung showed that these areas of consolidation have the characteristics of an infarction. The alveoli are filled with blood richly mixed with leukocytes. The alveolar walls are not entirely necrotic, but the epithelial cells are swollen and generally desquamated.

Examination of the vessels leading to these infarcted areas shows them to contain abundant nucleated cells—indeed, one section shows a large vessel almost entirely occluded by a great mass of cells which at first sight looks almost like a fragment of lymph gland. Closer examination, however, shows that this mass is not tissue, but merely a conglomeration of cells with some admixture of blood and fibrin filaments. The cells are smaller than the desquamated alveolar epithelium and their nucleus stains more deeply. It is a vesicular nucleus, usually round, but sometimes indented. The protoplasm is abundant and stains deep pink. Many of them are phagocytic and contain smaller cells or remnants of cells. There are also many smaller cells with clear protoplasm which have in general the character of lymphoid cells.

In the smaller vessels throughout the lung these cells are found in great numbers, frequently completely occluding the lumen. Often in the alveolar walls the capillaries are plugged and widely distended with little clumps of such cells. Occlusion of such small vessels seems, however, to be compensated for, and in sections of the lung where such plugs are very abundant no necrosis of the tissue is found.

We have to deal evidently with multiple hemorrhagic infarctions of the lung produced by the plugging of the branches of the pulmonary artery with masses of cells of the type of the lymphoid cells and larger mononuclear phagocytic cells. In other places we have this embolism without any resulting infarction. What, then, is the origin of these cells?

The cells must gain access to the veins and thus reach the heart to be propelled into the lungs, and there are at least three possibilities. They may be poured directly into some systemic vein, or they may pass by way of the

portal vein through the liver, or, lastly, they may enter the thoracic duct and be thus carried into the subclavian vein. Of these the last seems to offer by far the most plausible explanation, especially since examination of the liver fails to reveal any especial abundance of these cells in its vessels.

It is, however, quite easy to understand how the phagocytic cells which are so abundant in the lymph sinuses of the mesenteric glands could be transported through the lymphatic trunks into the thoracic duct—indeed, it is hard to imagine that such a thing could be avoided. After that, the propulsion of clumps of these cells into the subclavian vein, thence to the right heart and on into the vessels of the lung, is an easy matter.

Fortunately the thoracic duct had been preserved intact as a part of a museum specimen in this case, and on opening it coagulated masses were found which contained abundant large mononuclear cells. These could be seen both in smears from this mass and in sections through the hardened thoracic duct.

In a second case of typhoid fever the contents of the thoracic duct were carefully examined fresh and in smears stained as one would stain a blood film. In both these preparations the large mononuclear cells were found in numbers, and both in the fresh and stained specimens a number of them could be seen to be phagocytic, containing lymphoid cells within their protoplasm.

Similarly in a case of amebic dysentery with liver abscess in which the lymph sinuses of the mesenteric glands were packed with large phagocytic cells, such cells were found in the contents of the thoracic duct. It seems therefore hardly to be doubted that the embolism of the pulmonary arteries was in this case due to the transportation of masses of cells derived from the lymph sinuses of the lymph glands through the thoracic duct into the heart and thus into the pulmonary circulation. In the contents of the normal thoracic duct the small lymphoid cell is predominant, while eosinophile and neutrophile leukocytes also occur. The study of the lymph is apparently very little pursued, however, although it seems in the light of this observation to offer some very important materials indeed.

## THE ALBUMOSES: THEIR CLINICAL SIGNIFICANCE VIEWED FROM A MODERN STANDPOINT; THEIR DETECTION AND DISTINCTION FROM THE OTHER PROTEIDS FOUND IN THE URINE AS A MEANS OF LOWERING THE DEATHRATE IN OBSCURE SUPPURATIVE AND OTHER DISEASES.<sup>1</sup>

BY

THOS. J. YARROW, JR., M.D.,

of Philadelphia.

Pathologist and Bacteriologist to the Samaritan and Charity Hospitals; Member of the Philadelphia Pathological Society, Electrochemic Society, Franklin Institute, etc.

The difficulties attending the accurate diagnosis of the presence of pus, especially in the greater cavities of the body, make it imperative that we should summon to our assistance every aid possible. Unfortunately, many cases of concealed suppuration remain undiagnosed until the autopsy table is reached by the patient, whose life might have been saved if the presence of pus had been demonstrated earlier, as, for example, in appendicitis. With this fact set plainly before me, I commenced the following researches over five years ago, with the hope of finding evidence which would more easily lead us to pronounce with reasonable certainty whether suppuration was or was not taking place in the cranial, abdominal or thoracic cavities or in other locations (joints, bones, etc.) when it was impossible to ascertain its presence with certainty or the symptoms were misleading, as they are unfortunately in a comparatively large

<sup>1</sup> From the laboratory of Dr. Thos. J. Yarrow, Jr.

number of cases of intraabdominal suppurative conditions. In fact, I have heard a number of prominent surgeons remark that the diagnosis of any obscure abdominal affection was usually made either on the operating or the autopsy table. This should not be when we take into consideration the many aids that we have derived from clinical medicine and clinical pathology during the past few years, and which have contributed markedly toward lowering the mortality in various diseases. Hematology, bacteriology and urinary analysis, etc., have all contributed their share of valuable information in many instances already familiar to the reader. Concealed or masked suppuration is one of the most frequent, deadly and treacherous conditions that we have to deal with. And just when to say that pus is, or is not present, is at times most difficult and perplexing to determine, with which I think the medical profession will agree. My purpose in this essay is to show that we do possess a valuable aid in diagnosing concealed collections of pus which has not been used or taken advantage of to any extent. The confusion in the former classification and reactions of the proteids had much to do with this, but now that this obstacle no longer exists a valuable aid lies at our command, particularly in medicine and surgery.

It is well known that there are other proteids found in the urine besides serum albumin and serum globulin, but until comparatively recently the detection and distinction of protoalbumose, deutoalbumose and heteroalbumose from serum albumin, serum globulin, and "true" peptone had not been demonstrated. In fact, the condition known as "peptonuria," strictly speaking (as Kuhne points out), has never been proved to exist, digestive peptone never having been found in the urine. The similarity between peptone, globulin, albumin and the albumoses in some of their reactions is marked, especially in the case of the albumoses and peptone, which both give a rose-red color with the biuret reaction, this fact alone leading to confusion among many observers, and thus we find cases of peptonuria reported in which the presence of the latter had been based upon the biuret test alone. Then, again, albumose is confused with albumin, as many of their reactions are identical. This has led some observers into believing that they had discovered a new proteid in the urine (aceto-soluble albumin), when in reality they were dealing with the albumoses, probably deutoalbumose, the precipitate being soluble in an excess of acetic acid. There is scarcely a test used in the analysis of urine that is not open to fallacy unless very carefully performed. As an example: the heat and nitric acid test serves for the detection of serum albumin, serum globulin, and the albumoses, and although Purdy, of Chicago, states the contrary, potassium ferrocyanid and acetic acid precipitate in addition to serum albumin; also serum globulin, heteroalbumose and alkali albumin. The biuret test serves for the detection of serum albumin, serum globulin, "true" peptone, and the albumoses. Delicate reagents such as those of Spiegler, Millard, and Tanret are worse than useless in inexperienced hands, as they in addition to the proteids precipitate alkaloids, ptomains, etc. Trichloroacetic acid precipitates, in addition to the other proteids, nuclealbumin (formerly termed mucin). It will thus be seen that we possess no specific test for each of the proteids, and to illustrate the reactions for serum albumin and the albumoses, a solution of the albumoses (proto and hetero) was taken containing 1 gram in 200 cc. of distilled water, and a solution of serum albumin of the same strength.

Serum Albumin. Proto and Hetero Albumoses

HELLER'S TEST.

A deep flocculent band forms at point of junction, disappears on heating and shaking, does not reappear on cooling (former caused by great excess of acid present).

Behaves likewise.

Serum Albumin.	Proto and Hetero Albumoses.
<b>HEAT ALONE.</b>	
Solution becomes opalescent, and a precipitate forms; not intensified on cooling.	No opalescence produced until a few drops of nitric acid are added; becomes opalescent; greatly intensified on cooling.
<b>ETHYLIC ALCOHOL.</b>	
A dense white precipitate forms immediately.	A haziness appears, not so marked as with albumin. No precipitate formed.
<b>MILLON'S REAGENT.</b>	
A white curdy flocculent precipitate, changing to brick-red on boiling.	Behaves likewise.
<b>FEHLING'S SOLUTION.</b>	
Contact with (full strength) gives a violent band at point of junction.	Contact with, gives a rose-red or pink band at point of junction.
<b>ACETIC ACID.</b>	
Acetic acid added to excess produces a haziness, becoming more distinct on boiling.	Produces a slight cloud, disappearing on shaking.
<b>POTASSIUM FERROCYANID AND ACETIC ACID.</b>	
Gives a yellowish-white flocculent precipitate; on heating, the precipitate becomes more yellow, and finally bright green. Does not dissolve on addition of ammonium hydrate.	Gives a dense white flocculent cloud not clearing on boiling, but changing to a bright green color. It is instantly dissolved on the addition of ammonium hydrate.
<b>PICRIC ACID.</b>	
Gives a yellowish precipitate, becoming more cloudy, and a brighter yellow on boiling.	Gives a dense yellowish precipitate.
<b>SPIEGLER'S REAGENT.</b>	
A dense white flocculent precipitate.	A dense white, partly granular, but largely flocculent precipitate.
<b>MILLARD'S REAGENT.</b>	
Dense white flocculent precipitate.	Behaves likewise.
<b>TANRET'S REAGENT.</b>	
Acts as foregoing.	Acts as foregoing.
<b>SALICYL SULFONIC ACID.</b>	
Gives a dense white flocculent precipitate, becoming more intense on heating; is not affected by the addition of ammonium hydrate.	As foregoing, but clearing up entirely on heating. Also clears up in the cold on the addition of ammonium hydrate.
<b>PHOSPHO-TUNGSTIC ACID.</b>	
Contact with a saturated solution gives a dense white flocculent ring at junction.	Behaves likewise.
<b>PHOSPHO-MOLYBDIC ACID.</b>	
Behaves as foregoing.	Behaves as foregoing.
<b>CONCENTRATED SULFURIC ACID.</b>	
Contact with gives a white cloud, disappearing on shaking. The acid is turned pink.	Behaves likewise.
<b>FIVE PERCENT SOLUTION OF AURIC CHLORID.</b>	
Produces a pale yellow flocculent precipitate.	Behaves likewise.
<b>FIVE PERCENT SOLUTION OF PLATINIC CHLORID.</b>	
Behaves as preceding.	Behaves as preceding.

I beg to call attention to the effect of the addition of ammonium hydrate in excess (as noted in the tests given), and suggest it as a means of distinguishing between serum albumin and the mixed albumoses when used with the preceding reagents. When 1 cc. of the albumose solution was added to 10 cc. of a very dilute solution of methyl violet 6B, the latter was changed to a faint reddish-pink color. The change was not well marked. With Koch's "fuchsin," highly diluted, the color changed to a salmon pink. With methylene-blue, highly diluted, the color was changed to a bright peagreen. These changes may or may not be due to impurities in the albumoses, but they are interesting. With eosin (ordinary and the "blaulich") no change in the color was apparent, nor was the fluorescence affected. Probably one of the best reagents that we possess for the detection of serum albumin, serum globulin, and nuclealbumin, and for distinguishing them from the albumoses, is salicyl sulfonic acid as advocated by Roche, McWilliam, and myself. It is prepared by treating pure salicylic acid with chemically pure concentrated sulfuric acid, and allowing the resulting compound to crystallize by evaporation. It is best used in the form of a saturated solution, or the crystals may be purchased

and dissolved in distilled water. Primary albumoses are precipitated by a saturated solution; the precipitate clearing up on heating and reappearing on cooling. Deuteroalbumose is precipitated by the reagent when the suspected liquid is mixed with two or three times its bulk of a saturated solution of ammonium sulfate. True peptone or the peptone of Kuhne (not Brucke) is readily precipitated by salicyl sulfonic acid, in saturated ammonium sulfate solutions, and the precipitate is dissolved by the addition of water, glycerin, or the reagent in excess. With serum albumin it gives a white precipitate, varying from a mere opalescence to a dense coagulum, depending on the amount of albumin present. When albumoses alone are present it acts as above in the cold, but on heating the precipitate clears up entirely. The best method of performing the test, according to my own experience, is as follows: Take two test-tubes, half fill with carefully filtered urine, and if neutral or alkaline, acidify with a few drops of acetic acid. Add a small quantity of salicyl sulfonic acid ( $\frac{1}{2}$  to 1 cc. to a test-tube half filled with urine) and shake well; the opalescence or cloudiness, if any appear, is best seen against a black background, such as a coat sleeve. One test-tube is heated and compared with the other to see whether the opalescence clears up. This is easily detected when two test-tubes are employed, but difficult and at times impossible when only one is used. A third test-tube filled with untreated filtered urine may be used for comparison with the other two, if any doubt arises. It is exceedingly difficult to render certain specimens of urine clear, especially in cases of bacteriuria. The addition of a few drops of acetic acid and repeated filtering through several thicknesses of heavy Swedish filter paper may be attempted, or if this fails filtering by means of a vacuum pump (Chapman aspirator attached to faucet) through a heavy compact layer of absorbent cotton placed in a funnel; or, finally, if this is unsuccessful, through porcelain. Fortunately this measure does not often have to be resorted to. I may add here that I have observed that B-naphthalin sulfonic acid acts as well or even better than salicyl sulfonic acid, and is more sensitive than the latter. It is used in precisely the same manner, as is also phenolsulfonic acid, which may also be employed with advantage. I have used B-naphthalin sulfonic acid with markedly uniform results, especially for the detection of serum albumin and serum globulin, which are always present together in nephritis. Globulin rarely occurs alone, a possible exception being in amyloid disease.

The urine when testing for the albumoses should always be freed from serum albumin, serum globulin, and nuclealbumin (before performing the foregoing tests), though a faint trace of albumin does not interfere, as the characteristic reaction of the albumoses is the clearing up of the precipitate on heating, while serum albumin is thus rendered more turbid or cloudy. I have found these sulfonic acids also very useful in differentiating the various proteids occurring in the stomach contents in transudations, exudations, the contents of old abscesses, cysts, etc. To repeat emphatically, serum albumin, serum globulin, and nuclealbumin should always be separated from the urine before proceeding to examine for the albumoses when any doubt exists in preliminary testing. In all cases when it is important to ascertain the presence of albumoses in a suspected fluid, an accurate method of separation such as that of Hofmeister should be performed, or those of Salkowski and Devoto may be used. The method of Hofmeister is briefly as follows: Test the urine (or other fluid) first for albumin by the heat and nitric (or acetic) acid test, and if no precipitate forms, the presence of albumoses may be shown by the biuret reaction, but only when these bodies are present in abundance. A further test may be made by adding, first, acetic acid, and then a mixture of acetic and phosphotungstic acids; if opalescence occurs at once or after the lapse of a short interval,

albumoses may be concluded to be present. Taking it for granted that these methods have failed to reveal the presence of mucin (nuclealbumin), albumin or globulin, the urine is treated with neutral lead acetate and filtered, 500 to 600 cc. of the clear filtrate is acidulated with hydrochloric acid and then phosphotungstic acid is added until a precipitate ceases to form. The mixture is filtered at once, and the precipitate consists of albumoses combined with phosphotungstic acid, ptomains, and other substances. It is then washed on a filter with 5 parts of concentrated sulfuric acid in 100 of water until the fluid which passes through is colorless. The salts are thus got rid of, and the precipitate, while still wet, is washed from the filter with as little water as possible and placed in a watch-glass. Sodium carbonate is added to the point of alkalinity, and the mixture heated on a water-bath at a temperature of 212° F. for 10 or 15 minutes, and the biuret test applied. Albumoses are shown to be present by the bluish-red to violet color which forms; a dirty red or dull violet forms when only a trace is present. To procure the best results, according to Hofmeister, the whole preparation should be placed in a test-tube, when the precipitate will fall to the bottom and the supernatant liquid will show the characteristic color if any of the albumoses are present; otherwise the fluid remains of a dirty-greenish hue. If serum albumin should be detected by the preliminary tests it must be got rid of by combination with a metallic oxid. The best method is as follows: The urine is treated with a solution of acetate of sodium followed by perchlorid of iron. It is then neutralized exactly with potassium hydrate, boiled, filtered, and allowed to cool. The filtrate is then tested for iron and albumin and if free from both of these substances the process described is proceeded with. I cannot insist too strongly upon the care which should be exercised in freeing the suspected fluid from albumin. This method has the advantage of removing the color from highly tinted urines. Hofmeister and Maixner use a colorimetric method for the estimation of "peptone" (Brucke). Many other variations of this method have been proposed, but they all fail of their purpose and are not trustworthy. Devoto's method is as follows: Ammonium sulfate (80 grams to 100 cc.) is added to 200 or 300 cc. of urine and the mixture placed in a water-bath for half an hour, until the greater portion of the salt is dissolved. It is then placed in a steam sterilizer for half an hour at 212° F. Serum albumin, serum globulin, hemoglobin, deuteroalbumose, peptone, and nuclealbumin are precipitated, but only serum albumin, serum globulin, and nuclealbumin thoroughly coagulated. The fluid having been heated to 212° F. is at once filtered and should be free from albumin; should the fluid be turbid or react for serum albumin, etc., the process has been faulty and must be repeated. The precipitate on the filter is washed, first with warm water, then with cold. These washings are collected and tested for albumin; should this be absent the biuret test is performed and the usual rose-pink reaction indicates the presence of the albumoses. The method which I have used, on account of its being practical and speedily performed, is that of Salkowski. To 200 cc. of carefully filtered urine is added 20 cc. of hydrochloric acid, and then phosphotungstic acid until a precipitate ceases to fall. As soon as the precipitate has settled the overlying fluid is drawn off and the precipitate placed on a filter and thoroughly washed with cold water; it is finally washed off the filter into a small watch-glass and after settling the supernatant fluid is cautiously drawn off with a pipet and the residue dissolved in  $\frac{1}{2}$  cc. of caustic soda solution (20%) and heated until the greenish or blue color disappears. It is then tested with the biuret reaction. I have at times not only washed the precipitate with water (in the first part of the process) but have also used alcohol and ether successively. The ether and alcohol washings frequently showed the presence of hematoporphyrin. This was

especially so in the puerperal cases, a report of which will follow. By means of the spectroscope the hemato-porphyrin was easily recognized as acid hemato-porphyrin in alcoholic and ethereal solutions. The above method is not the original one of Salkowski but a modification of my own, which lessens the time of its performance.

The following proteids have been found in the urine: Serum albumin, serum globulin, protoalbumose, heteroalbumose, deuteroalbumose, acid albumin (syntonin), alkali albumin, and sometimes classed as such, nucleoalbumin or mucin, etc. The tests will be found in the

in the urine is an evidence of disturbance of digestion, and not of any disease of the kidney, while others wrongly associate it with albumin in nephritis. It was not traced to its true source, but was classified as a result of renal changes. In the second place it was confused with true digestive peptone, due to lack of thorough and complete investigation. In the third place it does occur in the urine in certain diseases of the kidney, notably suppurative nephritis due to injury or other cause, pyonephrosis, traumatic nephritis, and in certain cases of tuberculosis of the kidney when there exists much destruction or breaking down of tissues.

TABLE OF TESTS FOR PROTEIDS FOUND IN THE URINE (Modified from Allen).

accompanying table, taken from Allen's Organic Analysis. True peptone should have been omitted from this table, as it has never been proved to exist in the secretion of the kidney. It would seem impossible that peptone could be produced, except by the gastric or intestinal ferments acting on albumin or globulin. All evidence hitherto gathered is in favor of this view. On the other hand, it is easy to comprehend incomplete hydrolytic action, as in the transformation of proteid matter into primary albumoses as, for example, various bacteria produce on albuminous culture media. The so-called "peptones" are with the greatest probability albumoses. Peptone was formerly thought to be a constituent of pus, but this error has been rectified, and what was mistaken for peptone is in reality albumose or a mixture of proto-, hetero-, and deutero-albumoses. Although Ito has recently claimed to have discovered "true peptone" in urine, if one reviews his tests it will be observed that he probably confused peptone with deuteroalbumose, as this body approaches more closely to peptone in its characteristics than do the primary albumoses. Deuteroalbumose also is only partly precipitated as a rule in neutral solutions, and is only completely precipitated on the addition of an acid. Peptone is the only proteid which is not precipitated by saturation with ammonium sulfate. Hemoglobin might have been included in the table given.

In going through the literature of this subject one is surprised at the lack of attention hitherto paid to what is a most valuable aid in diagnosing concealed collections of pus, and we are all familiar with the extreme difficulty often experienced in locating such areas in the thoracic and abdominal cavities, and also in joints. There is a dearth of knowledge concerning the albumoses in this connection which is truly deplorable, and the standard textbooks contain no information of value. Many authors do not mention the subject, while others make statements so erroneous that it were better to have omitted them altogether. As an instance of this, one of our best textbooks states that the presence of "peptone"

In this country with the exception of Chittenden, Yarrow and Stengel, few observers have investigated the subject, the work requiring more time than the physician can generally afford to devote to it. Nearly all the work has been done abroad by a few men, among whom are v. Jaksch, Kuhne, Stirling, Neubauer, Hofmeister, Pohl, Vogel, Devoto, Pocanowski, Robischek, Maixner, William, Kosner, Koppen, Kohler, Senator, Loeb, Leube, Kottnitz, and Furstner. We agree with Kuhne that true peptone has never been found in the urine, and we have never been able to demonstrate its presence in a large number of specimens (4,000), many of which contained the albumoses. We used for the purpose of detecting "true" peptone the ammonium sulfate saturation method, which precipitates all proteids with the exception of peptone. Deuteroalbumose, however, is not as completely precipitated as are the primary albumoses, but it is readily made to do so by the addition of acid. Therefore it is strongly probable that what has been called peptone is in reality a mixture of the albumoses. The conditions in which albumoses are found in the urine are entirely foreign to those diseases in which the other proteids occur. The discovery of serum albumin in a specimen of urine makes us suspect a lesion of the kidney, or inflammation of the genitourinary tract. We may have of course an albuminuria without involvement of the kidney, the so-called "accidental" form. Albumoses are not caused to make their appearance in the urine by general circulatory disturbances, anemia, or nephritis, with the exception of what has been stated.

To a number of observers, v. Jaksch, Boeri, Robischek, Maixner, Pocanowski, and Fischel, belongs the credit of dividing albumosuria (or the Brucke "peptonuria") into four classes, viz.: pyogenic, inorganic, enterogenic, and puerperal. *Pyogenic*, the most common (pathologically), occurs chiefly in suppuration, wherever the seat of disease is located, provided that the pus is not walled off sufficiently to prevent the absorption into the circulation of its constituents. Hepatic abscess, pyosal-

pinx, pyothorax, empyema, suppurative osteomyelitis, purulent cerebrospinal meningitis in contradistinction to tuberculous meningitis (v. Jaksch), and malignant or ulcerative endocarditis are instances of this variety. *Inorganic*, such as scurvy, carbon monoxid poisoning, phosphorus poisoning, and tissue destruction generally. To these we may add leukemia, purpura hemorrhagica, and the resolution stage of pneumonia. *Enterogenic*, caused by the absorption into the circulation, through an ulcer of the stomach or bowel, of the products of proteolytic digestion. Gastric ulcer (also duodenal), typhoid fever (stage of ulceration), and advanced tuberculous enteritis are examples of this class. I have examined a number of specimens of urine, in cases of gastric ulcer occurring in young anemic females, and have been unable to detect the presence of "true" peptone. The patients were receiving peptonized milk at the time of the examinations,

Case I.—Daily amount of albumoses following normal childbirth

but the albumoses were invariably found present. *Puerperal*, which is really a subdivision of the second class, was first demonstrated as a normal constituent of the urine during the stage of involution of the uterus, by Fischel. Being much interested in septicemia following labor and also abortion, I made a large number of examinations of urine following labor and the latter condition. The proteids which I have found in the urine in these cases were serum, globulin, serum albumin, protoalbumose, heteroalbumose, deutoalbumose, and nuclealbumin. Hemoglobin and its alteration products (acid and alkali hematin) were derived from probable contamination, but hematoporphyrin was not. The serum albumin was derived both from contamination from the uterus and from the kidney and genitourinary tract outside of the vagina (globulin also), while the nuclealbumin came from the irritated genitourinary tract. Our interest being involved in the albumoses we will pass on to what

takes place after normal labor. The presence of all the proteids (after normal labor), with the exception of the albumoses, may be termed "accidental." The albumoses in the first case of normal labor (which may be seen in the accompanying chart) followed a rough though regular decrease, appearing to diminish in quantity in direct ratio with the rapidity of involution, and, to a great extent, with the size of the uterus. These results are the first quantitative estimations which have been obtained. The quantitative estimations were commenced September 11, 1899, and were carried on daily until with the most delicate reagents the urine ceased to react for the presence of albumoses. The amount generally used for analysis was 500 cc. of urine, though to test whether the amount of urine taken (from the whole 24 hours specimen) markedly affected the weight of the albumoses detected various quantities of urine were taken; as, for instance, on the seventeenth, when three analyses were made from the same urine, side by side. The difference in the results of the three examinations amounted to only a few milligrams, a very close result, and quite as accurate as quantitative estimations usually are, even when the greatest care is taken. After much laborious work I was able to determine with accuracy that the albumoses found in the urine after childbirth are protoalbumose, heteroalbumose and deutoalbumose, the latter in much smaller quantity than the former two. At the beginning of my work on this subject I soon found that hematoporphyrin proved a source of error in obtaining correct quantitative results, and also some inorganic combinations of phosphotungstic acid. Hematoporphyrin was got rid of by prolonged washings with acid alcohol, followed by ether until the precipitate was rendered colorless. These washings when placed before the slit of the spectroscope showed the characteristic bands of acid hematoporphyrin in alcoholic and ethereal solutions. The inorganic salts were got rid of by careful repeated washings with ice-cold water, to which a trace of chemically pure sulfuric acid had been added. Finally incineration was performed after previous careful weighing. No one more than myself (and I have heard Stengel express the same view) deplores the necessarily imperfect means at our disposal for the accurate and rapid quantitative estimation of the albumoses in urine, and it is with due consideration that I offer these results obtained from puerperal cases. The difficulties encountered in the performance of such analyses can be fully appreciated only by one who has been engaged in this work. Perhaps the most difficult procedure is the absolute and certain separation of other proteids as a preliminary measure. This is, however, of not so much importance in pyogenic cases, in which it is simply required to ascertain whether albumoses are or are not present. The following are the quantitative estimations obtained after normal labor (all primiparas):

CASE II.—First day, 1.9 grams; second day, .7 gram; third day, .56 gram; fourth day, 1.8 grams; fifth day, 2 grams; sixth day, .24 gram; seventh day, 1.04 grams; eighth day, .81 gram; ninth day, .61 gram; tenth day, .45 gram; eleventh day, .95 gram; twelfth day, 1.375 grams; thirteenth day, .54 gram; fourteenth day, .40 gram; fifteenth day, .60 gram; sixteenth day, .74 gram; seventeenth day, .46 gram; eighteenth day, .44 gram; nineteenth day, .48 gram; twentieth day, .23 gram; twenty-first day, a faint trace; and two days later the albumoses are absolutely negative.

CASE III.—First day, .45 gram; second day, 2.24 grams; third day, .93 gram; fourth day, .9 gram; fifth day, .8 gram; sixth day, .7 gram; seventh day, .3 gram; eighth day, .42 gram; ninth day, .87 gram; tenth day, .24 gram; eleventh day, .42 gram; twelfth day, .8 gram; thirteenth day, .4 gram; fourteenth day, .2 gram; nineteenth day, a trace; twenty-first day, negative.

CASE IV.—First day, .15 gram; second day, 1.62 grams; third day, .45 gram; fourth day, .8 gram; fifth day, 1.24 grams; sixth day, .72 gram; seventh day, .72 gram; eighth day, 1.365 grams; ninth day, 2.46 grams; tenth day, 1.4 grams; eleventh day, .84 gram; twenty-second day, negative.

There was no rise of temperature or disturbance to explain the late rise in the quantity of albumoses in Case

III. These observations are interesting as indicating the physiologic processes at work in the reduction of the bulky uterus after its function has been accomplished and the method by which nature rids herself of a now useless burden. It may be suggested that the manner in which this is accomplished is by the conversion of the albuminous bodies (composing the uterus) into simpler hydrolytic cleavage compounds by the action of a ferment in the blood or tissues of the uterus. Myoalbumin and myoglobulin obtained from muscle serum are very similar to those derived from the blood, the first is identical with serum albumin, and the second only differs by having another coagulation point (by heat). Myoalbumose is not coagulated by heat. The chemistry of the uterus during the stage of involution is apparently very complex, and it is idle to form conjectures. My object in these researches was to form a standard or to arrive at some idea of what takes place during the puerperal stage, with the view of separating this variety of albumosuria from the pyogenic form. I had hoped that light would be thrown on septicemia in a number of cases of this condition (following labor), but nothing positive was arrived at except that the quantities of the albumoses were very irregular, varying from a trace one day to as high as 2.5 grams on the following day.

Before passing on to the consideration of pyogenic or suppurative albumosuria, I wish to emphasize the necessity of examining urine freshly passed, or within at least four hours of its passage, as serum albumin and serum globulin are readily converted into their respective albumoses and globuloses by the action of putrefactive and pyogenic organisms. If it is not convenient to examine the urine immediately after its passage, it should be kept on ice. Putrefactive changes explain many of the conflicting statements observed regarding albumosuria in medical literature. If possible the urine should be examined at once.

It is hardly necessary to remind the reader that (toxic and otherwise) albumose-like bodies are produced by the action of various bacteria on culture media, and that they or bodies very similar in their reactions are found in snake venom. Some of these bodies are of astonishing toxicity, as the one just mentioned, and also the dried filtrate obtained from cultures of the tetanus bacillus, which is free from the presence of any germ to account for its poisonous effects. Brieger advanced the opinion that the diphtheria poison is a toxalbumin and disagreed with the "ferment" theory. In regard to the specific poison of tetanus he found the biuret reaction so imperfectly developed that he was inclined to believe that the toxin was not a proteid body. There are many conflicting theories on this subject which we will not dwell upon.

V. Jaksch has been engaged for some time in the study of albumosuria (Brucke peptonuria) and we quote him with great confidence in asserting that the presence of albumosuria as a symptom is of inestimable value clinically. We feel called upon, however, to remark that it will prove but a poor weapon in the hands of those who cannot exclude other causes of its appearance. One of our most prominent men (now deceased) stated about two years ago that "peptone" was regularly found in nephritis. This might be true, indeed, but its presence was not caused by the nephritis, as I will shortly demonstrate, but by decomposed serum albumin (action of germs), which, unless care be taken, might simulate an albumosuria to an inexperienced observer, giving rise to a totally erroneous impression of the case. We are much more careful to obtain fresh specimens of urine for analysis than we were ten years ago, and we are better acquainted with the reactions of the proteids contained in the urine, both in health and disease. The rapid dissolution of casts by the action of beginning fermentation, urinary ferments, etc., makes it imperative that we should procure freshly passed urine in order to secure an accurate diagnosis. I have examined with

great care the urine from 220 cases of chronic parenchymatous and chronic interstitial nephritis (in no case was the urine more than three hours old) without finding the slightest traces of the albumoses. In the urine in these cases, which contained albumin and had stood exposed for 10 to 24 hours, it was frequently present as the result of bacterial decomposition. I have also found it absent in arteriosclerosis, chlorosis, tetanus, symptomatic anemia, pernicious anemia, aortic and other aneurysms; acute and chronic bronchitis, bulbar paralysis, carcinoma of the stomach, liver, bowel, vulva, rectum, ovary, breast, penis, and uterus, cystic ovary, diabetes mellitus, diabetes insipidus, glycosuria, fatty kidney, lardaceous disease of kidney and liver, hepatogenous jaundice, urobilin jaundice, acquired and hereditary syphilis, melancholia and other insanities, miscarriage, abortion, self-induced and otherwise (at beginning of pregnancy), multiple neuritis, hysteria, delirium tremens, masturbation (both sexes), miliary tuberculosis, neurasthenia, nephrolithiasis, all forms of neuralgia, pulmonary tuberculosis (before cavity formation), sarcoma of the liver, suspected appendicitis, and typhoid fever (before the stage of ulceration), acute and chronic gastritis, catarrhal cystitis, chronic and acute rheumatic endocarditis, pruritus, toxic nephritis (due to lead), pneumonia (croupous and catarrhal before the stage of resolution), catarrhal appendicitis, pregnancy, lactation, pleurisy (without purulent effusion), accidental albuminuria, plumbism, etc. I have found it present in appendicitis (disappearing on localization and walling-off of the pus), hepatic abscess, abscess of the hip, and abscesses in all other locations; acute suppurative endocarditis (verified by postmortem examination), coxalgia (when accompanied by suppuration) invariably after abscesses from the use of the hypodermic needle, suppurating dermoid cysts, pneumonia (invariably at commencement of the stage of resolution), extensive suppurating burns of the cutaneous surfaces, pyosalpinx, carbuncle, septicemia (masked or sepsis occulta), gonorrhoea (both sexes), tuberculous peritonitis (late stage—early stage absent), purulent pleurisy, pyonephrosis, ovarian abscess, osteomyelitis, suppurating fibroid tumors, chronic carbon monoxid poisoning, ischiorectal abscess, purulent cystitis, traumatism followed by suppuration, perinephritic abscess, etc. The origin of the albumoses found in the urine in the suppurative cases, it is clear, is from the collection and subsequent destruction of leukocytes, so that the products of disintegration, including the albumose constituent, enter the circulation and are eliminated by the kidney. The albumoses of pus I have found identical in their reactions with those detected in the urine.

There has been some speculation as to whether the oppressive feeling experienced after a heavy meal is caused in part or wholly by albumoses circulating in excessive amount in the blood, thus causing torpor, headache, disinclination to mental or physical exertion, etc., in fact an autointoxication. With this object in view I obtained the urine from 10 individuals, who were habitual "over-feeders," and subjected the mixed 24 hours' urine to analysis, using 1,000 cc. for the purpose. These people always had good health (so termed), but usually ate a very heavy dinner, complaining of the sensations quoted. In all of the analyses I used the phosphotungstic acid method of Salkowski (also with phosphomolybdic acid, but found no difference in the results). In no case was there the slightest indication of the biuret reaction. It would seem rational to suppose that if excessive amounts of albumoses were circulating in the blood, a portion of them would be excreted by the kidney, but it is probable that albumoses have no part in the causation of these symptoms (unless they are not excreted by the kidney) and that other substances related to the xanthin bodies (adenin, leukomains, etc.) or the excessive intestinal fermentation (as shown by

the large amounts of indican) may play an important part in the production of the auto-intoxication.

The following will indicate the value of albumosuria as a symptom not to be lightly disregarded. In pneumonia it indicates the beginning of the stage of resolution or gray hepatization. The cell bodies are disintegrated, the exudate softened, and the debris rendered capable of being absorbed and eliminated to a certain extent by the kidney. This explains the appearance of albumoses in the urine. I have not found the retention and subsequent elimination of chlorids of any value as a symptom. At the time of the crisis, that stage looked for so anxiously by the physician and relatives, with the fall in temperature, and the appearance of the albumoses in the urine, the patient passes from a condition of marked discomfort and apprehension to a condition of comfort and a false crisis is guarded against. In differentiating malarial fever from typhoid albumoses in the urine would indicate that the stage of ulceration had been reached. Of course the finding of the specific organism would settle the diagnosis before this stage, but at times the plasmodium malarie is not easily detected. It frequently occurs that an apparently insignificant symptom is of great import. I have found it of value in indicating that ulceration and cavity formation had begun in pulmonary tuberculosis, which I have verified by repeated postmortem examinations; its presence in concealed suppuration, diagnosing this condition from acute inflammatory processes, serous effusions, transudations, exudations, etc.; its absence in acute inflammation of the ovary and its subsequent appearance when pus has formed being a valuable indication for immediate surgical interference; in appendicitis when, after the acute attack has subsided (suppurative form), its absence indicates that the pus has been walled off, and that an operation may be safely proceeded with, as the risk of infecting the peritoneal cavity is greatly lessened; in diagnosing tuberculous meningitis, in which condition albumose is usually absent, it must be remembered that it may arise "accidentally," and care should be taken to exclude ulcerative processes at work in other organs. According to v. Jaksch, it is valuable in diagnosing between tuberculous meningitis and encephalitis hæmorrhagica multiplex; albumose is present (usually) in the second disease, but very seldom in the first named. Its absence in the presence of the usual symptoms of meningitis is strong evidence of the process being tuberculous. In "latent" septicemia, or as it is sometimes termed "sepsis occulta," its value as a symptom is apparent, though I am not inclined to place as much value on it as a symptom in latent disseminated sarcoma as v. Jaksch does, a condition which, in my opinion, needs further study. Its presence in follicular ulceration of the intestine, stercoral ulcers, simple ulcerative colitis, and perforative ulcer followed by peritonitis, is of value in differentiating these conditions from carcinomas and catarrhal affections of the stomach and bowels. It is absent in intestinal obstruction. It may be noted that acute suppurative pancreatitis may produce symptoms which simulate intestinal obstruction. Its absence in catarrhal jaundice, and its presence in abscess of the liver, often distinguishes between the two conditions, and it is also absent in sarcoma of this organ. Suppurative processes in the gallbladder are thus distinguished from simple obstruction and tumors (carcinomas and sarcomas), also cholelithiasis. It is not present in either atrophic or hypertrophic cirrhosis. In suppurative pancreatitis it differentiates this form from the hemorrhagic, although we must not forget that the condition is extremely difficult to diagnose during life. Its presence in peritonitis distinguishes this condition from ascites and various growths. I have not found the albumoses present in simple ascitic fluid. It is present in both pneumonia and pulmonary abscess, but the presence of the physical signs and the detection in the sputum of

fragments of lung tissue and elastic fibers occurring in the latter condition (accompanied by the offensive odor of the breath) seldom leaves any doubt as to the nature of the trouble. The most important fact which I wish to emphasize is the necessity of studying the symptoms in each case very closely, excluding all other causes of albumosuria, and this is not a difficult task, except at rare intervals.

I will now give briefly a number of cases to illustrate the practical value of albumosuria as a symptom:

CASE I.—The patient was admitted to the Samaritan Hospital for operation. Diagnosis, supposed fibroid tumor or ovarian cyst. Her previous history pointed to a recent local pelvic peritonitis. Abdominovaginal examination revealed marked tenderness, and a large, firm mass could be felt in the right broad ligament. She had had a chill previous to entering the hospital. Her temperature now showed a septic curve, and the pulse was slightly accelerated but not "wiry;" complexion dusky, and her appearance suggestive of sepsis. Diagnosis, pelvic abscess. Urinary analysis showed marked renal involvement, with a deficiency in the amount of urea excreted. This occasioned the postponement of the operation, with the hope that an improvement in the condition of the kidney might take place and her condition be rendered more favorable for anesthesia and operation. The urinary analysis from day to day showed a constant reaction for the albumoses, but it is interesting to note that her general condition seemed to improve rapidly. Her temperature and pulse reached normal, and the pain and tenderness over the abdomen disappeared. She felt so much improved that she decided at this time not to have the operation performed. The mass in the pelvis remained the same as regards shape, size, and consistency. In the course of a week after this temporary improvement she began to complain, her temperature assumed a septic curve, pain and tenderness were again marked, and her general appearance was worse than it had been on the day of admission. Operation was decided upon, although the excretion of urea was very slightly below normal. The operation, performed by Dr. Hæhnlén, confirmed the diagnosis, it being a large multilocular abscess, involving the right tube, ovary, and broad ligament. Urinary analysis seven hours after the operation showed no reaction for the albumoses.

This case is very instructive in showing that although the patient was apparently becoming better (as regards her general condition) she was in reality slumbering over the edge of a precipice, and that her life was menaced until the operation was performed and the pus removed from her abdomen. Her subjective symptoms had been somewhat misleading, and the mass in the belly might have been confused with other conditions. The point which really determined the presence of pus in her abdomen was the persistent presence of albumoses in the urine.

CASE II.—Adult woman, symptoms of hepatic abscess; a diagnosis of this condition was made by the attending surgeon, and operation suggested; blood examination (polymorphonuclear leukocytosis, moderate); urine did not contain the albumoses. Operation revealed an inoperable sarcoma of the liver.

CASE III.—Adult man, symptoms of latent septicemia, suspected suppurative endocarditis; cultures from the blood showed pyogenic cocci; albumoses persistently present in the urine; blowing murmurs, systolic in time, at the mitral and aortic orifices. Postmortem examination revealed ulcerative endocarditis at both aortic and mitral valves (of gonorrhœal origin). Albumoses found in the blood taken from the heart cavities.

CASE IV.—Adult woman; had persistent albumosuria following operation for removal of the ovary (cystic). She did well after the operation, no rise in temperature or increase in the rapidity of the pulse. Wound healed by first intention, but albumoses appeared in the urine, and persisted. Wound was carefully examined for a possible stitch abscess, but no evidence of such was discovered. Finally, an overlooked hypodermic abscess was found on the left arm above the elbow. This was opened and the albumoses immediately disappeared from the urine. At the same time two counts of the leukocytes were made from blood taken from the affected arm and from the healthy one. There was no difference in the differential counts, nor practically in the total number, and an increase of the leukocytes was not present.

CASE V.—Patient of Dr. Hawley, Samaritan Hospital. Abdominovaginal examination revealed a large semisolid mass which filled the pelvis almost completely. The cervix was pressed high up back of the symphysis. The mass, which was of firm consistency, but not hard, was apparently continuous with the cervix uteri. The patient's condition being grave at the time of admission she could not be placed under ether for a more satisfactory examination. Urinary analysis showed a marked renal involvement and a constant reaction for albu-

moses. Operation revealed a suppurating dermoid cyst of the ovary, uterus normal. In this case we looked upon the persistent presence of the albumoses as indicative of suppuration, though the exact character of the condition was not determined until the laparotomy revealed it.

CASE VI.—Adult woman, septic temperature, rapid "wiry" pulse, condition grave, marked tenderness over the region of the ovaries. Abdominovaginal examination revealed enlarged tubes on each side, extremely tender to the touch; albumoses were persistently present in the urine until after operation. Diagnosis: double pyosalpinx. Operation revealed a double pyosalpinx as well as an ovarian abscess.

CASE VII.—Adult woman, had severe and intermittent pain over both ovarian regions, slight rise in temperature and increase in the pulse-rate, though the latter was not "wiry." Abdominovaginal examination revealed immense masses posterior to the uterus and in both broad ligaments. These masses were extremely tender to the touch. Uterus apparently normal in size. Urinary analysis showed a constant reaction for the albumoses. Diagnosis: pelvic abscess. Operation revealed multiple abscesses of the tubes, ovaries, and broad ligaments on both sides, besides a perirectal abscess. Dense intestinal adhesions everywhere present in the pelvis, and the appendix was bound down in a mass of lymph, but was not diseased.

CASE VIII.—Patient of Dr. John Boger, adult male, was admitted to the Samaritan Hospital with all the symptoms of appendicitis present in a marked degree: high temperature, rigidity of the rectus muscle on the affected side, with great tenderness over McBurney's point, and a rapid, "wiry" pulse. Urinary analysis showed a marked reaction for the albumoses. His blood showed a leukocytosis of 19,000, with the polymorphonuclear cells increased markedly. Operation was delayed at my suggestion, in hope that the inflammatory process would become localized and the pus walled off. The urine was examined daily until the third day after admission to the hospital, when the albumose grew rapidly less in quantity, and finally ceased. The symptoms became less aggravated and the patient felt much more comfortable. The leukocytosis had fallen to normal. Operation showed an extensive appendiceal abscess, completely walled off by dense adhesions of recently-formed lymph.

This case illustrates the value of albumosuria in determining the course of suppurative processes and the most favorable time for operation.

CASE IX.—Patient of Dr. Haehnlen, an adult woman, seen for the first time during the second week following an abdominal section. Had had hypodermoclysis in both breasts at operation. Septic temperature and great pain and tenderness in both breasts, which on inspection were found swollen and congested; no signs of fluctuation present. Urinary analysis showed the presence of the albumoses. Operation revealed both breasts filled with pus, deeply situated. The albumoses disappeared after operation very promptly.

CASE X.—Suspected ovarian abscess; albumoses present. Operation showed that the diagnosis was correct.

CASE XI.—Suspected osteomyelitis; albumoses present (Bence-Jones' bodies not found). Operation revealed the presence of pus.

CASE XII.—Coxalgia; albumoses present. Operation, pus found.

CASE XIII.—Suspected pyosalpinx; albumoses present. Operation verified the diagnosis.

CASE XIV.—Ischiorectal abscess; no fluctuation present, albumoses present. Incision revealed pus.

This patient was probably saved from a fistula by prompt operation, as the suppurative process had burrowed its way close to the rectum.

CASE XV.—Suspected perinephritic abscess; albumoses present. Operation revealed this condition.

CASE XVI.—Coxalgia; before sinus formation, pus could not be detected by inspection or palpation; albumoses present. Operation revealed the presence of pus.

CASE XVII.—Coxalgia as preceding case.

CASE XVIII.—Spinal caries; albumoses present in the urine, pus found on operation.

CASE XIX.—Suppurating fibroid (suspected); albumoses present. Operation verified diagnosis.

CASE XX.—Appendicitis; decided to be suppurative on account of the presence of the albumoses, symptoms somewhat obscure. Operation revealed appendiceal abscess.

CASE XXI.—Tuberculous adenitis of the neck; glands were soft, but no distinct fluctuation could be detected. Operation revealed pus.

CASE XXII.—Appendicitis; albumoses present. Operation verified the diagnosis.

CASE XXIII.—Catarrhal appendicitis; albumoses not present. Operation showed the absence of pus.

CASE XXIV.—Suppurative keratitis; a trace of albumoses found in the urine; pus formed in the eye.

CASE XXV.—Necrosis of the metatarsus; albumoses present; pus found at operation.

CASE XXVI.—Prostatic abscess (mistaken for hypertrophy); albumoses present in the urine. Operation revealed

the condition, which the attending physician would not consider previously at my suggestion.

CASE XXVII.—Epidemic parotitis, occurring in a patient of my own, a male child of 12 years. The condition commenced with pain and swelling beneath the right ear; temperature 103° F. He experienced great difficulty in opening his mouth and in masticating his food. The swelling remained localized on the right side of his face, and I was at a loss at first to decide whether we were dealing with a simple abscess or mumps. His mother displayed great anxiety, and inquired constantly whether I thought pus would form and an abscess result. A blood examination showed no leukocytosis and no relative increase in the percentage of polymorphonuclear elements.

I was aware that Cabot had examined the blood in five cases of epidemic parotitis and had found no leukocytosis. I examined the urine repeatedly for the albumoses for several days (during which time the swelling remained of the same size) but never found them present. I was now sure that we were dealing with unilateral mumps and not with an abscess. I had the pleasure of seeing the affection disappear in a few days without any suppurative process having taken place. In this case the absence of albumoses proved of extreme value, as did the negative count of the leukocytes.

CASE XXVIII.—Suspected otitis media in a male patient. The affection commenced with persistent pain the right ear, disappearing in a few days. Albumoses were present in the urine during all this period. On the fourth day pus issued from the external meatus.

CASE XXIX.—Pyosalpinx; albumoses found. Operation verified diagnosis.

CASE XXX.—Catarrhal appendicitis; history of three previous attacks; no albumoses present. Operation showed the absence of pus.

CASE XXXI.—Cystic ovary; albumoses not present. Operation verified the diagnosis.

CASE XXXII.—Patient had much pain and tenderness over the region of the gallbladder, with moderate rise in temperature and increase in pulse-rate. Was thought by the attending physician to be suffering from hepatic abscess. Albumoses were not present; in the course of a few days several gallstones were passed and the condition immediately subsided.

CASE XXXIII.—Patient admitted to the hospital with high temperature, running pulse, and marked pain over the left lung posteriorly, with considerable dullness; albumoses present. The diagnosis of empyema was verified by postmortem examination.

CASE XXXIV.—Carcinoma of the stomach, occurring in a man of 56. The pyloric orifice was reduced to the diameter of a leadpencil; the tumor was about twice the size of a walnut and was very difficult to map out. There had never been any pain, vomiting, in fact nothing except gradual loss of strength. The urine was repeatedly examined for the albumoses, but they were never detected. Postmortem examination showed a carcinoma of the pylorus.

CASE XXXV.—Carcinoma of the stomach (cardiac opening); albumoses were never present. Condition verified by postmortem examination.

CASE XXXVI.—Adult female; abdominovaginal examination revealed nodular tumors of the uterus; albumoses not present. Operation showed a fibroid tumor of the uterus.

CASE XXXVII.—Adult woman; abdominovaginal examination disclosed a globular hard mass in the right iliac fossa; albumoses not present. Operation revealed a unilocular cyst of the ovary. The fluid which this cyst contained did not show the presence of albumoses, but did show serum globulin and serum albumin.

CASE XXXVIII.—Patient had a mass in the right testicle, which was extremely tender to the slightest touch; albumoses not present. Operation revealed a carcinoma of the testicle.

CASE XXXIX.—Adult man; affection commenced with severe pain and swelling in the right shoulder-joint; had never had rheumatism; unlike rheumatism (acute articular), it did not move successively from joint to joint. Albumoses not present. Pain and swelling subsided rapidly under appropriate treatment. This patient occupied an important mercantile position, and it was of the greatest importance that a correct diagnosis be made. The blood examination was negative.

CASE XL.—A woman of 22 was admitted to the hospital with symptoms of septicemia; self-induced abortion suspected, as all other conditions were practically excluded; microscopic examination of the discharge from the uterus negative. Albumoses were persistently present in large amounts, and I adhered to my suspicion. She finally admitted that it was true.

CASE XLI.—Adult man, aged 79; had suffered from repeated attacks of catarrhal jaundice for 30 years, from which he easily recovered. When he came under my observation he was suffering from severe and intermittent pain in the region of the gallbladder, with marked tenderness. Albumoses were at no time present. His symptoms, taken together, made the diagnosis of hepatic abscess strongly probable. He had also a

leukocytosis of 27,000. At the postmortem examination carcinoma of the gallbladder was found.

CASE XLII.—Adult negro; necrosis of the parietal region; albumoses constantly present; was operated upon (bone cured); albumoses still present after operation. At postmortem examination a recent thrombosis of the superior longitudinal sinus was found directly situated under the necrotic area externally. The thrombus was broken down, softened and its contents partially liquefied and purulent.

CASE XLIII.—Adult male; consulted me for general nervousness; appeared hypochondriacal; a marked trace of the albumoses found in his urine. Other causes excluded, gonorrhea was discovered to be accountable for the symptoms of neurasthenia. This case is one of many in which I have discovered a previously denied attack of gonorrhoea.

CASE XLIV.—Female dog; abscess of the jaw, no signs of fluctuation or pointing; albumoses found; incision revealed the presence of pus.

CASE XLV.—Severe neuritis of the left arm, which was swollen and red from shoulder to finger-tips, skin was tense and shining; albumoses not present; symptoms disappeared under appropriate treatment. This case caused me anxiety as the inflammation was of such a high grade as to make impending suppuration seem certain.

CASE XLVI.—Adult female; abdominovaginal examination revealed a hard nodular mass attached to the uterus which was immovable. Patient had high temperature, rapid running pulse, and was completely prostrated. A diagnosis of probable suppurating fibroid was made. No albumoses were found. Operation disclosed a carcinoma of the fundus and body of the uterus with general involvement.

CASE XLVII.—Adult male; diabetes mellitus complicated with carbuncle. Albumoses found disappearing when the carbuncle had been thoroughly opened and the pus evacuated.

CASE XLVIII.—Adult male; diagnosis, acute pericarditis; albumoses found. Autopsy revealed the pericardium filled with pus.

CASE XLIX.—Abscess of kidney; albumoses present. Postmortem examination proved the diagnosis correct.

CASE L.—Suspected pyosalpinx; albumoses not found. Operation revealed a cystic ovary.

The presence or absence of leukocytosis in suppurative conditions has lately been the subject of considerable controversy. I have arrived at the conclusion from numerous leukocytic counts in suppurative conditions that a single count has rarely any diagnostic value, and is not to be relied upon. There are so many apparently insignificant causes of leukocytosis that great discrimination must be observed before coming to the conclusion that the process under consideration is suppurative. It may be that in a dozen or so cases we will find the presence or absence of leukocytosis of value, then again we will be deeply disappointed. There is a sound pathologic basis for this wide variation in results which I will not discuss. If I had depended on the presence or absence of leukocytosis in the cases given herein, I would have been lead widely astray. The great disproportion between the number of erythrocytes and leukocytes, counted on the Thoma-Zeiss blood-plate, also leads to error, if we consider the great difference in the result—if two or three leukocytes are or are not counted. The proper method (which it appears to me is little used in this country) is by means of the Friedlander counting plate, which makes the number of leukocytes counted equal to the number of erythrocytes counted on the Thoma-Zeiss plate.

In the diagnosis between simple leukorrhoea and gonorrhoea I have found the presence of the albumoses in the urine of value, as sometimes throwing light (especially in women) on an entirely unsuspected condition, the apparently good behavior and morals of the patient leading us astray. I have made it a rule, in these cases, to examine the discharge for the gonococcus, and have often seen a perplexing diagnosis cleared up. It is hardly necessary to remind the reader that great care should be exercised in announcing such a diagnosis before it is absolutely certain. In pleurisy I have found it of value in indicating whether the effusion was or was not purulent, and the cases of pneumonia in which I have observed its presence to indicate unerringly the beginning of resolution are numerous.

Dr. Yarrow, Sr., has had during the past eight years seven attacks of catarrhal pneumonia. In every attack albumoses were present during the stage of resolution, which was almost always protracted and exhausting.

Albumoses are often mistaken for serum albumin and serum globulin in urinary analysis, as so many of their reactions are similar with those tests which are commonly used for the detection of albumin. More than one case has come to my notice in which a diagnosis of chronic parenchymatous nephritis had been erroneously arrived at by a lack of care in distinguishing the proteids.

A host of conditions will suggest themselves in which the presence or absence of the albumoses will prove of great value in diagnosis. I have refrained from giving a longer list of cases which I have observed, as I think those already given will illustrate what I have endeavored to bring prominently before the medical profession, with the earnest hope that many lives will be saved through this important means of determining whether pus is or is not present in the body. We might broadly say that all pathologic processes rest on inflammation and retrograde metamorphosis as a basis. A change in the function of an organ or tissue leads to irritation or inflammation, which may terminate in recovery or proceed to degenerative changes, when the broken-down tissues must be got rid of or disposed of in some manner. Following inflammation many cells are so stimulated or irritated that their death is certain, and they must be disposed of to make room for new ones. It is hardly necessary to add that pus or the products of tissue destruction always seek to escape from the body. If the ordinary path is obstructed, nature seeks in two ways, principally, to rid herself of the useless and poisonous debris, first by walling off the pus to prevent its further absorption or invasion and subsequently slow absorption and elimination; second, by direct and more rapid absorption into the circulation and elimination by the kidneys, skin, lungs, etc. The second process results in general septicemia or pyemia in many instances, although there is no doubt that it takes place to a certain extent even where the pus is safely walled off, and gives rise to the usual symptoms of sepsis which we observe. Nature always endeavors to hem in the invading bacteria by a wall or barrier of leukocytes, and if the collection of pus is not large, it is disposed of quite rapidly by absorption. From the large number of cases of septicemia in which casts and albumin are observed in the urine, I cannot help being convinced that inflammatory or toxic changes are set up in the kidney in nearly every case of septic absorption. Especially have I seen this occur in septicemia following childbirth and abortion, when I had previously examined the urine and found it normal. With recovery the casts and albumin disappeared, and rarely was there any further evidence of a kidney lesion. That such lesion is occasioned by septic products passing through the kidney seems highly probable, as the condition disappears rapidly after the poisonous products have been eliminated. This condition is also observed during the last stages of many diseases, as, for instance, carcinoma, sarcoma, diabetes mellitus, etc. (acid intoxications). In the nephritis following or occurring during septicemia, we do not find that striking diminution in the quantity of urea excreted that we observe in chronic parenchymatous or interstitial nephritis, so characteristic of the latter as to be almost a symptom.

The prompt recognition of the fact that pus is present often relieves a situation of some of its danger, as an early operation may be performed with confidence and knowledge of the condition which has to be met and grappled with. Operations undertaken during the acute stage of appendicitis (when the suppurative process is spreading) give a mortality of 20% or higher, and may be followed by a relapse. Operations undertaken during the stage of quiescence are followed by a very low mortality, and it is here that albumosuria in indicating that this stage has been reached is of great value in saving life which otherwise would have been lost. Dr. Joseph Price has said: "Surely there is not a more pitiful sight than the little child, sweating, tossing, and

dying, its abdomen an arch, its heart a high-pressure pump, on a chair by the bed a basin and a bowl of cracked ice. To see this a few times makes the most conservative shudder and wonder." And I will add that this pathetic situation often originates or is caused by the doubt in the mind of the physician or surgeon as to whether pus is or is not present. According to Deaver, ptomain poisoning, food infection or autointoxication often gives rise to symptoms which strikingly resemble those of acute appendicitis. The presence or absence of albumosuria would afford a strong clue to distinguishing this condition from appendicular abscess. Deaver and myself are also opposed to placing absolute reliance on the presence or absence of leukocytosis in such cases. In the first seven cases of various intraabdominal suppurative conditions which I observed and studied carefully (when I had not as much confidence in albumosuria as I was forced to have later) the diagnosis was rendered unerring, the presence of pus disclosed at the time of operation, and all of the patients recovered. Since then my confidence has steadily increased.

From leukemia, in which affection the albumoses are sometimes found in the urine, suppurative conditions may be distinguished by the absence in the latter of the striking and characteristic blood changes observed in the former disease, such as the enormous increase in the number of leukocytes and the pathologic variations in the differential count of the same. The inorganic albumosurias would seem at first glance to confuse the diagnosis, but when they are studied the cause of the tissue destruction is made apparent, as in phosphorus poisoning, chronic carbon monoxid poisoning, scurvy and purpura hæmorrhagica. The history of the case and the characteristic symptoms of these conditions will readily serve as a guide in the large majority of cases to prevent confusion. After labor (as I have shown) the presence of the albumoses in the urine is the result of a physiologic process. The exact chemical nature of the products of retrograde metamorphosis resulting from the process of normal involution are still unknown, with the exception of the albumoses. It may, however, be safely assumed that these proteids disappear from the urine about the twenty-first to twenty-fifth day, and that their presence later than this would indicate some pathologic condition of the uterus. The disappearance of the albumoses shortly after operation (when the pus has been removed) is interesting and important. By its persistent presence I have often detected a wholly unsuspected stitch-hole abscess.

I may add that albumosuria is invaluable in indicating beginning suppuration following traumatism such as gunshot and stab wounds of the thorax and abdomen, also in meningitis resulting from contusion or fracture of the skull. I am sure that by closely observing what I have conscientiously endeavored to demonstrate the importance of, we can greatly lessen human suffering and prolong life, diminishing the number of those conditions which often bring life to a premature termination. The pathway of diagnosis is beset with difficulties, and light from a reliable source should be welcomed, if by its means life may be saved or prolonged. In conclusion, I wish to thank Drs. Deaver, Boger, Hæhnlén, Hawley, and Schell for the interest which they manifested in this work, much of it being carried on at the Samaritan Hospital.

**Homeopaths' Demand.**—It is reported that Mayor Ashbridge has recommended to the City Council that the homeopathic profession in Philadelphia be granted the right to take charge of a city hospital, entirely under the control of this school. Leading physicians representing the homeopathic profession have met and taken formal action respecting the matter, and have considered the best means to carry into effect the proposition made by the mayor. The society has asked that when a new municipal hospital is completed that the old Municipal Hospital be turned over to the homeopaths for the treatment of noncontagious diseases under municipal control and where homeopathic treatment only shall be practised.

## INFLUENCE OF MARRIAGE AND PREGNANCY ON DISEASES OF THE HEART.<sup>1</sup>

BY

M. J. BACKENSTOE, M.D.,

of Emaus, Pa.

A physician, consulted as to the advisability of marriage in cases of disease of the heart, should take into consideration a variety of circumstances.

In the first place he should consult in a certain measure the wishes and ideas of the person interested. I need not dilate upon the bad effects which may be produced in the case of a cardiac patient simply as a result of withholding consent to a marriage ardently desired. In addition, he must consider the degree of the lesion, particularly whether this lesion has already given rise to cardiovascular symptoms, such as hemoptysis or marked dyspnea. Under such circumstances the marriage should be disadvised, for if the heart disease under normal conditions of existence has given rise to even slight attacks of "asystole," indicating a certain tendency to cardiac "adynamia," it is probable that a pregnancy would render more marked and formidable these symptoms, on account of the new and certainly defective condition thus imposed upon the circulation. Even in such cases, however, it is well not to be too uncompromising. The various circumstances under which the symptoms have made their appearance should be carefully investigated, and the effect of treatment inquired into, so as to ascertain whether the cardiovascular disturbances have rapidly yielded to the medicinal substances employed.

The situation of the patient in respect to occupation and hygienic surroundings should also be taken into account, in order to learn whether there is anything in this connection which might result in her being exposed to prolonged causes of organic perturbations. Lastly, it should be ascertained whether she would be at liberty to keep perfectly quiet in case of unfavorable symptoms making their appearance.

If the conditions are all favorable there is no reason for objecting to marriage. However, the condition of the heart should be carefully watched, and the precautions required to be taken by the patient herself should be fully explained to her, as well as the necessity of avoiding so far as possible all effort and fatigue in case of pregnancy. Moreover, I would dilate considerably upon the importance of the preventive action of a mixed milk diet, the milk being consumed at the rate of two liters daily. This diet, rigorously applied from the third month of pregnancy, constitutes a powerful aid to the circulation by reason of its action on diuresis.

For my part, I should not offer serious objection to marriage in the absence of all cardiovascular symptoms of certain gravity, when the patient is willing to promise to observe this diet in the case of pregnancy. It appears to me that milk not only exerts a preventing action on gravid cardiac symptoms, but also on the appearance of albumuria. In fact, I consider a milk diet an excellent preventive treatment for pregnant women from the moment pregnancy is established. There can be no doubt, however, of the aggravation of the cardiac lesions under the influence of repeated pregnancies. Pregnancy, moreover, in some cases, may cause serious disturbances in the cardiopulmonary circulation by throwing an additional amount of work upon the heart. This is more likely in patients suffering with a mitral lesion, which by affecting the lesser circulation may, sooner or later, cause lung and heart symptoms, such as dyspnea and hemoptysis.

**CASE.**—The patient was a woman of 31, who had no particular family history and who was healthy during childhood and early life. The menstrual function was established early and was always regular. When 21 she had an acute attack of general articular rheumatism lasting with periodic exacerbations

<sup>1</sup> Read before the Lehigh County Medical Society, Allentown, Pa., November 11, 1902.

for nearly two years. During this time she suffered with involvement of the heart from the rheumatic infection. Since then she has had no further attack of rheumatism. However, when she returned to her usual occupation she noticed that she got out of breath easily, her respiration had become short and she suffered somewhat from palpitation. Her health, however, remained fairly good and she married at 24. The following year she had her first child, pregnancy and labor being quite normal. A second pregnancy at 26 resulted the same way. At 27 she had a miscarriage at four months without any evident cause. There were no apparent after effects and she considered herself in good health. A year later she again became pregnant and for the first time since her marriage she began to "feel her heart." Any ordinary exertion resulted in dyspnea, the palpitation became more marked than ever before, and at times she even had blood in her sputum. The pregnancy continued, however, and she was delivered at term without complications. At 30 she was delivered for the fifth time after normal gestation. The delivery seemed normal in every way, but immediately thereafter symptoms of acute asystole became manifest, evidenced principally by repeated spitting of blood and marked dyspnea. Her general condition was that of severe prostration. She suffered from severe oppression and want of breath. The face was cyanosed and the extremities were cold. Hemoptysis and weak and irregular action of the heart continued. Jugular pulsation, strong enough to be seen at a distance, was present. This showed the existence of tricuspid incompetence with dilation, as ascertained by percussion. No evident improvement appeared to be obtained from medium doses of digitalis for the first several days. Small doses of morphin appeared to be very soothing and restorative so far as the dyspnea and arrhythmia were concerned. Auscultation could then be done better and a systolic apex murmur was found over the ensiform cartilage, which confirmed the evident tricuspid regurgitation. The patient eventually made a fair recovery, but the heart never recovered the state of equilibrium in which it was before the last, and especially before the fourth, pregnancy.

As the mitral and tricuspid lesions were not both due to the same cause—rheumatism—there was, I think, reason to believe that the influence of repeated pregnancies aggravated the original mitral lesion, causing the disturbance of the pulmonary circulation and the dilation of the right half of the heart with functional tricuspid inadequacy.

## THE REPORT OF A CASE OF MALIGNANT EDEMA.<sup>1</sup>

BY

ISAAC RIDGEWAY TRIMBLE, M.D.,  
of Baltimore, Md.

Professor of Anatomy and Clinical Surgery, College of Physicians and Surgeons, Baltimore, Md.

The condition to which I wish to call attention is that of malignant edema, a rare disease in these days of perfected surgical technic. It is a rapidly spreading inflammation, in which the tissues become distended with the gaseous products of decomposition due to the infection of the parts by a special microorganism. This germ was first described in 1877 by Pasteur, who called it the *Vibrio septique*. It was carefully studied by Koch, in 1881, and called *Bacillus oedematis maligni*. It is a widely distributed microbe, and is found in the superficial layers of the soil, in dust, in decaying matter and in foul water. It is a bacillus from 3.0 to 3.5  $\mu$  long. It is often united in pairs or chains, and may form filaments. In its general appearance it looks like the anthrax bacillus, but on closer inspection is found to be thinner and to have rounder ends. The segmentation does not resemble that of *B. anthracis claviformis*. It forms oval spores which have a greater diameter than the bacillus itself. These are situated either toward the ends or centrally and cause swellings in the organism. It is stained by the usual dyes but decolorizes by Gram's method. It is anaerobic, liquefying and slightly motile. It grows best at 37° C., but also grows at the room temperature. The most characteristic growth is obtained by seeding it in gelatin liquefied by heat. The deeper ones develop into special colonies in two or three days. When examined with the low power they are found to be permeated with a network of filaments radiating from the edges of the colony. According to Kitt,

it is pathogenic for mice, guineapigs, rabbits, horses, dogs, sheep, calves and chickens. Arloing and Chauveau state that cattle are immune. When produced artificially the smaller animals generally die, while the larger ones usually survive.

After death the liver and spleen are found to be enlarged and soft and filled with numerous bacilli. If the autopsy is made immediately, the germs are not found in the heart's blood, but if made some hours after death, the blood of the heart will contain a great many of these bacilli. At this time they are found in all the organs and in the serous cavities. Mice are an exception to the general rule. In them the bacilli may invade the circulation before death so that they are found widely distributed even if the autopsy is made immediately.

Brieger and Ehrlich report two cases of typhoid fever complicated with malignant edema, which resulted from the hypodermic injection of impure musk.

Grigorjeff and Ukke have observed a case of typhoid fever in which after intestinal perforation had taken place there was a general infection with *B. oedematis maligni*.

The gangrenous and putrefactive phenomena which are marked features of the disease are said to be due, not to the specific organism, but to the admixture of the ordinary putrefactive bacteria. According to Park, when the bacillus is injected in pure culture, it produces an extensive hemorrhagic edema without gas formation, but when an impure culture or garden earth is used, the resulting lesion is a combination of emphysemic edema and gangrene.

This organism must not be confused with *B. aerogenes capsulatus* of Welch. This is an anaerobic, gas-producing germ. It is however, nonmotile, nonliquefying and does not form spores.

The case which I wish to report occurred in my service at the City Hospital, the patient having been referred to me by Dr. J. W. Chambers.

On July 1, 1900, at 3 p.m., the patient, a boy of 12, fell from a swing. He sustained a fracture at about the middle of his left femur. The upper part of the bone cutting through the soft parts ran into the ground. He was removed to his home, where his family physician cleansed the wound and put the leg in a side-splint. Dr. Chambers was called to see the boy at 10 p.m. At this time he had a temperature of 99° F., a pulse-rate of 90, and was resting quietly. However, early the next morning the boy became delirious, and his leg began to swell. He was seen by the consultant at 2 p.m., on July 2, when he had a temperature of 103° F., pulse of 160, and respirations 40. The leg and thigh were very much swollen and dark, and emphysematous streaks extended up the thigh and spread over the abdomen. From the wound there was discharging a dark-brown, serous fluid. The boy was ordered to the hospital, where I saw him at 5 p.m. of the same day.

At this time his temperature was 105° F., while the pulse and respirations were the same as earlier in the afternoon. The leg, abdomen, and back were covered with the characteristic brown, bacon-like streaks, and the tissues over these parts cracked on palpation.

Under ether anesthesia the thigh was amputated just below the greater trochanter. The muscles were bright pink in color. A dark-brown fluid filled with gas bubbles could be pressed out from the connective tissue between the muscles. Incisions were made over the abdomen, side and back. The amputation wound was left open, and no sutures were used. The wounds were packed, and a constant stream of 1-2000 mercuric chlorid solution allowed to run over the dressings. The boy was stimulated in every way. On July 3 he seemed better. He had retained all his nourishment, and his bowels had moved. The temperature was 101° F., the pulse 120, and respirations 30. When the wound was dressed the foul smelling, necrotic tissues were cut away. The disease continued to spread, however, and by July 5 the crackling could be felt over his shoulders. He died on July 7, six days after the injury. No autopsy was allowed.

On July 2 cultures were made from the secretion from the wound and from the necrotic tissues taken from between the muscles, and *B. oedematis maligni* was found in all the cultures. The cultures contained both bacilli and spores in great numbers, as well as some contaminations.

Dr. H. Westphal inoculated rabbits with the secretion from the wound and also with bits of the necrotic

<sup>1</sup> Read before the Journal Club, November, 1900.

tissues. These rabbits all died in 24 hours having shown the characteristic symptoms of malignant edema. In these animals the bacilli were found in all the organs. An examination of the blood of these rabbits a short time before death did not reveal any organisms, but a short time after death the blood was found to be filled with them. The secretions from these animals produced malignant edema on being inoculated into others.

On July 3, in the coverslip preparations made from the tissues deep down between the muscles, spores of the tetanus bacillus were found in addition to the malignant edema organism. The boy was given one vial of anti-tetanic serum. He did not at any time show symptoms of tetanus. It is not claimed that this single dose of serum prevented the disease, but it was thought wise to take this precaution after finding the tetanus germs which had evidently been in the wound 48 hours.

## BRIEFS ON PHYSICAL TRAINING.

BY

G. FRANK LYDSTON, M.D.,

of Chicago, Ill.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's Hospital.

No. 6.

### The Most Valuable Forms of Athletics, and General Conclusions.

The previous briefs on physical training embrace rational methods of muscle building which are open to every one and which require no great expenditure of time nor complicated apparatus and no associates. The aims of muscle building have already been outlined in general. It must be remembered, however, that the principal object is after all the preparation of the muscles for exercises of a general character, involving the elements of recreation, endurance—to a moderate degree—and skill. I am laying aside altogether athletics for prowess and professional athletics, excepting in so far as what I may say may be of service in the guidance of individuals whose trend is in one or the other of these directions.

In speaking of competitive athletics I refer chiefly to athletics practiced with the sole object of achieving a record or for prizes. Practical athletics cannot be absolutely dissociated from the element of competition in such forms as require more than one individual for their practice. Thus boxing, fencing, and wrestling must necessarily be in a sense competitive, otherwise there is no zest to their performance.

It is better for the unprofessional devotee of athletics for health not to specialize but to practise different forms of athletics. There are certain principles that should be inculcated at the beginning:

1. That rational athletics aim at symmetric development and health improvement, not at gigantic muscular development. The subject should understand that the latter can often be procured only at the expense of life.

2. An attempt should be made, not to excel in prowess another individual of perhaps an entirely different physique, but to get as much out of one's self as is consistent with normal capacity.

3. That athletic exercises in the open air are the ideal forms of athletics.

4. That athletics involving quick movements are of the most practical, useful, and beneficial type. A muscle which is developed by slow movements against weight ever remains a sluggish and comparatively useless muscle. Here is the chief source of disaster to phenomenally strong men whose immense muscular development has been acquired by hard labor when they are induced by overenthusiastic admirers to enter the field of competitive athletics. The professional strong man who goes into the prize-ring very rarely achieves

more than a second or third-rate reputation. When brought in competition with athletes to the manner born the end is rarely doubtful. There are, of course, exceptions to this rule, but they are rare. To formulate a rule the quality and action capacity of a muscle of given bulk is governed largely by the manner in which its development has been acquired.

5. Athletics, when properly selected, are not only beneficial to health but increase the chances of the individual in the battle of life, a point which will be expatiated upon later.

6. One of the most salutary features of proper physical training, one which should be achieved whenever possible, is play. It is possible for an individual to train exhaustingly with gymnasium apparatus without securing for a moment that diversion of the mind which is so essential to athletics for health. The student can swing Indian clubs by the hour without forgetting for a single instant the vexatious problems of his daily pursuit. The board of trade broker can worry about the price of wheat while vigorously exercising with the dumb-bells or rowing machine. The benefits of physical training under such circumstances are very dubious to say the least.

That play is essential to exercise, and, indeed, is a natural factor of physiologic exercise, is well illustrated by the habits of young animals during the period of active growth. The play of children is chiefly responsible for such physical development as they acquire.

Before undertaking practical athletics of any kind, a thorough physical examination should be made to determine (1) the general muscular development and capacity, as an indication of the quality and quantity of exercise that are most desirable; (2) to estimate as nearly as may be the general vitality and recuperative power of the subject. This is an important point, and one which cannot be very definitely settled save by subsequent observation and careful estimation of the endurance of the individual under special forms of physical exercise; (3) to determine the points of least resistance. For example, an individual with defective heart or lungs must take up such a course of exercise as is least likely to produce heart strain, or is best adapted to pulmonary development. It should be remarked in this connection that cardiac disease is not necessarily a contraindication to exercise. Moderate systematic muscle training is oftentimes beneficial to a heart, the integrity of which has been seriously impaired by disease. The advisability of exercises tending to pulmonary development being taken in the open air is at once obvious.

There are certain forms of exercises to which the play element and the cooperation of cheerful companions are necessary concomitants. The chief among these are boxing, fencing, wrestling, handball, baseball, and the modern, sensible fad of golf. It is not possible for the individual to indulge in any of these forms of exercise while at the same time permitting his mind to be engrossed with the cares of business. This is especially true of boxing, fencing, and wrestling. Should the individual allow his mind to stray from the work in hand, he is quite likely to be forcibly reminded of his negligence by his antagonist. There is a stimulus in the muscular and intellectual opposition of one's associates in exercises involving play and skill which can be obtained in no other manner. The battle of wits and muscles is always beneficial, providing the element of muscular competition is not carried beyond normal limits.

In my judgment, the ideal form of exercise, especially when it can be practiced in the open air, is boxing. All of the faculties are alertly engaged in a boxing bout, and every muscle of the body is put in play without great danger of serious strain if the individual be at all discreet. The game is by no means as rough as is ordinarily supposed, and, contrary to the usual belief, it is in nowise productive of rowdiness. Parents may,

without hesitation, have their sons instructed in boxing with the fullest confidence that the acquirement of the art will not have the slightest tendency to make bullies of them, but, on the contrary, will impart not only confidence in their ability to take care of themselves when necessity demands it, but also a wholesome respect for the rights of others. Boxing and fencing are alike in many ways. Both of these exercises train the eye, cultivate muscular equipoise, increase muscular command, improve the carriage, and impart judgment of distance. The spinal reflex is improved in such a manner that the individual often escapes from serious injury through the automatic reflex action of the voluntary muscles. Movements of the muscles which, primarily, are purely voluntary, become instinctive and automatic after thorough training in boxing, fencing, and, to a certain degree, in wrestling. I recall an incident in which a gentleman saved himself from serious injury by instinctively parrying, with a folded umbrella, a thrust from an iron rod which lay upon the bottom of a wagon that was suddenly backed in his direction. A trick in fencing, which had been learned by careful training of the voluntary action of the muscles, came suddenly and automatically into play in the presence of danger.

The training of the various faculties enumerated must necessarily result in improved brain development, and even though the improvement be chiefly in the direction of the motor centers, the higher centers of the brain must, of necessity, participate in it to a certain degree. Certain ignorant and more or less stupid individuals among wellknown athletes may be quoted in contradiction of this assertion, but it is safe to say that even these individuals are immeasurably superior in intelligence to what they would have been without systematic muscle training. I do not mean by this that extreme muscular development fits one for intellectual work of a high order. As I have already intimated, the contrary is the case. It must be remembered that I am extolling physiologic muscle building and athletics. I am also expatiating upon the effects of certain special forms of athletic exercises, involving increased muscle control and agility. It is hardly conceivable that heavy lifting and other forms of exercise tending to produce merely an increase in muscle bulk and power against weight could do otherwise than inhibit intelligence. The average intelligence of men and women who practise athletics in moderation is certainly higher than that of the mass of humanity.

Fencing is an ideal form of athletics for women, and should be more generally practised than it is at the present time. Lightness and grace, agility, suppleness of muscle, quickness, and a springiness of step are imparted by fencing to a greater degree than by any other form of exercise. It is often impracticable for individuals to secure partners for a boxing or fencing bout. The next best form of exercise under such circumstances is the use of the striking bag. In this form of exercise quickness of muscular movement and of eye are developed, without inordinate muscular strain. The effect in increasing lung capacity and general physical endurance is remarkable.

An important point for consideration in connection with such exercises as boxing, fencing, and handball is that the development of the brain centers and the training of the reflexes thereby acquired is of inestimable value to the subject throughout life. The battle of life is a contest in which one must proceed along the lines of least resistance if he would succeed. He who is quickest to recognize and to remove obstacles from his path with the least expenditure of energy is the most likely to arrive at the goal—success.

Wrestling, if kept within proper bounds, is a safe and beneficial form of exercise, but so long as human nature is as it is, its effects, upon the average, will necessarily be injurious. Violent muscular or visceral

strain and serious traumatic accidents are likely to occur, even when the contestants are good-natured and gentlemanly. Should the slightest element of viciousness enter into the exercise, its dangers are compounded. The most scientific wrestlers in the world are the Japanese. These people make the exercise play or manslaughter at will.

The advantages of ball playing, especially for growing lads, are too familiar to require extended mention. The dangers of this form of exercise are hardly worthy of notice, so far as its indulgence as a form of play is concerned. As a form of professional athletics, it is usually abused, and contains the same elements of danger as other violent forms of professional athletics.

Football as a play game for young lads is usually a safe and beneficial form of exercise. As the game is played between rival teams of adults, both professional and amateur, it is, in my estimation, one of the most dangerous and brutal forms of athletics. The records of the prize-ring are put to the blush by those of the football field, while the statistics of the killed and maimed in the Spanish-American war present a very modest showing when compared with the number of killed and maimed in football games for the last five years. The exigencies of match games necessitate danger to the contestants under the most favorable circumstances, and if, as is usually the case, one or more rowdies are embraced in the personnel of the rival teams, the dangers of the game are greatly enhanced. The temptation to injure a competitor when the act is likely to be undetected or attributed to the exigencies of the game is too great for such individuals to withstand, and so long as the members of the rival teams are merely human, it would be too much to expect that all should be actuated by principles of fairness and decency. It is so easy to plant one's elbow or knee in a vital spot in an opponent in the course of a football scrimmage that certain individuals almost invariably succumb to the temptation. Aside from the danger of rowdyism, there is the tendency of even the fairest minded athlete to lose his self-control under the stress of great excitement.

A moderate indulgence in rowing is one of the best possible forms of physical training in the open air. The bodily movements involved are such that practically all the muscles are brought into play, and, save in contests for speed supremacy, there is little likelihood of overstrain. Even under such circumstances the brunt of the strain is usually borne by the heart rather than by the muscles in general. Boat racing is perhaps the most dangerous to the heart of any form of athletics, and the professional oarsman or over-enthusiastic amateur who escapes cardiac damage is a rarity. Even a superficial observation of the crews of racing barges at the end of a hotly contested race should be sufficient to convince even the intelligent layman of the dangers of boat racing. I recall a case in which a very powerful man was invalidated for nearly two years as a consequence of hepatic and digestive disturbance produced by the strain of a barge race. His illness began immediately the race was over. He was taken from his seat in the barge by his companions, being himself unable to move.

So far as its cardiac effects are concerned, boat racing, to borrow an expression from Hamlet, "cracks" many a heart. A heart which is literally "broken" from overexertion is by no means so rare as is generally supposed—a valve may rupture under violent strain. It is, of course, understood that degeneracy of the heart structure is usually necessary in order that even violent strain should traumatize the organ, but such degeneracy is likely to be present in athletes who continue training until middle life, or past it. It would be just to apply the term "broken heart" to the heart of the athlete, the resistancy and recuperative power of which have become exhausted by overstrain. The heart is broken in the sense that its reserve is gone, and it can no longer meet emergencies. The failing heart of an otherwise

powerful individual under the stress of exhausting diseases, surgical shock or anesthesia, is often thus explained.

It is often necessary to specialize in the direction of pulmonary development while the individual is indulging in any or all of the forms of athletics which have been enumerated. When the proportionate chest development is fair, this is unnecessary, but in many instances the converse is true, and none of the exercises described serves to correct the disproportion. Very light dumb-bells and, when the facilities are at hand, the swinging rings will accomplish the desired result. The latter application is, in my estimation, the best developer of the chest afforded by the gymnasium. The individual who indulges in the swinging exercises necessarily acquires an improved chest development and pulmonary capacity without any effort upon his part other than that involved in swinging by the hands. Light Indian clubs, when scientifically used, have the advantage of being absolutely devoid of danger of overstrain. Their use brings into play every muscle of the body, and imparts grace and suppleness, which are greatly desired.

One of the most valuable forms of indoor exercise is handball. Its practice imparts agility, training of the muscular sense, and quickness of the eye, such as are acquired in very few forms of athletics. There is no strain involved in handball, and athletes who practice outdoor athletics actively during the summer, find no difficulty in keeping in condition by a moderate indulgence in handball during the winter season. When the fad of golf playing first came in vogue, I was very much inclined to ridicule it as a form of physical training. More careful observation, however, of the game has convinced me that it is one of the most valuable fads that has ever come into existence. The necessity of exercise in the open air, and the cheerful companionship involved in the game are at once obvious. So far as its dangers are concerned, it is like all forms of physical exercise. It is likely to be abused by persons whom physical disabilities of various kinds have long since incapacitated for any form of muscular exertion. The fatalities incident to heart disease and sunstroke among golf players should not be charged to the account of the game.

The intelligent application of bathing is absolutely essential to secure the best results from physical training. The stimulus of either very hot or very cold water applied to the skin greatly increases the benefits of muscular exercise. The alternate hot and cold shower gives the best results in some individuals. Great care should be taken not to prolong the bath, and to adapt the temperature and duration to the individual subject.

A stimulating and refreshing effect may always be obtained by the judicious use of the bath. Depression, on the other hand, is quite likely to result if the bath is not used intelligently, physical exercise being thereby rendered injurious rather than beneficial. Brisk rubbing of the skin after the bath is essential.

#### CONCLUSIONS.

1. The general trend of the profession is toward drug, rather than therapeutic nihilism.

2. Physical training along physiologic lines is an important department of both preventive and curative therapeutics, and should be taught in medical schools. The profession at large is woefully ignorant of the objects and principles of physical training.

3. The physician should endeavor to attain physiologic development, as tending to make a favorable impression on the *morale* of his patients.

4. Such departments of medicine as neurology and surgery, particularly orthopedic surgery, are especially enriched by a knowledge of physical training.

5. The end and aim of physical training should be to utilize the inherent physical capital of the individual and develop it to its normal physiologic standard. The

individual equation is the keynote of physical training. One should strive to develop and make ready to his command such muscular fiber as normally belongs to the individual subject.

6. A general adoption of physiologic muscle building would cause a marked improvement in the physical strength, endurance and beauty of the race. Model physiques are much rarer than they should be.

7. Physical and intellectual development should go hand in hand. Neither should be perfected at the expense of the other. The harmonious development of mind and muscle is the most important factor in human society.

8. A more thorough understanding and more general practice of physical training would tend to reduce pauperism and crime, and would materially decrease the expense of our ponderous legal machinery and penal system.

9. Estimating the developmental necessities and capacity of a given individual by comparative measurements is often fallacious. The idea that an individual of a given height and weight should present definite proportionate measurements of the various portions of the body is absurd.

10. The inherent capacity for muscular development possessed by certain individuals is extreme. The muscular development of a Sandow, under precisely similar conditions, is possible only to Sandow and exceptional individuals of his type.

11. Specialism in muscle building is justifiable only in so far as it tends to bring up any given portion of the body to the relative proportions normal to the particular individual, *i. e.*, to the normal symmetry.

12. In beginning the training of adults the occupation should be considered. The muscles of the highly-trained athlete are out of place, useless and perhaps injurious to the man whose occupation is sedentary. Unused muscular fiber and visceral capacity result in muscular and visceral degeneration.

13. Certain individuals tend to become muscle and joint bound under very moderate exercise, and great care should be taken in prescribing physical training for them.

14. The systematic practice of athletics, when carried to extremes, is likely to develop the athletic habit, *i. e.*, a condition of the body in which cessation of training produces serious impairment of health. Under such circumstances the individual is a slave to training.

15. Athletic overstrain is frequent, and occurs in two forms—acute and chronic. Its evils are manifested, first, in individuals who are out of condition; second, in individuals who, while in condition, undertake inordinate feats.

16. Serious disturbances of the heart, lungs, kidneys and liver may result from overstrain, the heart, especially, being often damaged. Even appendicitis may be produced by athletic overstrain. Competitive athletics, as the term is ordinarily used, are especially dangerous in their effects upon the viscera.

17. The average professional athlete at the age of 30 has exhausted his reserve fund of vitality, and should cease active training and athletic competition.

18. Symmetric muscle building should be a preparation for practical athletics of all kinds. This muscle building should involve increase of volitional muscular control and a development of the muscles up to the individual normal standard, no attempt being made to put large and bulky muscles upon individuals in whom such muscles are not normal. The first lesson the subject should learn is the necessity of putting his brain-cell in absolute command of his muscle fiber.

19. The ideal system of muscle building is that which involves the least expenditure of time, and the use of the least apparatus.

20. Abdominal muscle development is the keynote of success in physical training.

21. Of practical athletics the best forms are boxing, fencing and handball. All forms of athletics are most beneficial if practised in the open air. Golf is admirable in this respect.

22. The element of play should enter largely into all forms of athletics, diversion of mind and cheerful companionship being a *sine qua non* in obtaining the best results.

### SOME PROBLEMS OF PREVENTIVE MEDICINE.<sup>1</sup>

BY

BURNSIDE FOSTER, M.D.,

Of St. Paul, Minn.

President Minnesota State Sanitary Association; Editor St. Paul Medical Journal.

[Concluded from page 127.]

I have by no means exhausted the list of preventable diseases, nor have I gone into all the details of the prevention of those diseases which I have mentioned, being restrained by the limits of this essay. There are numerous other less important diseases which might with propriety be included in a more exhaustive discussion of this subject, and recent researches have even suggested that cancer may yet be shown to be of parasitic origin, and therefore to be placed in the same class.

It will perhaps not be out of place at this time to say something concerning sanitation as a business proposition.

It is strange that it should be so difficult to interest the average citizen in matters concerning preventive medicine and sanitary science. When a man is sick and in fear of death he is ready to give (or to offer) almost anything to be restored to health; when a community is threatened by, or is in the midst of an epidemic, there is no limit to the amount of money it will spend to stamp out the pestilence. When the individual has recovered from his illness, when the community has rid itself of the epidemic, how quickly the bitter lesson is forgotten, how slight the impression it has made!

*"Egrotat demon, monachus tunc esse volebat;  
Dæmon convaluit, dæmon ut ante fuit."*

It would seem that the arguments most likely to avail in the efforts of medical men to gain the active cooperation of the public in endeavoring to prevent preventable diseases are arguments addressed to the public pocket, and of such arguments there is surely no lack. Epidemics, both directly in the enormous expenditures of public funds which they entail and the private cost to individuals, and indirectly in their effect on business of all kinds, are expensive. This statement will not be disputed, but it is not so well known that the annual expenditure of a comparatively small amount of money in the improvement of sanitary conditions and in the investigation of sanitary problems would prevent many epidemics and in so doing would make the people not only healthier but at the same time wealthier.

The business which more than any other is directly concerned with the health of the people is the life insurance business, and when we consider the enormous amount of capital invested in this business and the enormous numbers of people, including both the insurers and the insured, who are interested in it, it would seem that life insurance companies might form a powerful combination which would be capable of accomplishing a vast amount of good in this direction. Fire insurance companies have found the support of salvage corps as adjuncts to the regular municipal fire departments to be a very profitable investment; in an analogous but somewhat different way I believe that life insurance companies would find it profitable to use their money and their influence in supporting the work of municipal boards of health, and also, perhaps, in pursuing and maintaining independent investigations of the many problems concerning sanitation which remain yet to be solved.

<sup>1</sup> Read before the Minnesota State Sanitary Association at its annual meeting in St. Paul, December 18, 1902.

The companies pay out annually millions of dollars for death losses which result from preventable diseases. Would it not be profitable from a business point of view alone to spend some of this money in endeavoring to prevent some of these diseases? Of course life insurance companies would be unable, in case they should pursue any such policy as the one suggested, to know just what lives they were saving, and they would probably assist in saving many lives that were not insured. Fire insurance salvage corps assume that all threatened property is insured and endeavor to protect it all; I believe that the life insurance companies could well afford to do the same.

If all the life insurance companies would combine and set aside each year a fund to be devoted to a cooperative investigation of some of the problems of preventive medicine an immense amount of good would be accomplished at an expense which would be trifling to each company, and the direct return to the companies would be very large.

A procedure which I believe has never yet been adopted by any of the life insurance companies would beyond doubt save them many premature death losses and would be of indirect benefit to preventive medicine; I refer to the periodic medical examination of all their policyholders, say once in five, or even once in ten years; by so doing early signs of disease which the applicant was unaware of would be detected, and in many cases appropriate medical treatment would prolong life. It has also been suggested, and the suggestion is a good one, that life insurance companies could strike a severe blow at quackery, and at the same time do a good stroke of business by refusing to insure those who were habitual consumers of patent medicines of unknown composition, and also those who, instead of seeking medical aid when they are sick, resort to christian scientists or other dangerous pretenders. It is a wellknown fact that very many individuals die each year whose lives might have been saved by proper medical treatment, and under the present conditions ignorant and unscrupulous persons, with no pretense to medical knowledge, are permitted in all communities to treat such of the sick as they can induce by persuasive advertisements or in other ways to place themselves in their hands, and there is no disease which they do not attempt to treat. These deaths are preventable, and it is one of the functions of preventive medicine to attempt to prevent them, and as these preventable deaths cause a by no means inconsiderable portion of the death losses which life insurance companies are called upon to pay, we may naturally expect that when they are brought to view the matter in its proper light they will lend a hand.

There are many ways, some of which have been already pointed out, in which the various enormous aggregations of capital which form the bulwark of the world of business can aid the cause of preventive medicine. The great corporations which control these vast sums of money, however, owe their first duty to their stockholders, and nothing can be expected from them for purely philanthropic purposes; but show them how a direct pecuniary benefit can be derived from money expended and this money will be readily forthcoming. The life insurance companies derive a more direct benefit from the prevention of disease than do other large corporations and it will be an easier matter to enlist their direct assistance. Transportation and manufacturing corporations devote much effort and money to the prevention of accidents and are thus aiding the cause of preventive medicine by preventing deaths which might otherwise occur, but I believe that they might readily be persuaded of the economic value of paying more attention to the prevention of disease among their patrons and employes.

An immense service to the cause of preventive medicine has been already begun in some of our large cities, although much remains to be done, in the matter of the more sanitary housing of the laboring classes. A preliminary step to improve the tenement houses would be to make concerted efforts to get as many as possible of their present denizens, especially those who are unsuccessful and discontented in their city life, to take up farming on some of the many millions of acres which are waiting to be tilled. Many of these people are more fitted for a farming than for a city life, and by a little encouragement and assistance they could be sent "back to the soil," where they

could make and maintain for themselves and their families prosperous, happy and healthful homes. This temporary relieving of the congestion, however, although it would be of immense value to the comparatively small number of individuals whose lives would thus be changed, would go but a short way toward solving the real problem. Others would at once rush in to take the places of those who had left and the tenement houses and the slums would be as crowded as ever. The solution of the problem would be to abolish the slums entirely, and to see to it that there are no tenement houses save those which have been constructed and arranged with a proper regard to sanitation, so that those who are forced to inhabit them may at least have the opportunity to enjoy their share of the fresh air and sunshine and pure water which nature offers so freely to all mankind. This is perfectly practicable, and it has been demonstrated time and again that properly constructed tenements for the poor man can be made a paying investment. A vast amount of the preventable disease in all large cities is the result of the unsanitary conditions among the poor, and the presence of these diseases among the poor is a constant menace to the rest of the community.

In order to get the people interested in this reform and to enlist their cooperation, the matter must be brought before them as an economic problem, which it really is, since by far the largest part of the capital of every municipal corporation consists in the lives of its citizens, and surely nothing can be of greater pecuniary value to the corporation than preserving and saving these lives. A very large amount of the vast sums now spent for the support of municipal hospitals and for outdoor relief of the poor would be saved by removing some of the conditions which make this relief necessary.

Hospitals and dispensaries will always be necessary adjuncts of all civilized communities, and most noble is the work that they do, but at the present time medical charity is overdone from two points of view. If a portion of the immense sums of money now annually devoted to the endowment and support of hospitals, both from the public funds and from private beneficence, were diverted and intelligently expended in the cause of preventive medicine, there would be fewer hospitals needed, and if a wiser discretion were exercised in the matter of free medical treatment, the really deserving poor would be given better service.

There are numerous other problems connected with general municipal sanitation which, while lack of space forbids their detailed discussion, deserve at least some mention in an essay such as this. Sanitary reforms are urgently needed not only in the homes of the working people, where they must eat and sleep, but also in many of the shops and workrooms where their days are spent. A brief visit during the busy hours of the day to some of the crowded department stores where hundreds of young men, women and even children spend from 10 to 12 hours every day in poorly lighted, overcrowded and insufficiently ventilated rooms, breathing over and over again the same air, often germ laden and always saturated with bodily exhalations and emanations, will convince any one of the fact that such an atmosphere and such surroundings are far from sanitary. Those who spend their days in these places, however, are in paradise as compared with the lot of those who work in the crowded attics and the dark, damp cellars known by the not inappropriate name of "sweat-shops." Municipalities owe it to their citizens to put an end to such conditions, and all places where large numbers of people are employed should be inspected as to their sanitary conditions from time to time, and the proper authorities should be held responsible for the persistence of the unsanitary conditions which are the direct cause of a very large amount of preventable disease.

Municipal as well as domestic sanitation in many of its phases offers, it seems to me, an excellent field for those women in every community who have the time and the inclination to take up special work aside from their ordinary occupations, and women's clubs which spend much time in the discussion of literary, religious and even political subjects might with great profit to themselves as well as to the communities in which they live devote some of their time and energy to the study of matters of public hygiene. The civic leagues are doing much good work along these lines, their efforts being chiefly directed

toward the beautifying of cities and the cleaning up of back yards and unoccupied property. This is distinctly sanitary work and should be highly commended and encouraged, as it will undoubtedly accomplish much good for the cause of preventive medicine.

The regulation of the smoke nuisance is being demanded in large cities and it is important upon both esthetic and sanitary grounds, and an active campaign by women would start a public sentiment which would go far toward remedying the evil.

Women of the upper classes, who set the fashions for all other women, could also do much for the cause of preventive medicine by making certain changes in their manner of dressing, particularly in regard to the length of the skirt worn out of doors. To see a well dressed and attractive woman trailing a long skirt over a muddy sidewalk and sweeping up the filthy droppings of animals and the still more filthy human expectoration which always lies there, is certainly a disgusting sight, and when that same woman goes home and shakes and brushes her skirt, the myriads of microorganisms which she has collected during an afternoon's shopping are freely scattered about the house to be later perhaps inhaled by herself, her husband, and her children. It can hardly be doubted that the germs of disease are thus frequently introduced into the home, and this danger would be lessened if women would never wear long skirts while walking out of doors. The educated and thoughtful women of our communities may in various ways be of immense service to the cause of preventive medicine, but they must first be made to realize the importance of the subject and how by a little intelligent and concerted action on their part they can assist in bringing about the various sanitary reforms which have been discussed in this essay.

Modern civilization and culture irrespective of creed gratefully and without reserve acknowledge their constantly accumulating debt, a debt which could hardly be itemized, to the Church and to Christianity. Without touching upon the other functions and duties of the Church, for our present purpose let us view only its power as an educator, or perhaps better, as a disseminator of education and knowledge. To very many persons there can be no stronger argument to cause them to accept as truth, not to be disputed, a statement or a theory, than the often eloquent and forcible declamation of the pulpit. The motives, too, of pulpit teachings, whatever they be sometimes the case with regard to their logic, are always the purest and the best, having almost invariably in view no other purpose than the honest desire to elevate and to strengthen those to whom they are addressed. To the Church, as a profession, belongs indisputably the high honor that its followers, much less than in any other calling, have selfish ends in view, or a desire for worldly gain. We have good reason to hope, then, that when in common with the other classes of individuals who receive the benefit of a higher education the clergy have their eyes more fully open to the possibilities of preventive medicine their aid will be freely given.

It was recently related in the *London Lancet* that a clergyman expressed to a health officer who was detailed to stamp out an epidemic of smallpox in a country district of England the desire to help, and asked what he could do. "Preach vaccination and revaccination," said the medical man. The next Sunday the clergyman took vaccination for his text, and told his congregation what it had done in the way of preventing smallpox and what smallpox had been before vaccination was known. During the following week the medical men in the parish had all they could attend to to vaccinate those who took the preacher's advice to heart. This is but an instance of what clergymen could do for preventive medicine if they would take the pains to inform themselves concerning preventable diseases, and if they would occasionally, both in their public and their private communications to their parishioners, mingle a little sanitary advice with their religious instruction. At the present time many clergymen, by giving their endorsement to quack methods of treatment and allowing their names to be used by those who advertise quack medicines, are doing great harm to the cause of preventive medicine, and I am inclined to think that if clergymen were less hostile to or less apathetic regarding scientific medicine, they would find more medical men in their congregations. It is time that both science and the Church

laid aside those ancient prejudices which have kept them apart so long and joined hands for the common good of all the people.

From the foregoing it is apparent that while the existing knowledge on the subject of preventive medicine leaves many problems still unsolved an immense amount of preventable disease exists at the present time which could be prevented if a proper application were made of the actual knowledge concerning such disease which is now in the possession of the medical profession. I have stated and reiterated that medical men alone without the cooperation of the people cannot bring to pass these urgently needed reforms, but it is entirely in the power of the medical profession to obtain this cooperation if a properly concerted effort is made to do so; and this brings me to what I believe to be the most important step toward the achievement of the possibilities of preventive medicine,—the organization of the medical profession.

There are at the present time more than 100,000 practitioners of medicine in the United States of America, the majority of whom belong to that class usually spoken of as "regular practitioners," and the rest claiming to belong to some special school or sect which has adopted a distinctive name supposed to define the method of practice of him who bears it. Many of these latter physicians are men of education, refinement, and culture, and all medical men know that their patients are treated according to the principles of modern scientific medicine and that the original significance attached to the name they bear has long since passed away.

The ancient and absurd prejudices which have kept these men apart and which have helped to maintain the so-called "schools of medicine" must be swept away, and dogmas and creeds must be laid aside as having no place in scientific medicine. Until medicine becomes an exact science, which is not at all likely to occur in the near future, there will always be differences of opinion concerning the details of the treatment of disease, but the broad principles of pathology once demonstrated are unchangeable, and are admitted as the basis of treatment by medical men of all shades of opinion. The administration of drugs, except in those few instances in which we possess specifics for certain diseases, is a mere detail in the practise of medicine, and although it often seems all important to the patient, those whose views are at variance concerning this really unimportant detail should no longer remain divided into different schools and factions. The time is coming, and there are not wanting signs that the time is near at hand, when all earnest medical men will gather together under one banner in the cause of scientific honesty and truth. Then we may expect to see the complete organization of the medical profession into a powerful army, which through its leaders can dictate to the people how they shall conduct themselves in all matters of public and private sanitation, and these commands will be heeded. This organization in this country must be accomplished through the American Medical Association, which instead of the 10,000 members which it now has should have 100,000 members, with subsidiary branches in every State and Territory in the United States. The preliminary steps for the accomplishment of this grand scheme have already been taken, and many earnest workers are now engaged in perfecting the machinery.

Truly we are approaching, indeed we have already entered upon, a new era of medicine, and although we advance with sometimes halting steps the advance is constant, and no backward step is taken. The crowning triumph of medical science is not the curing of the sick, or the relieving of pain, although these are the things which most medical men spend their lives in doing; the ultimate goal for which the medical profession is striving is the prevention of disease. Grand and glorious as have been the triumphs of medicine and surgery over existing disease, they must sink into insignificance when compared with those achievements which shall result from a realization of the possibilities of preventive medicine.

**Danger in Unsanitary Barber Shops.**—James Stettauer, a wealthy financier of Chicago, received a slight cut while being shaved in a barber shop. One or two days later erysipelas became manifest. This disease was followed by an acute nephritis, which resulted in death.

## NATIONAL BUREAU OF MEDICINES AND FOODS: FOR PURE AND HONEST DRUGS, CHEMICALS AND FOODSTUFFS.

BY

PHILIP MILLS JONES, M.D.,  
of New York.

The idea of establishing a board of qualified experts who should represent the interests and the support of the professions of medicine and pharmacy, and through the medium of such a board secure (1) more general conformity to the standards of the pharmacopeia; (2) drugs and chemicals, and foodstuffs that will be actually as labeled and can be relied upon; and (3) deal in a proper professional and ethical manner with the large and ever-increasing number of proprietary mixtures and preparations that are being presented to the medical profession, was first suggested by Dr. F. E. Stewart at the meeting of the American Medical Association in 1881.

This idea has been elaborated and plans have been formulated which it is thought will secure the objects desired. These plans have been approved by a number of representative manufacturers, physicians and pharmacists, and it is evident that if the professional interests and the people of this country (and especially the members of the American Medical and the American Pharmaceutical Association) really desire relief from the present unfortunate and distressing condition of materia medica and pharmacy, and of adulterated and dishonest foodstuffs, such relief is at hand.

Primarily, this plan contemplates the voluntary association of honest manufacturers and pharmacists who will agree with the board of experts representing medicine and pharmacy upon standards of identity, purity, quality and strength to which their products shall comply, and will further agree to carry out these standards and to comply with the necessary rules governing manufacture, etc.

Organization for the purposes indicated has been begun by the formation of a corporation on the membership plan—no stock issued and not for profit—under the name of the "National Bureau of Medicines and Foods," and all members of the American Medical and the American Pharmaceutical Associations are made members of this bureau. It is proposed that the board of directors governing this bureau be elected by these two associations, each having five directors, one from each association retiring annually and a successor elected for five years.

In order to indicate to the physician, the pharmacist or the purchaser such articles as comply with the standards of identity, purity, quality and strength, and may in consequence be relied upon to conform truthfully with the label affixed, and also to reward the honest manufacturer and pharmacist for his honesty and aid him in competition with dishonest or impure products, those manufacturers and pharmacists who affiliate with the bureau in this work will be authorized to print upon the labels of such of their products as are placed under the supervision of this bureau a certificate of identity, purity, quality and strength of a form to be indicated by the board of directors.

All possible precautions in the way of frequent inspection, analysis, or assay will be taken by the bureau in order to keep certified products up to standard and to protect the bureau certificate from fraud. In addition to the original analysis or inspection of each "batch," every article bearing the bureau certificate will be purchased in open market from time to time and submitted to analysis, assay and comparison with standard samples.

The bureau will also gather and diffuse reliable information relative to materia medica products, chemicals and foodstuffs, and to those who manufacture or deal in the same, and it is believed that in a comparatively short time such information will replace and do away with the one-sided and unreliable trade literature which is at present in many instances the only available source of information.

The work of the bureau will be purely commendatory, and not in any way condemnatory, so that it can in no event become an agent of blackmail.

As the bureau is not a commercial enterprise, is not organized for profit, nor for money-making, only the actual expense of doing the work required will have to be defrayed. It is pro-

posed to assess this actual cost upon the various manufacturers and producers whose goods are certified by the bureau, each in proportion to the amount and value of the goods so certified. This feature of the plan has been considered satisfactory by those who have signified a willingness to affiliate with the bureau.

In addition to the two associations already mentioned any scientific society that may vote to affiliate with the bureau may do so, and its members then become members of the bureau; and further, any person who so desires or who is willing to signify his approval of the aims and objects of the bureau, may become a member upon the payment of \$1.00 per year.

5. The Diagnosis of Brain Abscess. HERMAN H. HOPPE.
6. The Diseased Middle Turbinate. CHARLES H. BAKER.
7. Typhoid Fever with Perforation of the Bowel and Recovery. T. K. HOLMES.

1.—**Streptococemia in Scarlet Fever.**—L. Hektoen reviews the literature dealing with the frequency of streptococci in fatal scarlatina and also of studies of the blood during life, describing the technic and results of his own bacteriologic investigations. Streptococci occasionally may be found in the blood of cases that run a short, mild, and uncomplicated clinical course, but occur with relatively greater frequency in the more severe and protracted cases in which there also may develop local complications, and clinical signs of general infection, such as joint inflammations, but even in the grave cases of this kind spontaneous recovery may take place. Streptococci may not be demonstrable in fatal cases. The theory that scarlet fever is a streptococcus disease is not supported by these investigations. An argument for a specific primary infection is the durable immunity entirely different from anything we know of spontaneous or experimental streptococcus diseases. [H.M.]

Boston Medical and Surgical Journal.

March 12, 1903. [Vol. CXLVIII, No. 11.]

1. Limitations of the Uhlenhuth Test for the Differentiation of Human Blood. A. E. AUSTIN.
2. Report of a Series of Cases of Movable Kidney. H. D. CHADWICK.
3. The Composition and Alcoholic Content of Certain Proprietary Foods for the Sick. CHARLES HARRINGTON.
4. A Case of Habitual Dislocation of the Shoulder-Joint. J. COLLINS WARREN.

1.—**Limitations of the Uhlenhuth Test for Differentiation of Human Blood.**—A. E. Austin states that since Uhlenhuth showed that a rabbit or guinea pig injected several times with human blood would give a precipitin for human blood, various efforts and suggestions have been made for providing a "stock" preparation of this humanized rabbit serum ready for immediate use. The author states that his interest was aroused by these efforts to preserve this precipitin. A number of rabbits were injected exactly according to the directions of Uhlenhuth, when he found that the test was not as fully applicable as had been represented, and that only under the most limited conditions could it be employed; that other fluids of the human body, like effusions and exudates, were of little value, and that the fluid from placentas could only be used when it was strictly fresh, and that much longer time and more repeated injections were necessary than we had been led to suppose from the first oversanguine reports of the earlier investigators. His investi-

gations lead him to the belief that the precipitin resides in the hemoglobin rather than in the serum. The author gives in detail the results of his experiments. [A.B.C.]

2.—**Movable Kidney.**—H. D. Chadwick reports a series of 28 cases, 24 females and four males. In 1 man and 3 women the left kidney was movable, in the other 24 cases the right. In 1 woman both kidneys were movable. Ten of the women were married, and 8 had borne children. The author calls particular attention to the fact that many of these patients had been treated by various physicians for years, and some even submitting to gynecologic operations, without the true condition, movable kidney, having been found. Proper treatment in these cases depends on the severity of the symptoms. Palliative treatment in his hands has been unavailing. If symptoms are of sufficient severity to cause semiinvalidism, or even seriously to impair the patient's general health, nephropexy is indicated. Operation was performed in 15 of the above cases, one being a double nephropexy, with satisfactory results except in one case. Good results are as certain in these cases as in suspension of a retroverted uterus. [A.B.C.]

3.—**Alcohol and the Proprietary Foods.**—C. Harrington restricted his analyses to the percentage of alcohol, total solids and mineral matter. The yield of total solids was such as not to warrant expenditure of the time necessary for investigation of the nature of the several constituents. Liquid peptonoids yielded 23.03% by volume of alcohol, 14.91% of total solids, and 0.17% of mineral matter. Panopepton, alcohol, 18.95%; solid matter, 17.99% (including 0.97% of mineral matter). Hemapeptone, alcohol, 10.60%; total solids, 19.54%; mineral matter, 0.37%. Nutritive liquid peptone, alcohol, 14.81%; total solids, 15.20%; mineral matter, 0.69%. Hemaboids, alcohol, 15.81%; total solids, 6.36%; mineral matter, largely iron, 0.62%. Tonic beef, alcohol, 15.58%; residue, 18.16%, including 1.04% of mineral matter. Mulford's predigested beef, alcohol, 19.72%; total solids, 10.39%; mineral matter, 0.20%. The maximum daily administration recommended yields 1.25 ounces of nutriment, and the alcoholic equivalent of about 6 ounces of whisky, which might well be regarded as hardly adequate for an exclusive diet. [H.M.]

4.—**Operation for Habitual Dislocation of the Shoulder-Joint.**—J. Collins Warren reports that a man of 22 during four years had suffered a number of dislocations at the left shoulder-joint. Operation was performed in October, 1901. The tendon of the pectoralis minor was divided for the greater part of its extent. The capsule was exposed and a piece one inch in length by three-quarters inch in breadth was excised. The edges were approximated with silk sutures, putting the capsule on the stretch. Recovery was uneventful and now more than two years after the operation there has been no subsequent dislocation. [A.B.C.]

Medical Record.

March 14, 1903. [Vol. 63, No. 11.]

1. Some Observations on Vulvovaginitis in Children (with Special Reference to the Gonorrhoeal Form): Its Treatment and Possible Sequels. SAMUEL WYLLIS BANDLER.
2. Clinical Notes on a Series of Nine Consecutive Cases of Ectopic Gestation. HIRAM N. VINEBERG.
3. Mosquitos, Quarantine, and Some Statistics with Regard to Yellow Fever. QUITMAN KOHNKE.
4. The Indications for Opening the Pars Mastoidea. L. D. BROSE.
5. Hot Decinormal Salt Solution Injections in the Treatment of Hemorrhoids. LUCIEN LOFTON.

1.—**Purulent Vulvovaginitis in Children.**—S. W. Bandler thinks that the purulent vulvovaginitis in children in the majority of cases is due to the gonococcus, but sometimes to another small coccus found intracellular. A small Ferguson speculum is best adapted for examining the condition of the vaginal walls in a child. The best daily ambulatory treatment for this condition is (1) irrigation by boracic solution; (2) injection of protargol solution into the speculum; (3) washing the entire length of the vaginal canal with the aid of the speculum; (4) the introduction of the protargol stick; (5) the subsequent use of strong silver solution if necessary. If, however, one is dealing with an invasion of vagina and cervix, an absolute essential to a certain cure is rest in bed. By almost daily treatment a cure generally results within 6 to 12 weeks.

The importance of the sequels of vulvovaginitis is due to the fact that all the lesions of the adult may be reproduced in the child and a permanent injury to be avoided is one or other of the forms of atresia of the hymen or of the vagina. Atresia of hymen or vagina has generally been viewed as congenital, but the investigations of Nagel and Velt show that with a normal uterine canal it is usually acquired. Piering divided the acquired stenosis and atresia into traumatic, inflammatory, chemical, and thermal, the first two being the important ones. Bandler thinks that atresia in its various forms may occur as a sequence to gonorrhoea, to the milder forms of vulvovaginitis, or with or after various infectious diseases, most frequently after typhoid fever and scarlatina. The pathology of these different conditions is fully discussed in the paper. [w.k.]

**2.—Ectopic Gestation.**—H. N. Vineberg gives a clinical history of nine cases of ectopic gestation, the last one in its onset closely resembling an attack of acute appendicitis. In all but two there was more or less elevation of temperature. In two cases the temperature had reached 102.6°, and in one case it rose to 103.8°. It is generally taught that in the differential diagnosis between inflammatory disease of the adnexa and ectopic pregnancy the thermometer is of great aid, and that it usually shows an absence of fever in the latter condition. A series of cases like the foregoing disproves such teaching. It is evident, therefore, that we still have a good deal to learn in ectopic pregnancy, even from the clinical side. [w.k.]

**3.—Mosquitos, Quarantine, and Yellow Fever.**—Q. Kohnke, in criticising the position taken by Dr. Souchon, states that he believes that all quarantines in so far as they have been successful have been so because they prevented the entrance of infected mosquitos. He believes that the early date of introduction and number of mosquitos present—not the special virulence of individual cases—determined the extent of yellow fever epidemics in the past. The vagaries of quarantine service, actuated by an exaggerated fear of infection at one time and the interests of commerce at another, may well account for some of the phenomena of visitations improperly attributed to other causes. Kohnke illustrates the unreliability of statistics by presenting two differing records, this unreliability making five deductions valueless. He answers the assertion that the exemption of New Orleans from 1884 to 1897 was accomplished without any precautions being taken against mosquitos by showing that 40 days' detention was required in 1884, infected mosquitos probably dying in quarantine, and that from 1885 to 1895 sulfur fumigation was practised, and when this was abolished that yellow fever appeared in November of 1895 and October of 1896. [H.M.]

**4.—Indications for Mastoid Operation.**—L. D. Brose says operation is indicated in acute abscess of the mastoid: for any pus retention that cannot otherwise be relieved; external abscess formation with fistulous opening leading into the middle ear or mastoid, especially if occurring in an adult; cholesteatoma in the temporal bone; caries and necrosis; brain abscess; intracranial collections of pus, etc. As evidence of the necessity for operation in cases of caries, a case is reported by the author. The caries caused an acute mastoiditis, which terminated fatally. The paper is somewhat exhaustive, dealing particularly with the symptomatology in the conditions. [A.B.C.]

**5.—Hypodermic Injections of Hot Salt Solution in the Treatment of Hemorrhoids.**—Lucien Lofton reports the results of this treatment in 17 cases of hemorrhoids of the various kinds—external, mixed and internal. From one to two drams is injected hypodermically into each bag or hemorrhoidal protuberance. Gradual sloughing and disintegration takes place, healing by granulation occurs, no evil effects resulting. The solution is injected while hot—almost boiling—the exact temperature not being specified. The author knows of no one having used this treatment previous to his own efforts, and he hopes the profession will give the method a trial. [A.B.C.]

#### New York Medical Journal.

March 7, 1903. [VOL. LXXVII, No. 10.]

1. Some Scientific and Practical Aspects of Vaccination. P. H. BRYCE.
2. The Present Method of Medical School Inspection in New York. CHARLES HERRMAN.

3. Uterine Inertia: Its Causes and Treatment. JAMES MORAN.
4. Incomplete Transverse Congenital Occlusion of the Vagina, and a Theory as to Its Origin. SAMUEL M. BRICKNER.
5. Expression of the Lid Margin as a Therapeutic Measure in Blepharitis and Its Complications. PERCY FRIDENBERG.
6. The Detection of Renal and Vesical Calculi by Means of the X-rays. HENRY PERKINS MOSELEY.
7. A Case of Abnormal Temperature. LUCIEN LOFTON.

**1.—Vaccination.**—P. H. Bryce reviews the subject of vaccination and says that he believes the opposition to the operation lies primarily in the fact that vaccination laws are compulsory. He shows the necessity of such legislation, but also insists that we must be prepared to accept the fullest responsibility for the position taken, which must be that, if we insist on compulsion, we shall not through indifference or neglect allow anything to exist or take place by which any element of danger can enter into the results of the operation. He says that it is the conclusion of official opinion (1) that official supervision of the products of vaccine establishments by either State or Federal officers is imperatively demanded; (2) or that the production in State or Federal vaccine establishments of adequate supplies of vaccine of established quality to be sent out free or at cost to municipalities has become a necessity. He believes that no matter which scheme is adopted there is demanded before anything else adequate legislation whereby from year to year qualified public vaccinators must be appointed in every municipality who shall be empowered to vaccinate systematically and register all children born in any year. [C.A.O.]

**2.—The present method of medical school inspection in New York** is given by Charles Herrman. There are at present 80 medical school inspectors in the borough of Manhattan, each having three or four schools, with a total of 4,000 to 5,000 children to inspect. The inspector visits his schools before 10 a.m. every morning and examines, in a room set aside for that purpose, all pupils who have been isolated by the teachers as being possible sources of contagion. Once a week the inspector visits the class-rooms and examines each pupil. As he is seated at the window the children pass in line before him. Special attention is paid to the examination of the head, face, eyes, mouth, and throat. At the end of each week those pupils who have been absent for three or more days on account of sickness are visited and the character of the disease determined. [C.A.O.]

**3.—Uterine Inertia.**—James Moran enumerates the following most common causes of uterine inertia: 1. Distended bladder and rectum. 2. Paralysis of the uterus due to overdistention by the liquor amnii. 3. Rigidity of the cervix (and vagina). 4. A relaxed and pendulous abdomen. 5. The bearing of many children in rapid succession. 6. Premature rupture of the membranes and escape of the water, causing dry labor. 7. Prolonged pressure on the anterior lip of the cervix between the child's head and the pubic bone; this condition causes continued contraction of the os and the physician may mistake it for a rigid os. 8. The uterus may be weakened by wasting diseases and fevers or by profuse hemorrhage. 9. Deformed pelvis or in cases in which the child's head is out of proportion to the birth canal. 10. Carcinoma of the cervix, uterine tumors, and ovarian cysts. When the inertia is due to an overdistended uterus the membrane should be punctured and the excess of water allowed to escape. If it is due to having several children in rapid succession hypodermics of strychnin act well. In primary uterine inertia (or weak labor pains) if the os is rigid he gives 15 grains of chloral by the rectum every 20 minutes until three or four doses have been taken. He also gives hypodermic injections of morphin in doses of from  $\frac{1}{4}$  to  $\frac{1}{2}$  of a grain. In a few cases he has applied a 10% solution of cocaine to the cervix with good results. When the os is well dilated he gives strychnin and whisky and repeats in two hours if necessary. In cases of secondary uterine inertia it is necessary for the patient to secure sleep. To produce this from  $\frac{1}{2}$  to  $\frac{1}{2}$  of a grain of morphin with 30 grains of potassium bromid and 15 grains of chloral may be given, preceded by an egg-nog or milk punch. If the pains do not return after rest with sufficient force to complete labor it will be advisable to apply forceps or do version. [C.A.O.]

**4.—Congenital Occlusion of the Vagina.**—S. M. Brickner

reports four cases of incomplete transverse occlusion of the vagina. The condition is rare, occurring in about 1 in 5,000 cases. The transverse septa are derived from an inclusion by Müller's ducts of cells from the Wolffian duct or ducts after the formation of the genital cord, and are therefore epiblastic in origin. Their perforation is proof of the normal conduct of Müller's ducts in all other respects. Transverse septa of the vagina being normal in adult sheep, whales, dugongs, the manatee, and the chimpanzee, the author states that they represent in the human being a reversion, "a return to an ancestral type." Their function is purely speculative, but may have to do with the facilitation of conception; and when they appear in the human female may have a similar purpose in harmony with other minor defects of development. The treatment of this condition is excision of the septum with suturing of the cut edges. In unmarried women no treatment is necessary. If the septum is first seen early in pregnancy, it may be excised; if during labor, a crucial incision will be sufficient with subsequent removal of the septum. The prognosis for the child is usually bad, unless the septum is incised early, or unless it is not too strong to be burst by the advancing head; for the mother it may result in serious lacerations or fatal hemorrhage. [C.A.O.]

**5.—Lid Expression in Blepharitis.**—Percy Fridenberg calls attention to expression of the lid margin as a therapeutic measure in blepharitis and its complications. In the first case reported the condition of the lid margin was so evidently one of pus retention that expression and massage were performed as a cleansing procedure preliminary to making local applications. The improvement was so marked and prompt that mechanical treatment was made a routine measure with excellent results. It is now a part of routine treatment to express, massage, and disinfect the lid margin in all cases of superficial inflammation in which there was the slightest evidence of retention. [C.A.O.]

**6.—Röntgen Ray Diagnosis of Calculi.**—H. P. Moseley says that radiographic examination is the only positive means of detecting the presence of renal or vesical calculi by the x-rays. Good radiographs are necessary. Negatives are satisfactory only when the negative shows (a) good differentiation between the various tissues; (b) the outlines of the vertebral bodies, the intervertebral spaces, the transverse and spinous processes; (c) the last ribs, and (d) the psoas, iliacus and quadratus lumborum muscles. Two radiographs should be made and compared before any opinion can be formulated, and it is very necessary also to consider the clinical history of the case. To prevent errors due to shadows of pits or fruit stones and to increase the permeability of the abdomen to the rays, the gastrointestinal tract should be prepared almost as carefully as for a celiotomy. Calculi of oxalates, phosphates and the combinations of the different urinary salts usually give good shadows. [C.A.O.]

### Medical News.

March 14, 1903. [Vol. 82, No. 11.]

1. The Etiology of Colds. JAMES J. WALSH.
2. Surgical Treatment in Nonmalignant Diseases of the Stomach: Results and Indications. HENRI HARTMANN.
3. The Etiology of Ectopic Gestation. SAMUEL WYLLIS BANDLER.
4. Apparent Fetal Substitution; Medicolegal Note. ALLEN J. SMITH.
5. The Elective System in Medical Schools. DANIEL N. EISENDRATH.
6. The Symptomatology of Tabes: An Analysis of 140 Cases of Locomotor Ataxia. (Concluded.) JOSEPH COLLINS.
7. Primary Tuberculosis of the Ear Followed by Mastoiditis: Report of Four Cases. M. A. GOLDSTEIN.

**1.—Etiology of Colds.**—J. J. Walsh gives the predisposing causes as draughts, nasal hypertrophies and deformities, lack of sufficient humidity in artificially heated rooms, and breathing through the mouth during severe exercise, which allows free access of cold air. Everything points to germ invasion as the exciting cause. He emphasizes the necessity of cleansing and disinfecting places of public assembly. Treatment consists in measures to eliminate the toxin from the blood. [H.M.]

**2.—Surgical Treatment in Nonmalignant Diseases of the Stomach.**—Henri Hartmann, of Paris, reports a series of 60 cases operated upon as follows: Three pylorotomies; 1 excision of ulcer of the lesser curvature; 1 resection of a band constrict-

ing the pylorus; 1 duodenostomy in a case of inflammatory and ulcerative lesions due to burns; 1 gastrorrhaphy and gastropexy combined; 53 gastroenterostomies. There was a mortality of 16½%. Statistics divided into two periods show a marked difference in mortality. In 23 cases operated upon from 1895 to 1899 there was a mortality of 26%; whereas in 37 cases from 1900 to 1902 there was a mortality of 10½%. Remote results were ascertained from 29 patients operated upon for from one to six years. One pylorotomy well after 18 months; 1 combined gastropexy and gastrorrhaphy well after two years; of 18 gastroenterostomies 16 were cured. The author insists that the mortality in the operations for nonmalignant diseases of the stomach depends almost entirely upon the physician and the early diagnosis. [A.B.C.]

**3.—Etiology of Ectopic Gestation.**—S. W. Bandler, in considering the history of those cases of ectopic gestation which have been closely noted, finds that it occurs most frequently in multiparas; that a sterile period of varying length precedes this pathologic development; and that during this period the tubes have usually suffered some inflammatory processes. The observation and studies of Duhrssen, Veit and others on this subject lead us at the present day to seek in the microscopic changes of the tubal mucosa, *i. e.*, injury to the cilia, the etiologic factor in tubal gestation. [W.K.]

**5.—Elective System in Medical Schools.**—D. N. Eisen-drath believes this should be generally introduced, that it would wake up those of the teaching force whom compulsory attendance has made negligent, and prevent the graduation of automatons who have been made such by overcrowding and resultant confusion of ideas. [H.M.]

**6.—Symptomatology of Tabes.**—J. Collins classifies the various types of tabes as (1) neuralgic; (2) that in which disturbance of the sympathetic system predominates; (3) that with predominance of motor symptoms; (4) with early optic symptoms; (5) cervical or high tabes; (6) slow development of disease; (7) precipitate development; (8) cases with cerebral symptoms not paresis. The subjective symptoms are variable, the objective constant. The prognosis varies with the clinical form. He reports cases illustrating each form. In studying the initial symptoms he finds that the patient gives not the first but merely those which have prompted him to consult a physician. Pain was the initial symptom in only 40% of his cases, while it was noted in the course of the disease in 90%. The following shows the percentage of the frequency of the most conspicuous subjective and objective symptoms in 140 cases: Lancing pain, 90; Romberg's sign, 85; loss of Achilles-jerk, 88; loss of knee-jerk, 84; Argyll-Robertson pupil, 77; ataxia of gait, 73; hypotonia, 72; paresthesia, 73; anesthesia, 67; analgesia, 58; bladder symptoms, 55; impotency, 50; crises, 20; ocular paralysis, 10; arthropathies, 5; trophic symptoms, 8; optic atrophy, 14; girdle sensation, 30; impairment of deep sensibility, 63; diplopia, 22. [H.M.]

**7.—Primary Tuberculosis of the Middle Ear Followed by Mastoiditis.**—M. A. Goldstein reviews the literature on the subject and reports four cases. He believes in each of these cases the disease was primary in the middle ear. Of these four cases three involved the mastoid cells extensively, and showed an unusually active and rapid invasion. All developed from a preexisting suppurative chronic otitis media, and appeared as direct infection by *Bacillus tuberculosis*. In the three cases in which the mastoid operation was performed the wounds healed by firm granulations, and all evidences of tuberculous trouble ceased. This is in direct contrast to the healing of wounds in which the systemic tuberculous invasion is present. Each of these cases pointed to definitely localized specific infection of the cavum tympanum and mastoid cells, with the definite demonstration of *Bacillus tuberculosis* in each case. [A.B.C.]

### Philadelphia Medical Journal.

March 14, 1903. [Vol. XI, No. 11.]

1. Tropical Diseases: Eighth Lecture in a Course on Tropical Diseases. CHAS. F. KIEFFER.
2. Occlusion of the Superior Temporal Artery of the Retina in a Young Anemic Girl. G. E. DESCHWEINITZ.
3. Collective Investigation Concerning the Value of Silver Nitrate Injections in the Treatment of Pulmonary Tuberculosis. THOMAS J. MAYS.

4. Some Points in the Management of Infectious Diseases. A. G. YOUNG.  
5. The Treatment of Tropical Dysentery with Sulfur. T. H. WEISENBURG.

1.—**Tropical Diseases.**—Charles F. Kieffer considers the filarias and the diseases caused by these parasites. [F.C.H.]

2.—**Occlusion of the Superior Temporal Artery of the Retina in a Young Anemic Girl.**—G. E. deSchweinitz presents this case as a contribution to the literature of alterations in the vessels of the retina which result in stoppage of the bloodcurrent. The case is that of an American girl, 15 years of age. The visual field was obliterated in its lower and inner quadrant, elsewhere it was normal. The ophthalmoscopic lesions in the case evidently consisted of an occlusion of the upper temporal branch of the superior division of the central artery and beyond a large area of exudate, and beyond this again interruption of the branch curving above the macular region, followed still later by complete conversion of the larger stem of the vessel into a white cord and disappearance of its peripheral ramifications, associated with gradual subsidence of the exudate and the formation of a lozenge-shaped area of atrophy and pigment heaping. [F.C.H.]

3.—**Silver Nitrate Injections in the Treatment of Pulmonary Tuberculosis.**—Thomas J. Mays details the results obtained in treating 55 cases of pulmonary tuberculosis with silver nitrate injection and considers that the therapeutic results which have been obtained proves that the silver nitrate injections possess a decided antagonism to the pathologic and complex process which we know as pulmonary tuberculosis. The cough very frequently yields immediately to the injections; vomiting is either entirely relieved or abated in most of the cases in which it is found; in the majority of instances of night-sweats they are improved, while in a certain percent they cease; the improvement in general strength at times is decided and rapid gain in weight occurs, sometimes to an unexpected degree. [F.C.H.]

4.—**Some Points on the Management of Infectious Diseases.**—A. G. Young lays stress upon the value of a diagnosis in all infectious diseases. Unless cases of pulmonary tuberculosis, diphtheria, measles, scarlet fever, typhoid fever, whoopingcough, cerebrospinal meningitis, smallpox, cholera and typhus fever are reported to the local board of health no efficient measures against the spread of the disease are observed in 90% or more of the cases. The two most potent factors in the spread of scarlet fever are mild cases which do not come to the knowledge of the physicians and health officers, and the failure to maintain isolation until the very end of the period of desquamation, until the hands and feet are entirely smooth. [F.C.H.]

5.—**The Treatment of Tropical Dysentery with Sulfur.**—T. H. Weisenburg details the value of sulfur in the treatment of tropical dysentery as observed in a series of cases under treatment at a large effervescing sulfur spring in the island of Marinduque, P. I. It may also be interesting to record that dhobic itch, the ever-present skin malady of the tropics, rapidly disappeared as a result of the baths. [F.C.H.]

A. O. J. KELLY

### REVIEW OF LITERATURE

**Congenital Elephantiasis.**—After considering the literature concerning elephantiasis, Bernhard and Blumenthal<sup>1</sup> report the case of a child of two years, afflicted with the disease, confined to the penis and the left lower extremity, the latter existing at birth. A phimosis operation was performed when the child was two weeks old, after which the diseased state of the parts became much more marked. They give a minute description of the penis and limb; much of the deformed tissue of the penis was excised. This was followed by gradual and general improvement of the parts. The interesting points of the case are: Its similarity to the picture of acquired elephantiasis; the proliferation and enlargement of the lymph vessels

among the proliferated connective tissue; a diagnosis of elephantiasis could not be made without the microscope; the furrows present are not amniotic, but correspond to the normal attachment of the fascia; the condition could not be traced to either heredity or inflammatory influences, nor did a bacteriologic examination reveal the cause of the disease. The case must be considered one of congenital lymphangioma. [E.L.]

**A Clinical Study of Beriberi.**—Bailey<sup>1</sup> writes an instructive article on this disease, based on observations of cases in the Japanese settlement at Cumberland, B. C., where 40 to 50 cases occur yearly. Nearby, in practically the same surroundings, is a Chinese village, but these people are never attacked by the disease. The diet of the Japanese consists mostly of rice, fish, milk, and eggs, with a few fresh vegetables. The people are employed in and about coal mines, in logging camps, salmon fisheries, etc. Beriberi is present among them at all seasons of the year. A detailed synopsis of the symptoms of 23 cases that occurred during 1900 accompanies the article. There was one female and 22 males. As to age, 12 were under 30 years, the oldest being 43, the youngest 19. All made good recoveries, 21 being office patients when first seen. Treatment consisted in change of diet, rice being forbidden, and meat and eggs recommended. A cathartic was given at the outset, and repeated as required. Five grain Bland's pill and strychnia were given t.i.d., with electricity and massage where there was paralysis. [A.G.E.]

**Human and Bovine Tuberculosis.**—Raw<sup>2</sup> states that there are two distinct varieties of tuberculosis affecting the human body—one produced by human tubercle, the other produced by bovine tubercle; that human and bovine tuberculosis are separate and distinct; that bovine tuberculosis entering the alimentary canal in milk may set up tabes mesentericus, more especially in children; that bovine tuberculosis is probably the cause of enlarged lymph glands, tuberculous joints, and lupus; that true human tuberculosis of phthisis pulmonalis is always conveyed from one person to another by infection, and generally from advanced cases of phthisis; that every effort should be made to stamp out tuberculosis in cattle; and that milk should be boiled before use by children. [A.O.J.K.]

**Spontaneous Levulosuria and Levulosemia.**—For some time it has been known that diabetic urine frequently contains other carbohydrates beside glucose or dextrose. Rosin and Labaud<sup>3</sup> have studied the occurrence of levulose or fruit sugar in the urine, and have found it in appreciable amount not only in the urine of many diabetic patients, but also in their blood. They therefore maintain that levulose plays an important role in the carbohydrate metabolism of diabetics, and is worthy of further study. The test most depended on by them for the qualitative demonstration of levulosuria is that of Seliwanoff. It consists in the production of a brilliant red coloration when equal parts of urine and fuming hydrochloric acid are heated with a few crystals of resorcin. The quantitative determination is also described in detail. A case is reported in which the amount of grape sugar was so small in comparison with that of fruit sugar that the case might well be called one of levulosuria rather than glycosuria. Such cases have not been reported previously, but it is probable that they are not infrequent. The question as to the cause of levulosemia and levulosuria cannot yet be answered, and must be left open for further investigation. [B.K.]

**A True Aneurysm of the Right Sinus of Valsalva.**—Kraus<sup>4</sup> reviews the literature and reports a case in which the patient died of a true aneurysm of the right sinus of Valsalva rupturing into the right ventricle. This condition is very rare. The patient, a young man of 27, had been perfectly healthy until four years ago, when he overexerted himself during his military service. At that time he experienced palpitation of the heart with dyspnea, but no pain. Since then the dyspnea grew worse and he developed cyanosis, edema, and hemoptysis. Examination showed the apex beat to be diffuse and situated in the sixth interspace, 2 cm. outside of the maxillary line. There was a systolic thrill in the second interspace, and a slow,

<sup>1</sup> Deutsche medicinische Wochenschrift, December 11, 1902.

loud and rough bruit over the sternum. The Röntgen rays failed to show an aneurysm. At autopsy, including the ruptured aneurysm, the heart showed hypertrophy and dilation. [W.E.R.]

**Bacilluria and Cystitis in Typhoid Fever, and the Action of Urotropin Thereon.**—H. E. J. Biss<sup>1</sup> thinks the frequency and importance of bacilluria have not been adequately grasped, and cystitis in typhoid is not uncommon. If turbidity be due to bacillary particles a shimmer is seen if the liquid is whirled in a test-tube. In a series of 311 cases of typhoid, he found bacilluria in 18 and cystitis in 13. Bacteriologic examination would probably have increased the cases of bacilluria to one-fourth of the total. Cystitis results from specific infection, or from retention with perhaps unclean catheterization. There is little connection between severity of attack and either complication. Bacilluria occurs on an average about the forty-third day, and has been delayed till the one hundred and eighteenth. Bacteriuria in typhoid is not always specific. *B. coli* and pyogenic cocci may be the causal organisms, but for practical purposes all cases should be treated as infectious and urotropin administered. No serious effects have ever followed its use. A slight irritation and hematuria occasionally brought on have passed off when it was discontinued. It should be given as soon as the urine becomes cloudy, at frequent and equally distributed intervals, and in sufficiently large doses, and be kept up for a considerable period after the cessation of the condition to avoid relapse. On account of expense, Biss gives it in 5-grain doses every eight hours, on alternate days, as a routine method. [H.M.]

**An Improved Method for the Microscopic Diagnosis of Malarial Fever.**—Ross<sup>2</sup> advocates the spreading of a thick drop of blood, which having been perfectly dried in the air is covered with an aqueous solution of eosin for 15 minutes. As the film of blood has not been fixed, the solution of eosin takes out the hemoglobin of the dried corpuscles, and at the same time stains the residual mass, consisting of the stroma of the corpuscles, the leukocytes, platelets, and parasites. The eosin is washed off with a gentle stream of water, and the preparation is then covered with a weak solution of methylene-blue (Romanowsky stain) for a few seconds. This being washed off, the preparation is dried, and mounted in Canada balsam. The preparation containing no hemoglobin permits of the ready detection of parasites, and as the preparation contains 20 times as much blood in a given space as the ordinary blood film, the detection of even few parasites is much facilitated. [A.O.J.K.]

**A New Variety of Diphtheria Serum.**—Diphtheria antitoxin neutralizes the toxin of the diphtheria bacillus, but does not influence the diphtheria bacillus. Wassermann's<sup>3</sup> experiments tend to produce a serum which will act directly on the body of the bacillus. He injected from 2 to 4 cc. of a solution of dead diphtheria bacilli, which he prepared according to the method of Aaronson, and to which he had added sufficient antitoxin to neutralize the toxin still present, into the veins of rabbits. He succeeded in producing a serum which, when added to a culture of diphtheria bacilli, brought about their precipitation, an action not possessed by the antitoxin. He concludes from this that the preparation of a serum does not depend upon the biologic peculiarity of the bacteria in question, but rather upon the substances (bacteria or toxin) used in the treatment of the animals. With this serum it may be possible to differentiate between the true and the pseudodiphtheria bacilli. By combining this serum with antitoxin in the treatment of diphtheria, we may be able to produce a cure quicker, and especially will it be of use in cases in which the diphtheria bacilli remain in the throat long after the patient has recovered. [E.L.]

**Acute Leukemia of the Hemorrhagic Form.**—A case of hemorrhagic leukemia has been observed by Hayem and Bensaude.<sup>4</sup> The patient was a woman of 60, who for some time had inexplicable lassitude. Gastrointestinal disturbances finally appeared and, during the last 15 days, fever and multiple hemorrhages, cutaneous, mucous and visceral. Epistaxis and metrorrhagia were moderate but hematuria was severe. There

was no enlargement of liver, spleen, nor lymph nodes. The course of the disease lasted about three months. In blood removed before death coagulation occurred in ten minutes, but at the end of 24 hours the clot had not retracted and no serum had exuded. With this was associated a diminution in the number of hematoblasts. [A.G.E.]

**Bence-Jones Albumosuria.**—Anders and Boston<sup>1</sup> report three cases of Bence-Jones albumosuria, detail the reactions of the substance, and give a valuable bibliography. They state that Bence-Jones albumose is a body more or less allied to peptones, globin, histon, and the digestive albumoses, but it displays certain characteristics unknown to these substances. It is a normal constituent of spermatic fluid, and may be found in the bone-marrow in cases of myeloma. When present in the urine it is valuable as a diagnostic feature in cases of obscure multiple myeloma in which no other symptoms of the disease exist. It also serves in differentiating multiple myeloma from other bone lesions, as carcinoma, sarcoma, osteomalacia, etc. Albumosuria, if continuous, is of grave prognostic significance, and but a single exception is recorded wherein the disease has not proved fatal in less than two years. When the albumose has persisted for some time, its disappearance signifies approaching danger, and probably an early fatal issue. Since serum albumin is a common coexistent of Bence-Jones albumose, its disappearance from such urine may also presage complications of a serious character. [A.O.J.K.]

**The Relation of Mental Symptoms to Bodily Disease.**—N. Raw<sup>2</sup> in discussing these symptoms limits himself to temporary disturbances. The diseases in which curious mental states are observed are chiefly those of the heart, lungs and stomach. In phthisis pulmonalis the mental symptoms are often pronounced, depression, irritability and even delusions developing, the latter disappearing with the arrest of the phthisis. Hallucinations, wild delirium, or exaltation of feeling, appear during failing compensation in heart disease. The physician must not treat his patient as a hysteric or a lunatic. In the gouty contracted kidney, especially in young adults, acute mania is not uncommon. Patients have been sent to asylums as lunatics in the early stages of uremic poisoning. In gout we find the extremes of maniacal excitement and profound melancholia. In acute attacks the patient may be so irritable as to be unapproachable. In exophthalmic goiter delusions of impending danger and suspicion develop. In myxedema there is slowness of perception and conduction, and either mania or melancholia may occur. In diabetes irritability and sometimes suspicious delusions come on. In chorea we find constant fear and occasionally acute mania. Patients with pneumonia are liable to sudden frenzy. Too often a patient exhibiting mental symptoms is certified and sent to a lunatic asylum. These swell the recovery rate. They are not really insane, and it would be to the public advantage to treat them in a hospital for mental diseases, with expert physicians and a clinic of students, and where the patient and his family might be spared the stigma of his having been detained in an asylum as a lunatic. [H.M.]

**Unilateral Conformation Errors of Thorax and Corresponding Upper Extremity.**—In a case described by Schoedel<sup>3</sup> the sternocostal portion of the pectoralis major, the pectoralis minor, and a small part of the third costal cartilage were missing; the corresponding upper extremity shows muscular atrophy, syndactyly and brachidactyly. He has collected the literature on the subject, and concludes the deformity to be congenital, mechanical influences between the sixth and ninth week of fetal life producing it. [E.L.]

**Some Problems of Tuberculosis.**—Under this title Curtin<sup>4</sup> discusses three subjects: (1) The attitude of the State and the public toward resorts for tuberculous subjects; (2) the attitude of the physician toward marriage between tuberculous subjects; (3) pulmonary birthmarks versus the contagiousness of pulmonary tuberculosis. Regarding the first point he believes that a locality which can cure the disease can purge itself from any contaminating influence remaining after-

ward. As to the second, it is useless and unwise to enact laws that it would be absolutely impossible to enforce. By pulmonary birthmark Curtin means the pulmonary lesions or scars in unusual situations which are transmitted to the progeny of persons with diseased lungs. He has observed that in a number of families in which either the father or mother had physical signs of tuberculous disease situated in unusual localities in either lung, especially if the disease occurred in early life, the children, although apparently healthy, would present physical signs of defect in localities precisely corresponding with those in the diseased parent. Four instances of this condition are detailed. Instances of what is called cured apical tuberculosis, so frequently found in postmortem-rooms, may have some connection with such a condition as was found in Case II, where a child was marked in utero by the latent disease in his mother. [A.G.E.]

**The Value of Boracic Acid and Borax in the Preservation of Meats.**—Boehm<sup>1</sup> says that boracic acid and borax when introduced into the animal organism in considerable quantities are deleterious to the health, and should therefore never be used as preservative agents for meats. [E.L.]

**A Curative Serum for Combating Morphin Poisoning and Similar Intoxications.**—Hirschlaff<sup>2</sup> discusses the theories concerned in immunizing animals against the ill-effects of the different poisonous drugs. He describes in detail a series of experiments performed on mice and rabbits that led to the discovery of a successful antimorphin serum. By gradually increasing the dose of morphin in animals, a resistive substance is obtained, which, when injected into other animals, will cause immunity to the action of morphin poison. Hirschlaff tried his serum on a patient who had taken double the fatal dose of morphin. Two injections were given and in eight hours all symptoms of poisoning had disappeared. Several chronic cases were treated in a like manner with excellent results. [W.E.R.]

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

### EDITORIAL COMMENT

**Joint Disease and Hemophilia.**—The occurrence of chronic inflammations as a result of bleeding into joints in patients with a hemorrhagic diathesis was first noted by König several years ago, but still frequently passes unrecognized. Though one of the more unusual forms of joint affection it is met with frequently enough so that its occurrence should always be kept in mind. This is especially important from the fact that operation, which might seem indicated if the condition was not understood, is necessarily attended by such disastrous results. Carless,<sup>3</sup> in a paper on surgical affections of joints, quotes statistics of Poillet, of Lyons, who has analyzed 252 cases collected from literature: This large number of cases indicates that the affection is possibly more frequent than is generally known. In his original paper König describes three stages of the affection: First, the joints become distended with blood, usually spontaneously, without any history of injury. There is a feeling of tension and pain but no tenderness or symptoms of inflammation. Ecchymosis may appear within a few days. Usually the effusion is absorbed in a short time and at first little damage is done. If the hemorrhage is repeated, however, and this is usually the case, a chronic form of arthritis is produced. The synovial membrane becomes thickened and rough, the periarticular structures infiltrated and the articular cartilages and synovial membrane are discolored with blood pigment and may be covered with partially organized fibrinous tufts and the muscles are atrophied. In the third stage of the affection loss of function and deformity

occur caused by proliferation of periarticular tissue and fibrous outgrowths. The affection appears usually in early life, frequently between the fourth and sixth years, practically always in the male sex. Traumatism does not seem to be an etiologic factor. The knee is affected in nearly half the cases, the elbow in about one-fourth of the cases and the ankle next most frequently. The prognosis is always bad in hemophilia, it being estimated that 60% of the patients die before the age of eight years, but strange to say children affected with arthritis do not seem to have so great a mortality. It is extremely important that the condition be recognized, for a considerable number of cases have been operated upon, with fatal results in nearly every case. Not even puncture or massage is advisable. The limb should be put at perfect rest, cold applications should be made and gentle compression applied. Very little can be done to arrest the progress of the disease, but if suitable apparatus be applied much can be done to prevent deformity and relieve pain.

### REVIEW OF LITERATURE

**Operations in Diabetes.**—Kausch.<sup>1</sup> These patients should be operated upon only when indications are most urgent. If possible it is best to wait and treat the patient until the urine is free from sugar, or at least until the percentage of sugar is considerably reduced. In many cases the indications for operation disappear when the sugar disappears from the urine. The asepsis should be as strict as possible. Antidiabetic therapy should be continued after as well as before the operation. Kausch considers general anesthesia dangerous in these cases and advises as limited use of it as possible. Ether he considers preferable to chloroform as an anesthetic. For sometime before the operation the patient should be given large doses of sodium bicarbonate in order to lessen the liability to diabetic coma. [M.B.T.]

**Adrenalin.**—To determine whether adrenalin could be substituted for gelatin in cases of hemorrhage induced Letmann<sup>2</sup> to perform a number of experiments. In the case of the first animal his experiment was a total failure. He excised a section of liver and applied pledgets of cotton soaked in  $\frac{1}{10}$ % adrenalin solution to the bleeding surface. In the author's opinion the adrenalin could not come in contact sufficiently with the tissues on account of the flowing blood. In other cases he injected 2 ccm. of the same solution into livers before excising. After some few minutes the section would be absolutely bloodless, and no bleeding took place when pieces of liver of various sizes were excised. No hemorrhage occurred even after hyperemia replaced the anemia of the cut surface. He believes this to be due to a formation of thrombi in the capillaries, which prevents secondary hemorrhages when the part becomes hyperemic. He recommends preventive adrenalin injections in operations performed on vascular organs. [E.L.]

**Ureterocystostomy, with Traction of the Ureter.**—Smith<sup>3</sup> advocates the anastomosis of the ureter with the bladder whenever ureteroureterostomy is excluded, even though much traction on the ureter be needed to approximate the two organs. Warnings against performing anastomosis are due to fear of the ureter tearing loose from the bladder. This is apt to occur if the usual method of operating is followed, but oblique implantation of the ureter into the bladder, fully described by Smith in five steps, secures a much firmer fixation, as demonstrated by him in experiments on the excised genitourinary tract. He also performed operations on 10 dogs, with the view of determining the maximum length of ureter that could be excised and still obtain firm union with the bladder. From one to three inches were excised, union following in all but one case. In nearly every case some degree of interstitial nephritis ensued, this in some instances resulting in atrophy of the kidney on the side of operation. In a few cases nephritis of less degree was found in the opposite kidney. This was not due to obstruction, as the ureteral openings were patulous in

<sup>3</sup> Northwest Medicine, February, 1903.

all except two cases. To determine if traction on the ureter was responsible for this kidney change a ureter in each of four dogs was severed at its normal site and implanted in the fundus of the bladder without loss of substance. The results excluded traction as the sole cause of nephritis, suggesting interference with the blood and nerve supply as a probable cause. The suggestion is made that atrophy of the kidney probably results from these operations on human beings. [A.G.E.]

**Lister's Relation to the Development of Operative Surgery.**—Watson Cheyne<sup>1</sup> gives interesting data taken from his notebook made in 1872, while a student of Lister at the University of Edinburgh. Interesting facts given serve to remind us that many of the present aseptic and antiseptic surgical procedures which are regarded as of recent origin were then practised by Lister. Among these may be mentioned cutting down upon and wiring with perfect success a fractured olecranon; wiring with good results ununited fractures of the radius and femur; the removal of exostosis with chisel and hammer; osteotomies for correction of deformities; removal of the breast with a thorough cleaning out of the axilla; division and removal of the pectoral muscles; free incision, scraping and drainage of psoas abscess; free incision and tubular drainage for unabsorbed hematomas; and similar treatment for housemaid's knee. He reintroduced the operation of suprapubic cystotomy for the removal of stone. In so doing he accidentally opened the peritoneum, which was sutured with catgut. A large stone was removed and recovery followed. [A.B.C.]

**Interposition of Rubber Tissue Without Removal of the Gasserian Ganglion.**—Robert Abbe<sup>2</sup> reports five cases successfully treated by this method. In one case the cure has lasted over 6 years, one for 5 years, one for 2½ years, one for 3½ years, and another for 6 months. Abbe finds this method very much safer than the operation for removal of the gasserian ganglion and in his hands it has proved equally effective. In performing the operation he believes the external carotid artery may be ligated with advantage. He makes a vertical incision over the middle of the zygoma, through the temporal muscle, scraping the muscle to either side and retracting it. A small opening into the skull is then made with a mallet and gouge. The dura is pressed away and the nerves are exposed. The nerve trunks are grasped with clamps near their foramina of exit and either cut or torn from the ganglion by rotation with the forceps. A thin piece of gutta percha tissue is then laid over the foramen rotundum and ovale and is pressed into place by iodoform gauze. After a few moments the gauze may be withdrawn and the gasserian ganglion is allowed to settle down upon the rubber tissue. He finds this operation simple, speedy, and safe. [M.B.T.]

**The Leukocytes in Appendicitis.**—Coste<sup>3</sup> has made careful leukocyte counts in 29 cases of appendicitis to determine if any relation existed between their number and the appearance of pus. He divided the cases into three groups: (1) In which the clinical symptoms indicate a pure appendicitis without recognizable exudate; (2) in which dulness exists without well-defined clinical cause; (3) the purulent peritonitis. He concludes from his observations: If during an acute appendicitis the number of leukocytes remains normal or shows only a transient increase to an inconsiderable height the process is localized to the appendix or the exudate is serous. In such cases the disease usually runs a mild course. A fecal stone, however, may at any time produce a perforation leading to suppurative peritonitis; such an accident would not be announced by an increase in the number of leukocytes, but rather by an increase in the severity of the symptoms. If the number of leukocytes reaches 22,000, an abscess may be counted upon with certainty. In purulent peritonitis the number of leukocytes increases only if the organism possesses sufficient resisting power against the infection. A sudden fall in the number of leukocytes is a bad omen from a prognostic standpoint. [E.L.]

**Nephrectomy for Endothelioma of the Kidney.**—The patient in the case reported by Sanford<sup>4</sup> was a man of 47 whose

illness began two years before as an attack of hematuria lasting two days. These attacks became more frequent and painful and large casts the size of goose-quills and as long as six inches were passed. Operation revealed a large, irregular and hard kidney, that was removed after resection of four inches of the twelfth rib. The patient did well, after 48 hours of shock, until the thirteenth day, when he suddenly died. Microscopic examination of the tumor showed it to be an endothelioma. [A.G.E.]

**The Evolution of Modern Surgery.**—Hector Cameron<sup>1</sup> states that the period during which Lister was developing his antiseptic treatment of wounds, in Glasgow, extended only from 1865 to 1869. During this short time surgery was revolutionized. Wounds were found to heal without inflammation, suppuration or constitutional disturbance; compound fractures and dislocations were robbed of the former dangers which surrounded them; large chronic abscesses connected with diseased bone were proved to be no longer incurable, even when occurring in the adult; arterial trunks were ligatured in their continuity without fear of secondary hemorrhage or infection; joints opened by accident or by the surgeon's knife healed perfectly; ununited fractures were treated boldly by removing the ends of the fragments and preventing infection. He was the first to do a deliberate osteotomy, even cutting into the ankle-joint, to correct a deformity. He was the first to do a complete removal of the female breast, clean out the axilla and resect the pectoral muscles, for malignant disease of the mamma, the woman dying three years later without recurrence at the site of operation, but of a metastatic growth in the liver. [A.B.C.]

**Etiology and Treatment of Congenital Muscular Wryneck.**—Fridberg<sup>2</sup> reports the result of his studies in 29 cases of congenital muscular wryneck. Sixteen of these children were breech presentations, 6 were difficult forceps deliveries, and only 7 presented normally by the occiput. In 26 cases the torticollis was seen immediately or shortly after birth; in 3 only did the condition show itself for the first time after the third month. Etiologically the condition therefore, in his opinion, is due in the majority of cases to the pathologic changes arising in the sternomastoid as the result of birth trauma. In isolated cases it may arise from a pathologic position of the head during development of the fetus in utero. Eighteen of the patients were operated on for the condition and in every instance the macroscopic and microscopic picture of myositis was found. Whether a purely degenerative process, the result of the trauma, or whether a bacillary inflammatory infection arises he is not able to decide. The treatment in all cases resolves itself to extirpation or resection of a part of the muscle; in some few cases plastic prolongation of the muscle may be attempted. The clinical details of the 29 cases are appended. [E.L.]

**Lupus Treated in the Electrical Department of the Western Infirmary.**—D. J. Mackintosh<sup>3</sup> reports that in beginning a Finsen light treatment a test exposure of 10 minutes to a current of 10 amperes is given, and if the reaction is not too violent the sitting is increased to 15 or 20 minutes and the current to 12 amperes, care being taken that the part be kept closely applied to the lamp to ensure its being rendered as anemic as possible. In a few cases such violent inflammatory reaction with vesication has occurred that the time of exposure has been reduced to five minutes, and in others treatment has been discontinued for some days to allow the skin to recover from blistering. In other cases no satisfactory reaction has appeared for days or even weeks. The greater the reaction to test exposure the greater the hope of ultimate cure. The reaction generally follows immediately, but the patient is not conscious of any unusual sensation until some hours afterward, when heat and tingling set in, and the local redness seen immediately after the exposure is intensified. The department has not employed the high frequency current alone in any case of lupus of the skin, but when the affected area has become skin-whole after treatment by light they use it in treatment of the

dense, inelastic scar, a relapse occurring otherwise. After some weeks of this the scar becomes thin, white, elastic, and scarcely noticeable. In places inaccessible to the lamps, as the mucous membrane of the mouth and nose, they employ the high frequency current by means of glass electrodes with marked benefit and without pain. In several cases of lupus at the edge of the nostrils the granulations became excessively fungoid after light treatment, perhaps because the part could not be made sufficiently anemic to permit penetration of the violet and ultraviolet rays, which then acted as a superficial irritant. [H.M.]

## GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

### REVIEW OF LITERATURE

**Diabetes Mellitus and Gynecologic Operations.**—Futh<sup>1</sup> reports from different operators several instances in which the patients after undergoing abdominal operations for uterine cancer were apparently doing well and suddenly two or three days after operation were seized with diabetic coma, from which they died. He cites also two instances in which 48 hours after operating for cataracts the patients were seized with diabetic coma, causing death. Futh therefore considers the presence of sugar in the urine a contraindication to any operative surgery requiring general anesthesia. Many minor operations, including plastic perineal operations, may be performed under local anesthesia. Before any operation, however, whether major or minor, upon a diabetic patient it is well to prepare the patient by a longer or shorter course of diet to reduce the amount of sugar in urine and blood, as its presence renders the wound more liable to infection or diabetic gangrene. In some grave cases lumbar anesthesia may be preferable to any other form. [W.K.]

**A Study of Fertilization with Reference to the Occurrence of Ectopic Pregnancy.**—J. Oliver,<sup>2</sup> after investigation, believes that destruction of the ciliated epithelium of the fallopian tube is not responsible for ectopic gestation. After such destruction it is more than probable that the ovum would traverse the tube more rapidly and increase the chances of the germ and sperm elements meeting in the cavity of the uterus. Separately considered, these elements may be perfectly healthy, but for some unknown reason display an absolute indifference toward each other. If the affinity is of feeble character, the sojourn of the ovum in the tube may be unduly prolonged, favoring the occurrence of tubal gestation. If the elements fail entirely to attract each other, their coalition is impossible, and we have the variety of sterility attributed to sexual incompatibility. Fecundation usually, if not invariably, occurs in the tube, and arrest in this structure is due to some disproportion in size. The ovum may be inordinately large, or may become jammed because fertilization occurred too near the ovary. Whatever tends to delay descent favors ectopic gestation. For this reason impairment of sensitivity or paresis of the tube will be a potent factor. Occasionally shock, fear, and mental anxiety by their paralyzing action may bring about this result. In the methods adopted for the prevention of conception is a still more powerful influence, exerting a very prejudicial effect on the nervous organization of the woman, directly affecting the wellbeing of so highly sensitive a structure as the tube, and interrupting its physiologic processes. Chronic salpingitis lessens the irritability of the tube, and the sclerosed changes later narrow the lumen, thus interfering with transit. [H.M.]

**Bossi's Dilator in Eclampsia.**—J. W. Ballantyne<sup>3</sup> has used Bossi's fourbladed dilator in three cases of albuminuria in pregnancy, two of which went on to eclampsia. The first was a primipara, aged 23. She had four convulsions and the os was about 1 inch in diameter; the fetal position was r. o. p. He used Bossi's dilator and had full dilation in 20 minutes. As the child was dead and on account of the narrow pelvis he could not rotate

the head, he performed basilysis and rapidly extracted it. There was no laceration of the cervix and the mother rapidly recovered. In the second case, as after 50 hours labor the os remained only 2 inches in diameter without any increase for many hours, he used the dilator and completed the dilation in half an hour, and then with forceps delivered a living child weighing over 7 pounds. The third case was a primipara, aged 24. When 6½ months advanced in pregnancy she had five convulsions. There was much albumin in the urine and the cervix was very rigid, the os being an inch in diameter. With the dilator he in 35 minutes increased its size to 3 inches and delivered the fetus with forceps, it not being viable. He has dealt with many cases of eclampsia and thinks that if we accept the principle of early completion of labor as the treatment of the condition, then the Bossi dilator enables us to do this more quickly than any other means; further, it would seem to do so with safety if properly used. In none of these cases did he have the opportunity to try any prophylactic measures. [W.K.]

**Anencephalus: Spina Bifida.**—O. W. Parker<sup>1</sup> reports these two abnormalities in two successive pregnancies of a Swede woman of 30. Five normal male children had been born previously. The anencephalic monster was born in August, 1901, the body being fairly well developed. Sex, male. The child having a meningo-myelocele was born in October, 1902, and lived two weeks. It was also a male. The only history of illness in the mother was a prolonged menstrual flow lasting two months that occurred four months before conception of the anencephalic child. The father is a healthy miner. [A.G.E.]

**The Treatment of Labor in Narrow Pelves in Private Practice.**—According to Mueller<sup>2</sup> the prognosis of the course of labor depends not only upon the size of the pelvis, but upon the size and contour of the head, and also upon the hardness of the skull bones. He thinks the best method of determining the comparative size of the head and the pelvis is by impression, and he describes the manner of doing this. If the physician is cognizant of this unfavorable condition in time, a prophylactic measure not to be neglected is the lowering system of Prochowick. This care of diet, beginning in the fifth or sixth month of pregnancy, with the reduction by limiting the amount of carbohydrates and the measure of fluids, may ensure a slender child with soft head bones which can be delivered through the narrow pelvis. If, however, induced labor is indicated, then the most modern procedure is accouchement forcé with metal dilators. A number of these have been devised, but none better than the Bossi dilator. The highest service of Bossi, however, appears to Mueller to be the fact that he has again brought to our knowledge that the rapid distention of the os is possible. This rapid distention of the os may be secured by the fingers and hand, the classic method, which though long abandoned was never completely forgotten. The obstetrician is wont to use surgery only in exceedingly rare and exceptional cases. [W.K.]

**Electric Light in Gynecology.**—A. T. Orlor<sup>3</sup> has experimented with electric light in various gynecologic affections. The "cold" white light was employed by means of a specially constructed apparatus. Incandescent lamps furnished the light, its intensity varying from 5 to 16 candle-power. Reserving details for a future report, the author offers these conclusions: Light treatment is indicated in a series of inflammatory gynecologic conditions, as metritis, parametritis, oophoritis, salpingitis, etc., in the acute as well as chronic stage; the chief action of light treatment is striking relief of pain; exudates, serous and purulent, decrease in size and occasionally disappear completely; dysmenorrhea, retroflexion of the uterus, ovarian neuralgia, cervical erosions, and uterine catarrh, especially the gonorrhoeal variety, are all benefited by the method. On the other hand, light treatment is contraindicated during menstruation, uterine hemorrhages, and pregnancy. Untoward results, such as general debility, paresthesias, etc., are apt to follow the first three or four applications. Altogether, in spite of its favorable action, the method needs further investigation. [L.J.]
